This book is dedicated to my wife, Lisa, and our children, Keith Nicholas Myers, Brett Alexander Myers, and Blake David Myers, and to my parents, Eugene and Barbara Myers.

—JNM

This book is dedicated to my wife, Sylvie, for her grace, sacrifice, and support throughout my career; our daughters, Gabrielle Grace (Gigi) Hanna and Camille Lauren Hanna, for the joy and blessing they bring to our lives; my parents who encouraged me to follow my dreams; my mentors who inspired me to pursue excellence; my residents and students who continue to teach me; and my patients whose endurance, resilience, and faith continue to amaze me.

—EYH

This book is dedicated to my wife and best pal, Barbara; our son, Jeffrey N. Myers, MD, PhD, his wife, Lisa, and their sons, Keith N. Myers, Brett A. Myers, and Blake D. Myers; our daughter, Marjorie M. Fulbright, her husband, Cary, and their sons, Alexander F. Fulbright and Charles J. Fulbright, who are a constant source of joy and inspiration; to my parents, the late Dr. David and Rosalind N. Myers, whose dedication to patient care was a way of life; to the late Dr. John Conley with whom I learned the

principles of Head and Neck Surgery; and to Dr. James Y. Suen who invited me to be his partner in writing Cancer of the Head and Neck.

PREFACE

The management of cancer of the head and neck requires the efforts of a well-integrated multidisciplinary team for patients to achieve their highest oncologic outcomes and functional potential. Critically important team members include extirpative and reconstructive surgeons, radiation and medical oncologists, specialized radiologists and pathologists, as well as oral and maxillofacial surgeons and prosthodontists, speech pathologists, nutritionists, social workers, physical therapists, medical specialists, and anesthesiologists and pain management providers. In different practice settings, the team members may or may not necessarily work in the same office, clinic, or inpatient unit, and therefore, excellent communication, leadership, and agreement of all team members that the patient's well-being is the highest priority are needed for the team to be maximally successful. The head and neck surgeon often assumes the role of team leader as most head and neck cancer patients are initially referred to a head and neck surgeon. However, as the concept of nonsurgical organ preservation has become widely practiced in our field, it appears that chemotherapy and radiation therapy have become the first line of treatment for many patients with upper aerodigestive tract squamous cancers, necessitating that nonsurgical oncologists share the leadership role in coordinating multidisciplinary oncologic and rehabilitative care.

Cancer of the Head and Neck was written primarily for surgeons in its earlier editions, and while this edition maintains a surgical focus, it provides a comprehensive multidisciplinary approach to the entire head and neck cancer care team. In this fifth edition, we have incorporated disease- and site-specific chapters and have also given more emphasis to reconstruction and rehabilitation of the patient. The major change has not been so much in new chapters as in new authors, and we have searched for colleagues both in the United States and abroad to contribute to the book to make it contemporary and not to overlook any item that would contribute to the understanding and

management of this disease. The book remains faithful in this edition to its original intent, which is to provide a practical guide to practitioners, trainees, and allied health professionals caring for patients with head and neck cancer while maintaining a scholarly, contemporary, and comprehensive coverage of the complexity of head and neck oncology.

We hope that you will find this book helpful as you care for your patients.

CONTENTS

1 Perspectives in Cancer of the Head and Neck

Eugene N. Myers

PERSPECTIVES IN HEAD AND NECK CANCER

In the years which have passed since the 4th Edition of Cancer of the Head and Neck, many changes have taken place in the management of benign and malignant tumors of the head and neck. When my career as a head and neck surgeon began 46 years ago, most cancers of the head and neck were treated surgically using an external approach. Halsted’s concept of en bloc resection to be certain that the cancer was adequately removed often left the patient with cancer of the head and neck a functional cripple and a dreadful sight to behold. The only flaps available were delayed from a distant site such as the abdomen or the back. This form of reconstruction took many months, and by the time the patient’s reconstruction had been completed, often the cancer had recurred. The patient who underwent a total laryngectomy had little chance of ever speaking again and became a social outcast.

Radiation therapy was used with curative intent to treat early cancers of the tonsil and larynx or those deemed unresectable. Salvage surgery for those who failed radiation was fraught with danger due to the high doses used and because little attention was given to the fact that these patients were nutritionally depleted. This set of circumstances led to poor wound healing, necrosis of skin flaps, carotid artery blowout, and death. Even those who survived had great difficulties swallowing and often spent their remaining time on earth being nourished through a gastrostomy tube.

Chemotherapy was in the early developmental phase and used exclusively in the setting of massive local regional recurrence or distant

metastasis. Thus, each of the major modalities used to treat head and neck cancer today was quite primitive in comparison to today's state-of-the-art treatments.

A major advance in head and neck surgery occurred in 1965, when Dr. Bakamjian[1] introduced the deltopectoral flap. I performed many of these flaps during my fellowship with Dr. John Conley in 1967. This was a game changer since it was the first regional flap that could be used nondelayed in the reconstruction of the head and neck. The fact that even the largest wound could be reliably reconstructed immediately pushed the envelope so the surgeons could take on more advanced cancers and create more radical operations. This flap was largely replaced when the pectoralis major myocutaneous flap was introduced by Dr. Steven Ariyan in 1979.[2] This flap could also be used without delay, and creative surgeons have found many uses for this flap, which is widely used even today.

Cranial facial surgery for skull base tumors was first described by Dr. Alfred Ketcham[3] at the NIH in 1963, and this technique still plays an important role in the management of these tumors despite the introduction of endonasal endoscopic skull base surgery.

During my career, I have witnessed the introduction of many new techniques including transoral CO_2 laser microsurgery for vocal cord cancers by Strong and Jako[4] and the use of this technology by Steiner[5] in the excision of cancers of the supraglottis and hypopharynx. Weinstein et al.[6] later adapted the surgical robot (da Vinci) to successfully remove cancers of the oropharynx. The use of these techniques has preserved the historic role of the surgeon as a key individual in the management of cancer of the head and neck.

For those unfortunate patients who require total laryngectomy, the introduction of microvascular free tissue transfer has played a major role in reconstruction of these wounds particularly in the setting of postradiation salvage surgery. Singer and Blom[7] made a huge contribution to the quality of life of these patients when they introduced the valve that uses pulmonary-driven air to allow the patient to speak by occluding the stoma—a powerful contribution, beautiful in its simplicity.

The importance of the surgical robot was grasped by many head and neck surgeons who recognized the versatility and precision built into this machine.

O'Malley and Weinstein[8] developed the transoral robotic surgery (TORS) technique, which has provided a corridor to resect cancers of the base of the tongue thereby eliminating the need for the classic external approaches such as the transhyoid or transmandibular approach of yesteryear. With the current epidemic of HPV-related squamous cell carcinoma in a younger, healthier, nonsmoking population, the TORS approach fills the need for complete cancer resection with clear margins with preservation of swallowing function. The swallowing function was often compromised after larger external techniques were used as well as with patients who in recent years had been treated with nonsurgical means by chemoradiation. When it was recognized that these cancers were more curable in this subset of patients, Genden et al.[9] recognized the advantage of "dose de-escalation," which included primary TORS surgery and when necessary postoperative radiation therapy in lower doses that preserved swallowing function eliminating the patient's long-term dependence on PEG tubes.

Management of the neck remains the keystone in the management of cancer of the head and neck. Prof. Gordon Snow from Amsterdam,[10] in his lecture to the American Society of Head and Neck Surgery in 1979, introduced the concept of extracapsular spread (ECS) of cancer in cervical lymph nodes and the poor prognosis it portended. This concept captured my imagination, and in our department, we studied more than 500 radical neck dissections from patients with squamous cell carcinoma of various sites and validated Snow's findings. Because of the poor prognosis with ECS, we introduced the use of postoperative chemoradiation with a significant improvement in survivorship.[11] Level I evidence for this approach was subsequently provided by Cooper and colleagues in the North America and Bernier and colleagues in Europe.[12]

The teaching of Dr. Hayes Martin,[13] Chief of the Head and Neck Service at Memorial Hospital, was that the use of any technique less than a radical neck dissection and then only when metastatic lymph nodes were present was irrational and he stated, "In my opinion, it is no more logical or tenable to propose any form of partial neck dissection in the treatment of cancer than it is to advocate a partial axillary or partial groin dissection." This concept was challenged by Bocca[14] in 1984 when he published a series of 843 cases of functional neck dissection, which preserved such vital structures as the spinal accessory nerve and jugular vein. The selective neck dissection, which

preserves all of the nonlymphatic structures and can be used in both N_0 and N_+ necks, has gained popularity in recent decades. This technique can also be used in the postchemoradiation setting and even be limited to one level, a concept introduced by Robbins[15] in his Rad Plat treatment program.

Koh,[16] in Korea, has introduced the use of a surgical robot to do neck dissections. This can now be done using a rhytidectomy approach, which leaves a barely perceptible scar. Chung,[17] in Korea, has also done several thousand thyroidectomies using the surgical robot.

One of the factors that has made our field so dynamic is the collaboration of our surgeons with industry in devising technological advances to solve what have been surgical dilemmas. This collaboration has led to improved quality of life for our patients. A few examples in addition to the surgical robot include endoscopic-assisted thyroidectomy, endonasal endoscopic skull base surgery, and transoral laser excision of oropharyngeal lesions.

The formation of teams to manage cancer of the head and neck has led to fundamental improvements in both the oncologic outcome and the patients' improved quality of life. The incorporation of radiation oncologists, medical oncologists, speech–language pathologists, maxillofacial prosthodontists, plastic and oromaxillofacial surgeons, head and neck nurses, and nutritionists has vastly improved the overall care of the patient with cancer of the head and neck. The concept of forming major centers for the resource-intensive care of these patients also results in improved cure rates. Dr. Amy Chen[18] pointed out that hospitals where large volumes of surgery were done achieved higher cure rates than did small-volume hospitals.

Of course, none of the above would have been possible without the tremendous improvement in training specialists in this field. Credit should be given to pioneer surgeons such as Hayes Martin, Alando Ballantine, Richard Jesse, Joseph Ogura, George Sisson, John Conley, and Hugh Biller. All of these individuals were leaders of either Residency Training Programs or Fellowship Programs or both. They taught their trainees, many of whom stayed in academic programs, and subsequently passed on their knowledge and experience to their own trainees. In 1977, the Joint Council for Advanced Training in Head and Neck Oncologic Surgery was formed through the collaborative efforts of the American Society for Head and Neck Surgery and the Society of Head and Neck Surgeons. This was chaired by Dr. John Lore,

Jr., and was comprised of otolaryngologists, surgical oncologists, and plastic surgeons who collaborated in the organization of a formal Head and Neck Fellowship Training Program. This program has undergone an evolution over the years, and now, most of these programs offer a one-year Clinical Fellowship in Head and Neck Surgery while others with the appropriate resources and support for scientific research offer programs of two or more years, which include surgical training and a meaningful experience in scientific research. The programs are carefully monitored through periodic site visits and a rigorous accreditation program. This ensures a high-quality group of 35 accredited programs producing well-trained head and neck surgeons who have become the leaders in our specialty.

The role of research in our field cannot be overemphasized. In otolaryngology, where most of the head and neck surgical specialists originate, all residents must have an exposure to research and are assigned a block of time with a faculty research mentor.

A group of head and neck surgical scientists has emerged in our specialty including Jeffrey N. Myers, Robert Ferris, Joseph Califano, James Rocco, and Wendell Yarborough. These individuals are all accomplished head and neck surgeons and are also NIH-funded research scientists. These individuals serve as role models for trainees in our field who aspire to eradicating cancer through scientific research. A remarkable stimulus to scientific research in our field is the Specialized Programs of Research Excellence (SPORE) grant program sponsored by the NIH. Recipients of these grants include the University of Pittsburgh, MD Anderson Cancer Center, University of Michigan, Johns Hopkins University, and Emory University. Through the study of the biologic and genetic bases of cancer development, progression, and response to treatment, we should be able to identify more effective and less toxic means to prevent and treat these deadly cancers that we deal with on a daily basis. Developing precision treatment of these tumors will enable molecular targeting of drugs for specific tumors. This is exemplified by the use of cetuximab, which followed the discovery of EGFR and the demonstration of its importance in squamous cell carcinoma of the head and neck tumor progression.

I didn't begin my career in medicine wanting to be a head and neck surgeon because little was known about it and it seemed sort of primitive, but I'm proud to have spent my career as a head and neck surgeon, saving a

myriad of lives using cold steel and training a myriad of residents and fellows to do the same. I'm extremely proud of the progress made in our specialty, and I have no doubt that this cadre of remarkable surgical scientists will be leaders of our field and that they will continue to strive for prevention using basic science discoveries while taking care of those already afflicted with this meanspirited disease.

2 Pathogenesis and Progression of Squamous Cell Carcinoma of the Head and Neck

Ryan M. Aronberg, Natalia Issaeva and Wendell G. Yarbrough

Over the past few decades, advances in cellular and molecular biology have led to an accelerated understanding of the pathogenesis and hallmarks of neoplastic disease. More recently, the development of array technologies and high-throughput genetic sequencing have helped to identify many of the underlying molecular defects involved in carcinogenesis and resistance to therapeutics. These capabilities have led to an overwhelming volume of data, requiring advances in bioinformatics to keep pace. The wealth of information being produced has laid the foundation to develop new treatments targeting these defects. Future goals will be the identification of biomarkers to guide diagnosis and therapy, the development of new targeted and combined therapies, and the personalization of therapy based on the molecular characteristics of individual tumors. It will become ever more important for clinicians to understand the molecular characteristics of the disease in caring for their patients. Overall, recent advances in the understanding of tumor biology and related fields (e.g., immunology) make this an exciting time of discovery that should translate into increased survival and improved quality of life for our patients.

This chapter will provide a framework to be used as a basis for exploring the pathogenesis of neoplasia, with an emphasis on the latest findings in head and neck squamous cell carcinoma (HNSCC). We will first introduce general concepts of carcinogenesis and then review the characteristics of the neoplastic phenotype and genotype seen in HNSCC. Along the way, recent biologic insight and therapeutic applications for HNSCC will be explored.

THEORIES OF CARCINOGENESIS

Clonal Evolution and Molecular Progression Models

It is widely accepted that an accumulation of alterations in several genes ultimately leads to a transition from normal to dysplastic to a neoplastic phenotype. Clonal evolution theory, proposed by Peter Nowell in 1976, likens cancer to an evolutionary process involving clonal proliferation, genetic diversification, and subclonal selection.[1] Random mutational events, in conjunction with selective pressures within the tumor environment (tissue barriers, the immune system, induction of programmed cell death, anticancer therapeutics), allow genetic diversification and drift. The cumulative loss of tumor suppressor genes or activation of oncogenes leads to changes in cellular behavior, which confers a survival or proliferative advantage over other cells, ultimately resulting in territorial expansion.[2] Eventually, the further accumulation of defects can confer new traits such as immortality, angiogenesis, or the ability to invade.

Colon cancer represents the first and most comprehensive molecular progression model.[3] In the model, events including oncogene activation and tumor suppressor inactivation lead to progression from normal mucosa, to benign adenomatous growth, to carcinoma in situ, to invasive carcinoma. As in colon cancer, it is the accumulation of these events, rather than an ordered occurrence, that leads to HNSCC,[4] and a similar histologic progression occurs from normal mucosa, to dysplastic mucosa, to carcinoma in situ, to frank invasive carcinoma.

Field Cancerization

For decades, it has been observed that the “normal” mucosa adjacent to head and neck cancers has histologic and genetic alterations not unlike the cancer itself. Additionally, it is not uncommon for satellite lesions or second primaries to occur in HNSCC. These observations led to the “field cancerization” hypothesis that an entire field of mucosa, which is exposed to the same environmental factors, is at risk for carcinogenesis (Fig. 2.1).[5] This theory proposes that although a cancer develops from a small localized segment of the mucosal field, the surrounding cells within a larger field of

mucosa exist on a dysplastic spectrum and share some genetic alterations with the cancer. Early on, lesions can appear clinically and histologically normal, but molecular signatures can help identify altered cells at risk for progression to cancer.

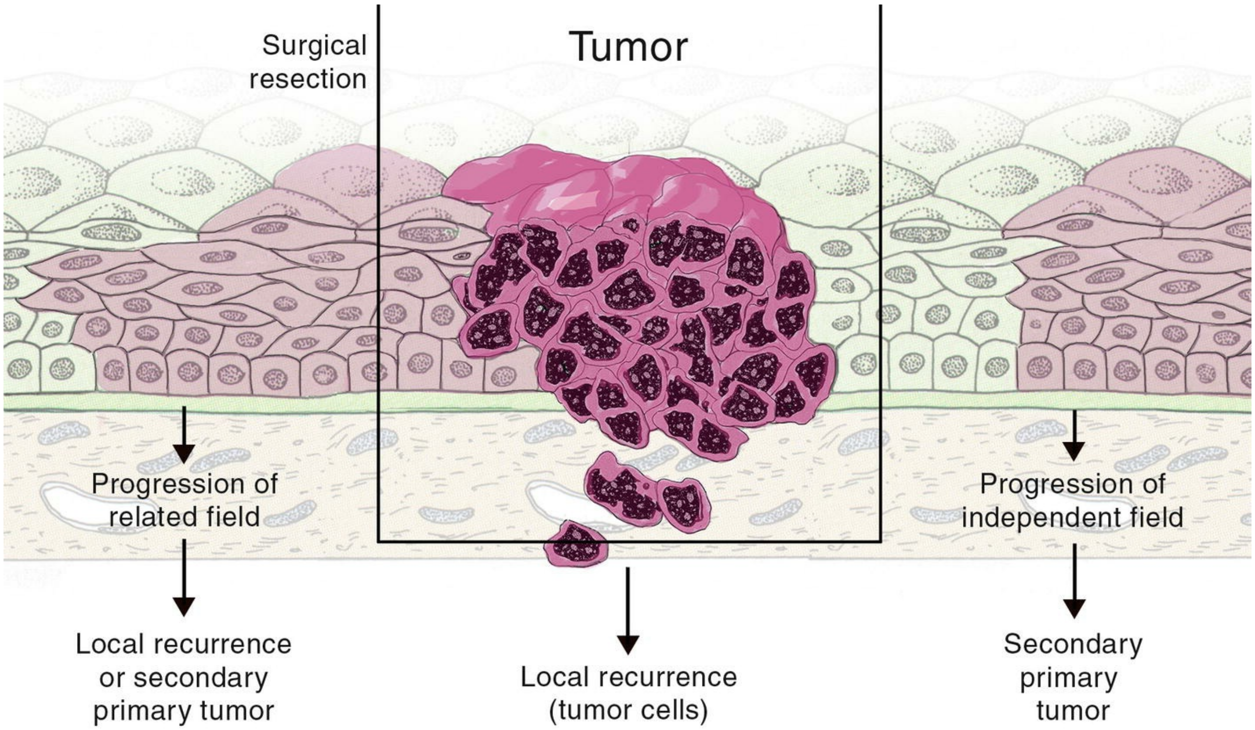

Figure 2.1. Field cancerization. Field cancerization is defined as the presence of one or more mucosal areas consisting of epithelial cells that have cancer-associated genetic or epigenetic alterations. A preneoplastic field (shown in *light pink*) is monoclonal in origin and does not show invasive growth or metastatic behavior, which are the hallmarks of an invasive carcinoma (*dark pink*). Field cancerization has been supported by molecular data and provides a theoretical explanation for multiple primaries. (Adapted from Leemans CR, Braakhuis BJ, Brakenhoff RH. The molecular biology of head and neck cancer. *Nat Rev Cancer.* 2011;11(1):9–22.)

Cancer Stem Cells

When tumor cells are grown in vitro or in a xenograft model, only a small fraction of the cells have the ability to form a new tumor.[6,7] In HNSCC, isolation of a population of cells expressing surface marker CD44 and aldehyde dehydrogenase (ALDH) was shown to have significant tumorigenic

potential, whereas CD44(−) cells did not.[8] The cells that possess the necessary characteristics of self-renewal and differentiation have been termed “cancer stem cells.” They constitute a minority of the cells within the tumor itself but are responsible for much or all of its tumorigenicity. The ability of these cells to self-renew can provide a near-endless supply of new tumor cells, and the ability to differentiate in phenotypically diverse ways allows them to produce a heterogeneous population of cells. Their capacity to differentiate and produce cells with new properties has linked them to cancer initiation, treatment resistance, local tumor recurrence, and metastasis.[9] Meanwhile, due to their slow growth and ability to adapt, these cells are not easily targeted by radiotherapy or traditional chemotherapies. For example, after irradiation of breast or glioblastoma xenografts, cancer stem cells were found to be enriched in the surviving tumor tissue.[10,11] These surviving cancer stem cells were found to possess fewer reactive oxygen species (ROS) (mediators of radiation-induced damage) and activated DNA damage response/repair pathways in response to the radiotherapy. Knowledge of the biologic nature and response of stem cells has led to the hope of targeting these resistance mechanisms therapeutically.

Tumor Heterogeneity

Like most cancers, HNSCCs are not simply an aggregate of a genetically identical cell population, but are composed of cells with marked genetic and cellular heterogeneity (Fig. 2.2).[12] This unexpectedly high degree of heterogeneity is thought to result from a combination of genomic instability, clonal evolution, and the effects of diverse, highly selective, microenvironments within a cancer. Recent evidence indicates that cancer stem cells may be principally responsible[13,14] for creating a heterogeneous population of cells, but that clonal evolution and the effects of the tumor’s microenvironment act in a synergistic manner (i.e., the cancer stem cells themselves may undergo clonal evolution and be affected by local influences in the tumor environment). Higher levels of intracancer heterogeneity have also been correlated to tumor progression, poorer survival, and adverse outcomes in patients with HNSCC. Recently, levels of tumor heterogeneity, when factored with HPV status, were found to be useful in predicting clinical outcome[15] in HNSCC.

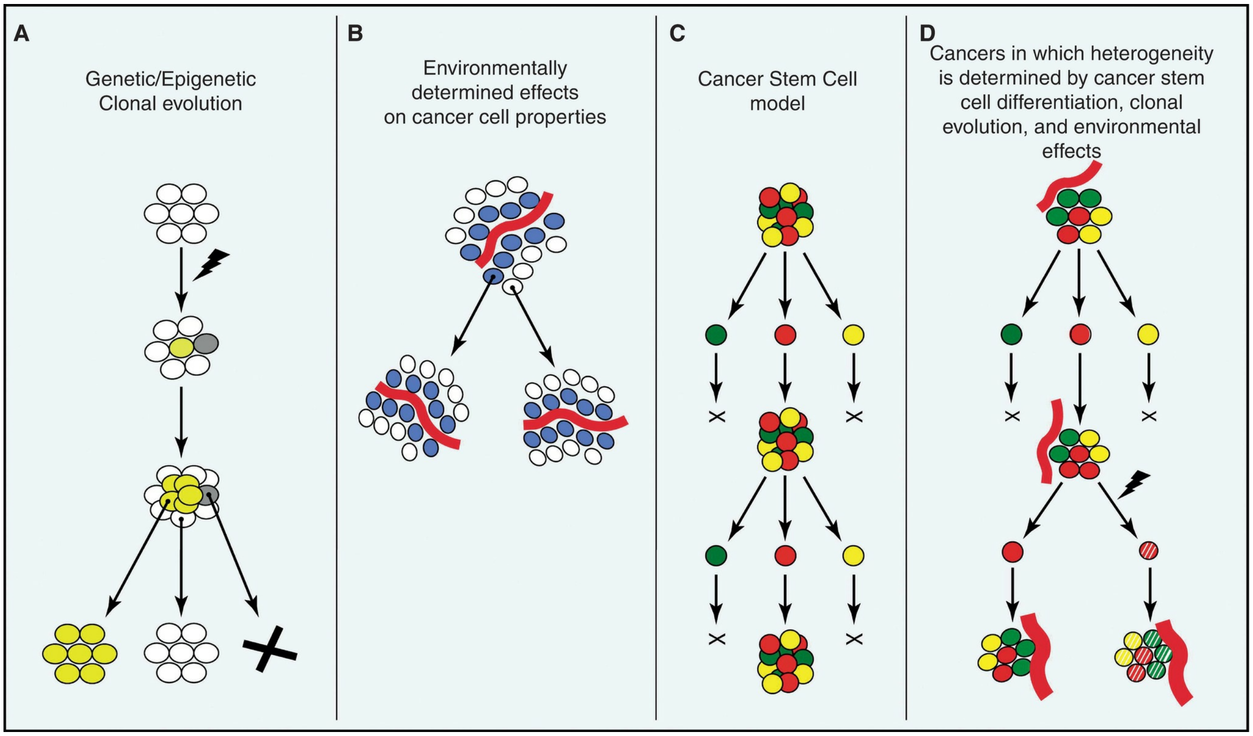

Figure 2.2. Tumor heterogeneity. Heterogeneity can arise within tumors through: **(A)** the stochastic process of clonal evolution, **(B)** extrinsic environmental differences within tumors, and **(C)** the presence of cancer stem cells that variably differentiate. These processes are not mutually exclusive, but rather synergistic in producing a heterogeneous population of cells **(D)**. (From Magee JA, Piskounova E, Morrison SJ. Cancer stem cells: impact, heterogeneity, and uncertainty. *Cancer Cell.* 2012;21(3):283–296, with permission.)

Intratumor heterogeneity makes it unlikely that a single biopsy will fully capture the histologic or genomic landscape of a patient's cancer. New methods have attempted to measure heterogeneity in an attempt to incorporate it into diagnostic workup and treatment, with the applications such as predicting metastatic potential, identifying treatment resistance, and predicting responses to targeted therapies. While performing multiple samples of a cancer (spatially or temporally spaced) may prove challenging and potentially dangerous, future efforts may focus on collecting the DNA of circulating cancer cells or even using molecular imaging to survey multiple areas of the cancer.[16]

RISK FACTORS AND ETIOLOGIC AGENTS

HNSCC has traditionally been, and continues to be, believed to be a cancer caused by environmental elements. Until the 1990s, almost all cancers of the head and neck were thought to be caused by tobacco-related carcinogens. Over the last 20 years, a remarkable shift has taken place, with the human papillomavirus (HPV) becoming responsible for a growing proportion of cancers of the head and neck, specifically of the oropharynx. HPV(−) and HPV(+) HNSCCs are now widely recognized as having distinct etiologies, risk factors, patient populations, clinical attributes, responses to therapy, and prognosis (Table 2.1). Given these observed clinical differences, it may come as no surprise that recent molecular analyses of hundreds of their cancers show a clear and marked distinction between HPV(+) and HPV(−) HNSCCs with regard to mutational profile, gene expression, methylation patterns, and signaling pathway activation.[21]–[24] The molecular and clinical differences between HPV(+) and HPV(−) tumors are clear indicators that we must no longer consider HNSCC as a single disease. Going forward, subtypes of HNSCC defined by the molecular characteristics of the tumor, as well as the genetic background of the patient, will guide therapy, with the goal of personalized cancer treatment. Accordingly, we explore HPV(−) and HPV(+) HNSCC separately in this chapter.

Table 2.1 Distinct Clinical Features of HPV(+) and HPV(−) HNSCC

Characteristic	HPV(–) HNSCC	HPV(+) HNSCC
Etiology/risk factors	Smoking, alcohol	HPV (high-risk sexual practices)
Incidence	Decreasing	Increasing
Age	Older	Younger
Gender	Male	Male
Race/ethnicity	AA > Caucasian > others	Caucasian > AA[a]
Socioeconomic status (SES)	Lower SES	No predilection
Site	All head and neck	Oropharynx
AJCC staging (TNM)	Higher T, lower N (79)	Lower T, higher N
Histopathology	Most commonly moderately to well-differentiated SCC, producing keratin (70)	Most commonly poorly differentiated or basaloid SCC, with koilocytes
p53	Inactivating mutations	Inhibited by E6
Rb	17p LOH, p16 mutation, deletion, or promoter hypermethylation	Inhibited by E7
p16 expression	Decreased	Increased
Chemoradiotherapy response	Good, but with high rate of recurrence	Good, with low rate of recurrence
Survival/recurrence	Poor for advanced stages	Good, but worse if smokers

[a]Data show a difference in racial/ethnic population affected by HPV(+) compared to HPV(−) HNSCC, though precise incidence rates have not been reported because data are from small cohort studies. Environmental Toxins

The vast majority of HPV(−) HNSCC are caused by exposure to environmental carcinogens. Fifty-five thousand HNSCC cases were estimated to occur in the United States in 2014.[25] The exact incidence of HPV(−) HNSCC is difficult to determine because HPV testing is not universal and reporting is not required. Long considered the traditional risk

factors, tobacco and alcohol are known to dramatically increase the risk of head and neck cancer.[26,27] While the risk from consumption of alcohol alone is modest, it synergistically increases risk when combined with tobacco.[28,29] In addition to the direct trauma to mucosal surfaces induced by these agents, tobacco products are composed of dozens of known carcinogenic compounds, including polycyclic aromatic hydrocarbons (PAHs), oxidizing substances, and free radicals. Following metabolic activation by endogenous enzymes (often cytochrome p450s), these carcinogens form covalent DNA adducts and/or induce epigenetic changes. These DNA adducts must be repaired by designated DNA repair machinery or else risk causing errors in replication (resulting in mutations).

Because many more people use tobacco than develop cancer, there are probably individual factors that moderate the risk of cancer development following exposure to the more than 60 known carcinogens in tobacco smoke.[30] The role of individual factors as modulators of the risk of cancer development has been examined with a focus on enzymes that metabolize the carcinogens. For example, the increased incidence of HNSCC in first-degree relatives of patients who have HNSCC supports a role for genetic predisposition that could be related to carcinogen metabolism.[31] Studies of gene–environment interactions are difficult and frequently underpowered, and in the case of tobacco carcinogen detoxification, the genes implicated exist in large families, which functionally overlap. Despite these constraints, polymorphisms in glutathione-*S* transferase (GST) and uridine 5′-diphosphate-glucuronosyltransferase (UGT) have been identified as possible risk factors.[32,33] That being said, the overall increased risk attributable to the presence or absence of any detoxifying enzyme polymorphism is modest, and mechanisms for translating knowledge of polymorphisms into decreased risk are not clear. As has been proven by recent decreases in cancer incidence,[25] a more fruitful area for impact is advocacy and education to decrease the use of tobacco.

Human Papillomavirus

HPV was first linked to cervical carcinogenesis in the 1970s by Professor Harald zur Hausen. The idea of a virus causing cancer went against the prevailing views of that time, and he was awarded the Nobel Prize in Medicine for this important discovery in 2008.[34] Soon after, an association

between HPV and head and neck malignancies was demonstrated when HPV antigens were detected in preserved histologic specimens.[35] However, it remained unclear if the HPV in these cancers was truly a causative agent or simply a passenger or contaminant. More recently, multiple lines of evidence have shown that HPV can be causative of HNSCC, particularly those arising in lymphatic-associated epithelium of the palatine and lingual tonsils. Epidemiologic data show that since the 1980s, there has been a decrease in the incidence of cancers of the head and neck in many developed countries, directly mirroring the decline in tobacco consumption. However, the incidence of cancer of the head and neck in nonsmokers has increased dramatically, along with the incidence of HPV-related cancers.[36] High-risk HPV is now causatively linked to the majority of oropharyngeal squamous cell carcinomas (OPSCCs).[37] Known aspects of HPV biology and mechanism of malignant transformation, as well as differences between HPV(+) and HPV(−) HNSCCs, will be discussed in depth later in this chapter.

Familial Disorders

As opposed to the modestly increased risk associated with polymorphisms in carcinogen-metabolizing enzymes, the risk of developing cancer in patients with familial cancer syndromes is dramatically increased. Fanconi anemia (FA) is an autosomal recessive disorder caused by mutations in any of a number of DNA repair genes (including the FANC and BRCA genes) that are primarily responsible for double-strand break repair. Disruption of these genes leads to chromosomal instability, an abnormally large number of mutations, and susceptibility to DNA-damaging agents. About 3% of patients with FA develop HNSCC, which represents a 700-fold increase over the general population.[38] Fanconi patients are also at a 50-fold increased risk for all cancers combined and are particularly susceptible to cancers caused by HPV,[39] leading to the hypothesis that the DNA damage response may be required for repairing DNA defects caused by HPV. Alternatively, defective DNA repair could accelerate HPV-driven tumorigenesis, HPV replication, or tolerance of HPV DNA. While DNA damage is considered an important component in the development of all types of solid tumors, it is unclear why HNSCCs represent such a high proportion of cancers in these individuals. Other familial disorders that predispose to HNSCC are Bloom syndrome, Lynch II syndrome, xeroderma pigmentosum, ataxia telangiectasia, and Li-

Fraumeni syndrome—all of which are associated with DNA damage repair deficiencies (Table 2.2). This underscores the critical role that DNA damage plays in HNSCC carcinogenesis.

Table 2.2 Familial Syndromes and HNSCC

Syndrome	Gene Affected (Function)	Risk of HNSCC	Other Associated Cancers	Other Characteristics
Fanconi anemia	FANC (DNA repair)	500-fold increased	Hematologic	Growth retardation, café au lait spots, skeletal malformations, bone marrow failure, renal anomalies
FAMMM	CDKN2A (cell cycle control)	Described rarely in families	Melanoma, pancreas	Familial melanoma/atypical nevi, early-onset pancreatic cancer
Bloom syndrome	BLM (DNA helicase)	Moderately increased	Leukemia, lymphoma, other carcinomas	Dwarfism, sun-induced skin rash, café au lait spots, facial abnormalities (normal IQ), immunodeficiency
Xeroderma pigmentosum	XP-A to XP-G (DNA repair)	Moderately increased	UV-induced skin cancer	Severe photosensitivity, ocular problems, neurologic problems (retardation, neuropathies)
Ataxia telangiectasia	ATM (DNA damage detection/repair)	Moderately increased	Leukemia, lymphoma	Progressive ataxia, telangiectasias, immunodeficiency
Li-Fraumeni	p53 (cell cycle, DNA damage response, others)	Moderately increased	Sarcoma, breast, glioblastoma, leukemia, lymphoma	No other associated abnormalities

FAMMM, familial atypical multiple mole melanoma syndrome; UV, ultraviolet radiation.

(From van Monsjou HS, et al. Head and neck squamous cell carcinoma in young patients. *Oral Oncol.* 2013;49(12):1097–1102. Reference 40.)

The CDKN2A gene encodes a protein ($p16^{INK4a}$) important in cell cycle regulation, as detailed later. Loss of functional $p16^{INK4a}$ by deletion, mutation, or promoter methylation is found in more than half of all cancers of the head and neck. Interestingly, families with germline $p16^{INK4a}$ mutations also have a very high incidence of malignancies, including melanoma, pancreatic cancer, and HNSCC.[41–45] Overall, due to the rarity of these predisposing syndromes and germline mutations, patients with HNSCC with these syndromes constitute a very small percentage of all HNSCC.

Prevention

Treatment and detection of HNSCC has become more sophisticated over the past few decades. However, primary prevention, early detection, and close surveillance of those at highest risk remain the strategies with the most impact to reduce morbidity and mortality from the disease. Clinicians are

among those responsible for communicating the importance of minimizing exposure to traditional risk factors such as tobacco and alcohol. Additionally, encouraging awareness of the signs/symptoms of cancers of the head and neck, implementing head and neck screenings, and improving access to appropriate health care can help diagnose these cancers at earlier stages as well as afford opportunities to initiate discussion regarding the risk factors for the disease.

Approved HPV vaccines are effective in preventing new infections from the HPV genotypes linked with cancer of the cervix and head and neck, and it is expected that the vaccine will have a major impact on the prevalence of both types of cancers. It is the responsibility of health care professionals to ensure that male and female children, adolescents, and other candidates receive the potentially lifesaving vaccine. The number of sexual partners and type of sexual practices are risk factors for HPV-related head and neck malignancies, so limiting risky sexual practices also minimizes risk in nonvaccinated individuals.[17]

TYPES OF GENETIC ALTERATIONS IN HNSCC

As is true for all cancers, genetic defects are at the root of carcinogenesis in the head and neck. Genetic defects leading to cancer can be inherited or acquired through defective DNA replication or repair, exposure to mutagens/carcinogens, or infection by microorganisms and viruses. The initiation and progression of cancer involves a stepwise accumulation of these genetic insults (or “hits”). These “hits” are usually alterations in tumor suppressor genes or oncogenes. They can accumulate in many forms, including mutations, copy number variations (CNVs), epigenetic changes, and others. We will discuss the alterations that contribute to development or progression of HNSCC (Fig. 2.3). While genes such as p53 and p16 are altered in the vast majority of HNSCCs, most affected genes in HNSCC occur in fewer than 30% of the cancers. Despite the enormous number of potential alterations, they tend to cluster in a limited number of biologic pathways, which helps to organize and understand the pathogenesis, and will be discussed afterward.

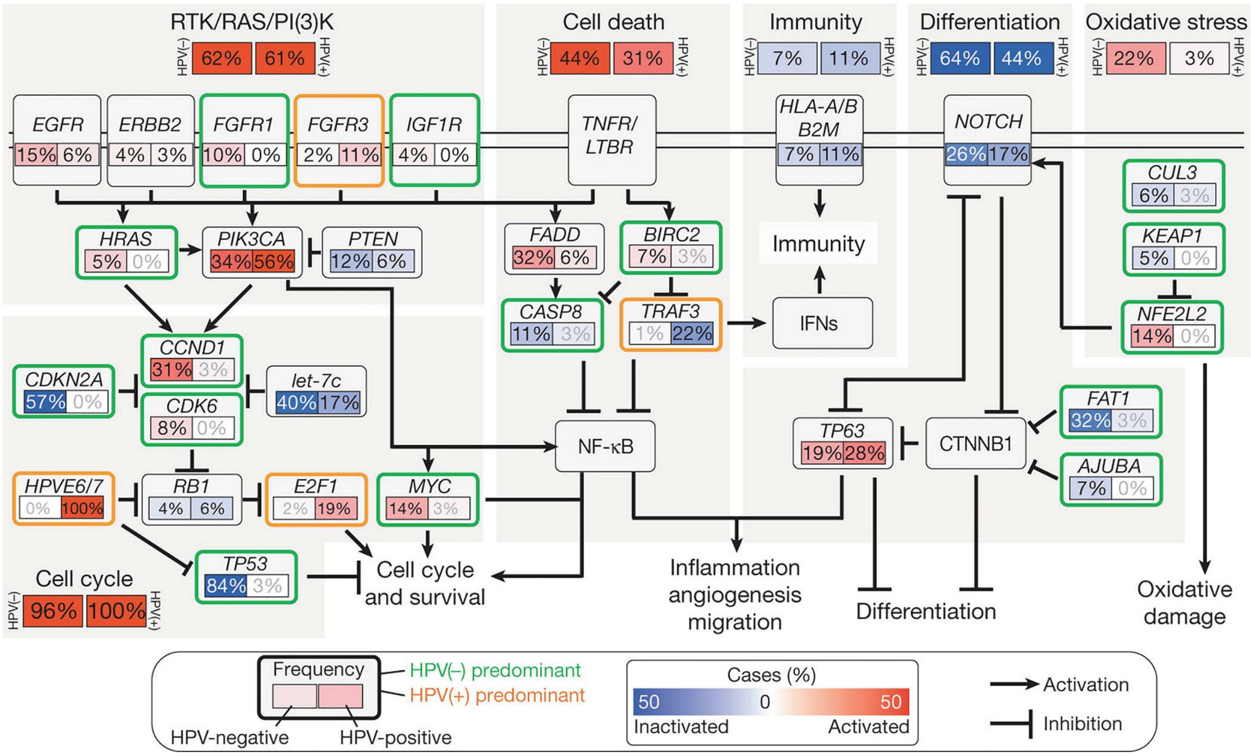

Figure 2.3. Pathways affected in HNSCC. Signaling pathways frequently altered in HNSCC, based on recent TCGA analysis. The frequency (%) of genetic alterations for HPV(−) and HPV(+) tumors is shown separately within subpanels and highlighted. (From The Cancer Genome Atlas N. Comprehensive genomic characterization of squamous cell carcinoma of the head and neck. *Nature*. 2015;517(7536):576–582, with permission.)

Mutations

Mutations describe alterations in the sequence of DNA itself and can occur in the form of nucleotide substitutions, deletions, or insertions. Their effect on the function of the protein is variable, as they may be categorized as silent (causing no change in the encoded protein), missense (leading to an altered amino acid sequence), or nonsense (truncation of the protein). The mutational landscape of HNSCC is being increasingly revealed by high-throughput, “next-generation sequencing.” HNSCC is associated with one of the highest mutation rates of any cancer, possibly due to the association of these tumors with environmental carcinogens known to induce DNA damage. Though there are a few characteristic mutations in HNSCC (Table 2.3), there is a large amount of genetic variability between tumors. Tumor suppressors including p53 (71%), CDKN2A (22%), FAT1 (23%), and NOTCH1 (20%)

are the most frequently mutated genes in HNSCC, with only one oncogene (PIK3CA, 21%) having a mutation rate >20%.[21] These frequently mutated genes map to a diverse set of biologic pathways including DNA repair (p53), cell cycle regulation (p53, CDKN2A), apoptosis (p53, PIK3CA), and cell differentiation (NOTCH1). Importantly, the mutational landscapes of HPV(−) and HPV(+) HNSCCs are quite different (Table 2.3),[46] as will be discussed later.

Table 2.3 Common Gene Defects in HNSCC

Oncogenes	**% HPV(+) tumors**	**% HPV(–) tumors**
PIK3CA	20 + 28 + 8 = 56	16 + 14 + 4 = 34
CCND1	3	31
EGFR	6	11 + 3 + 1 = 15
MYC	3	14
FGFR1	10	—
ERBB2	3	3 + 2 = 5
HRAS	—	5
Tumor suppressor genes	***% HPV(+) tumors***	***% HPV(–) tumors***
TP53	3	83 + 1 = 84
CDKN2A	—	33 + 25 = 58[a]
PTEN	3 + 3 = 6	2 + 10 = 12
NOTCH1	19	7
TRAF3	14 + 8 = 22	—
NSD1	—	10 + 2 = 12

Amplification; Activating mutations; Amplification and activating mutation;

Inactivating mutation; Deletion; Protein down-regulation; Total. The Cancer Genome Atlas N. Comprehensive genomic characterization of head and neck squamous cell carcinomas. *Nature*. 2015;517(7536):576–582. Reference 21.

[a]A significant proportion of HPV− tumors also display CDKN2A promoter hypermethylation (not shown).

Overall, it is clear that mutational changes drive cancer initiation and progression, but we are just beginning to understand the functional significance of many of them. Additionally, each tumor may have hundreds of mutations, and it can be difficult to determine the effect of each on the encoded protein, as well as whether a given mutation is a “driver” (directly causing carcinogenesis) or a “passenger” (having little impact on tumor cell fitness but co-occurring with driver mutations).

Copy Number Variations

A CNV consists of a structural change in a chromosome effecting a gain or loss of a portion of that chromosome, which can involve a single or multiple contiguous genes. They can come in the form of deletions, duplications, inversions, or translocations. Though prevalent in the normal human genome, CNVs that involve a loss of tumor suppressors or gain of oncogenes can predispose to neoplastic transformation. They can also result in a gene moving to come under the control of abnormal promoters or regulatory elements (e.g., BCR-Abl—the Philadelphia chromosome). CNVs in cancer cells have historically been detected using cytogenetic techniques such as chromosomal banding or fluorescent in situ hybridization (FISH), but next-generation sequencing has accelerated detection of CNVs and fostered an understanding of their crucial role in cancer.

CNVs are important in the pathogenesis of HNSCC. Each HNSCC harbors on average over 100 altered copy number segments, indicating a high degree of genomic instability. In HNSCC, the most common alterations are gains in chromosomal regions 3q, 5p, and 8q and loss of 3p and 8p.[21] These particular segments are gained or lost with such frequency because of the growth/survival advantage they confer (due to loss of tumor suppressors or gain of oncogenes). In HNSCC, deleted chromosomal segments include known tumor suppressors such as FAT1, NOTCH1, SMAD4, and CDKN2A. Recurrently amplified regions often include receptor tyrosine kinases (RTKs)

involved in growth signaling (growth hormone receptors EGFR, FGFR1, and ERBB2). The 3q region that is frequently amplified contains oncogenes important for survival, squamous differentiation, and stemness (PIK3CA, p63, hTERT, and SOX2). Many CNVs observed in HNSCC are common to epithelial cancers occurring elsewhere in the body, suggesting a common underlying pathophysiology. For many CNVs, the driver behind the change is unknown. Often, several contiguous genes are affected, making it difficult to decipher which genes are drivers versus passengers.

HPV(+) tumors display a distinct pattern of CNVs compared to HPV(−) HNSCC. The differences in CNVs reflect unique selective pressures that occur in HPV(+) versus HPV(−) HNSCC. For example, HPV(+) tumors express the oncoproteins E6 and E7, which through their inactivation of p53 and Rb diminish the pressure to delete either p53 or p16 in HPV(+) cancers. On the other hand, some CNVs (such as 3q amplifications and 3p deletions) are shared between HPV(+) and HPV(−) HNSCCs and are thus likely required for maintenance of squamous cells regardless of the etiologic agent.

Epigenetics

Epigenetics is a broad term that refers to self-perpetuating changes in gene expression that do not affect the actual sequence of DNA. The most well-characterized epigenetic alterations are DNA methylation and histone modifications. By altering the nonsequence structure of DNA and the histones that package it, epigenetic modifications can make genes more or less accessible to activators of transcription and therefore modulate their expression. Methylation is the most frequently studied epigenetic change, partly because there are well-established methods to examine it. Promoter methylation, as well as global hypermethylation, has been shown to facilitate tumorigenesis by the silencing of tumor suppressors. In HNSCC, promoter methylation of genes such as CDKN2A (encoding $p16^{INK4a}$ and $p14^{ARF}$), DAPK, RASSF1A, RARB2, APC, and MGMT is often an early event during neoplastic progression.[47–49] It has been postulated that epigenetic changes are complementary to the genetic changes, for example, silencing a wild-type tumor suppressor allele when the other is inactivated by mutation.

Additionally, whole-exome sequencing studies have revealed that several of the genes responsible for histone modifications are recurrently mutated in HNSCC (e.g., EZH2, MLL2, MLL3, NSD1).[21,50,51] Mutations of these genes

result in aberrant chromatin structure and gene regulation. This finding also underscores the role that epigenetics plays in HNSCC tumorigenesis.

Studies have shown that HPV(+) HNSCCs have increased global methylation compared to HPV(−), and clustering based on methylation can predict HPV status.[52] The clinical implications of epigenetics in HNSCC have yet to be firmly established, but it is likely that certain methylation patterns will be prognostic of tumor aggressiveness and/or predictive of therapeutic response.[52] Increasing knowledge about epigenetics has also helped to produce a new group of rational therapeutics, targeting histone deacetylases (HDACs) and DNA methyl-transferases (DNMTs), aimed at reversing aberrant epigenetic changes.

In addition to epigenetic alterations, gene expression can be modified at the transcriptional and translation level by microRNAs (miRNAs). These are small ~20 nucleotide RNA oligonucleotides, which complementarily bind mRNA, altering its fate through one of several mechanisms.[53] Although miRNAs are a normal, evolutionarily conserved process in plant and animal cells, tumor cells up- or down-regulate certain miRNA, which can enhance malignant properties. In HNSCC, expression of specific miRNA are consistently altered to deregulate expression of genes involved in cell cycle regulation (e.g., PTEN, p21)[54] and other cancer-related processes (e.g., KRAS). Presence or absence of certain miRNA has been correlated to prognosis, metastatic likelihood, and resistance to treatment; however, most miRNAs have several targets,[55,56] and their analysis is complex. In the future, miRNA signatures may be applied to identify tumor-specific subtypes or to guide treatment. Techniques for efficient delivery of miRNAs are being developed in hopes that they can be used therapeutically.

LINKING GENETICS TO PATHWAYS

The recent developments of whole-exome sequencing and other high-throughput techniques have added a wealth of data to the large preexisting body of work in the molecular biology of HNSCC. Although these data have allowed a more complete picture of defects in HNSCC, they have also highlighted the complexity of its pathogenesis. Understanding the role of even a single gene requires integrating the various types of genetic and epigenetic changes that affect it in the cancers of different patients, the

molecules it interacts with, and how the gene is affected over time and in spatially distinct areas of each patient's cancer. For example, though p53 itself is found to be mutated in around 70% of HNSCCs, it can also be deactivated in the remaining tumors by overexpression with or without amplification of MDM2 (which facilitates p53 degradation) or by expression of the HPV E6 oncoprotein. As the realm of tumor-related data has expanded to include mutations, amplifications/deletions, mRNA and protein expression profiles, microRNA expression, immune profiling, and epigenetic events, multiplatform data must be simultaneously considered to determine the drivers of carcinogenesis and direct therapy. Recent analyses suggest that data from different platforms carry overlapping information and omission of one type of data from multiplatform analyses does not necessarily alter classification.[57]

Categorizing defects into cancer-related biologic pathways can be a useful approach to organize and assign meaning to the wealth of data. For example, PIK3CA, a cell survival and growth gene, is mutated in 21% of a recent HNSCC cohort[21]; but when copy number amplifications were considered, that number rose to 36%, and when "hits" to other genes in the PIK3CA pathway were included, its pathway was affected in the majority of tumors.[21,58] For this reason, studies have shown that mutational data may be more useful when placed into pathways.[59] Though most of the early therapeutic successes in targeted cancer therapy have been based on individual mutations (e.g., BRAF in melanoma or EGFR in lung adenocarcinoma), understanding the mechanisms and pathways involved may help illuminate the most promising molecular targets for future treatments.

In the following section, we describe biologic pathways that are most commonly affected in HNSCC. Increasing knowledge of the normal function and interactions of these genes has laid a framework to fit the observed alterations into a narrative of cancer initiation and progression (Fig. 2.3). However, there is significant overlap and interaction between these pathways, and some pathways may be more affected in one tumor versus another. Genetically speaking, there are many different routes to cancer, which is why treating the disease in the future will likely require an equally sophisticated approach.

HALLMARKS OF HEAD AND NECK CANCER

In HNSCC, the transition of epithelial cells from normal to neoplastic involves a multistep process of accumulated genetic changes, which produces characteristic changes in biologic pathways that can be observed at the phenotypic level. The characteristic phenotypic changes, or “hallmarks,” seen in cancer cells have been frequently described and updated in recent years (Fig. 2.4).[60] We use these events as a framework to review the recent developments in the study of HNSCC. While we review the hallmarks with a focus on HNSCC, a comprehensive review can be found elsewhere.[60] The hallmarks discussed here include genomic instability, cellular proliferation, invasion and metastasis, angiogenesis, resisting cell death, replicative immortality, and reprogrammed metabolism. Additionally, interplay with the immune system (evasion of immune detection and tumor-promoting inflammation) will be discussed.

Enabling Characteristics

Figure 2.4. Hallmarks of cancer. Hanahan and Weinberg initially described, then expanded, attributes needed for cancer development. (Adapted from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation. *Cell.* 2011;144(5):646–674.)

Genomic Instability

Normal cells possess a very high-fidelity system for DNA replication, such that errors occur once per 100,000 copied bases. Even those “rare errors” are corrected 99% of the time by DNA repair machinery, bringing the final error rate to one per ten million bases. A wide variety of systems known as “caretakers” detect and repair errors in the genome or, if unsuccessful, freeze the cell cycle and activate cell death.[61,62] Some mechanisms directly inactivate or intercept mutagens even before they damage DNA. The “clonal evolution theory” suggests that many alterations are needed for cells to gradually transform into cancer. Although the chances of this happening in a normal cell are infinitesimally small, damage to caretakers through genetic or epigenetic changes can lead to instability of the genome, increasing the error rate and allowing propagation of defects to subsequent generations of cells. Thus, by allowing the series of alterations required for neoplastic change, genomic instability is considered an enabling characteristic common to nearly all cancers.[63] The quintessential tumor suppressor p53 plays a central role in guarding the genome by activating DNA repair, cell cycle arrest, or apoptosis in response to genetic damage or cellular stresses.[64]

Endogenous and environmentally induced defects accumulate much faster without these proofreading capabilities, and although many of those genomic defects may be phenotypically silent, some (e.g., affecting tumor suppressors or oncogenes) will be involved in the carcinogenic processes described in the following sections. Across all cancers, HNSCC has among the highest levels of mutations, chromosomal rearrangements, and copy number alterations, highlighting the importance of instability within the genome to the pathogenesis of this disease.[65]

Dysregulation of Proliferative Signaling

Cells within normal tissues have a tightly regulated balance of proliferative and antiproliferative signaling that govern cellular growth and replication,

thus ensuring homeostasis between cell population and host resources. Progrowth signals most often come in the form of growth factors in the cells' environment that bind receptors on the cell surface and initiate signaling cascades within the cell. There also exist mechanisms to inhibit growth, ensuring that mitogenic signals are only transient and even inhibited in the presence of certain stimuli (such as DNA damage or absence of sufficient resources). Even in the presence of growth signals, cellular proliferation is tightly regulated, and cells must progress through many checkpoints and phases in the cell cycle in order to duplicate their DNA and divide into two daughter cells. In cancer cells, cell cycle checkpoints are universally circumvented to allow for aberrant cellular proliferation. One of the most fundamental characteristics of neoplastic cells is their ability to sustain proliferation, by either acquiring autonomous proliferative signaling or evading inhibitory mechanisms.

Progrowth Proliferative Signaling

Normal cells require a basal level of growth signals in order to survive and proliferate. Typically, growth factor molecules are released by distant or neighboring cells and bind to tyrosine kinase receptors on the cell surface, which relay that signal to a branching network of downstream effectors. By producing a growth factor ligand autonomously, increasing the quantity/efficiency of growth factor receptors, or constitutively activating downstream effectors, cancer cells routinely acquire autonomous growth signals.[66] In HNSCC, the epidermal growth factor receptor (EGFR) and its pathway are altered in a significant proportion of HNSCCs. Whereas mutations to the EGFR gene are uncommon, amplification and overexpression of EGFR are very common.[67] Other RTKs that are amplified or overexpressed and less frequently affected include hepatocyte growth factor receptor (MET), fibroblast growth factor receptor (FGFR), and insulin-like growth factor (IGFR).[21] Chief downstream effectors of growth factor receptors are also directly implicated in the pathogenesis of HNSCC, such as the PI3K/Akt/PTEN/mTOR,[58] JAK/STAT,[68] and RAS/RAF/MEK/MAPK pathways, each of which initiates a complex cascade of proliferative, survival, metabolic, or related functions.

Loss of growth inhibition is also common. Transforming growth factor beta (TGF-β) acts as an antiproliferative signal for normal epithelium, and its

downstream effector, SMAD4, is down-regulated in up to 20% of HNSCC.[21] As part of their greater functions as tumor suppressors, both Rb and p53 help to suppress proliferative activity as well. Although there is not a single growth factor or receptor that is universally altered in HNSCC, summation of various insults to the compilation of growth signaling pathways supports the concept that aberrant growth factor signaling is required for HNSCC development.

Cell Cycle

The normal cell cycle, the process by which cells replicate their DNA and divide, is guarded at various checkpoints to ensure that cells divide only when it is appropriate to do so (Fig. 2.5). The cell cycle consists of four phases: G1 (gap phase 1), S (DNA synthesis), G2 (gap phase 2), and M (mitosis). Progression through the cell cycle is mediated by activity of cyclin-dependent kinases (CDKs), interacting with cyclins. Additional regulation is introduced by expression of CDK inhibitors (CDKi) that can result in stalling of the cell cycle or permanent arrest. The quantity and phosphorylation status of cyclin–CDK complexes, as well as expression of CDKi, largely determine if a cell will initiate DNA replication and begin a round of the cell cycle. Proteins that regulate cell cycle progression are known as “gatekeepers” that prevent the cell from replicating unless conditions are appropriate. The tumor suppressors Rb and p53 are the canonical gatekeepers that halt cell proliferation in response to extracellular growth arrest signals or intracellular signals of DNA damage and resource limitations. They operate within complex circuits, which can also activate DNA repair or cell death if necessary. Gatekeepers must be circumvented for the aberrant cell cycle progression that occurs in cancer cells.

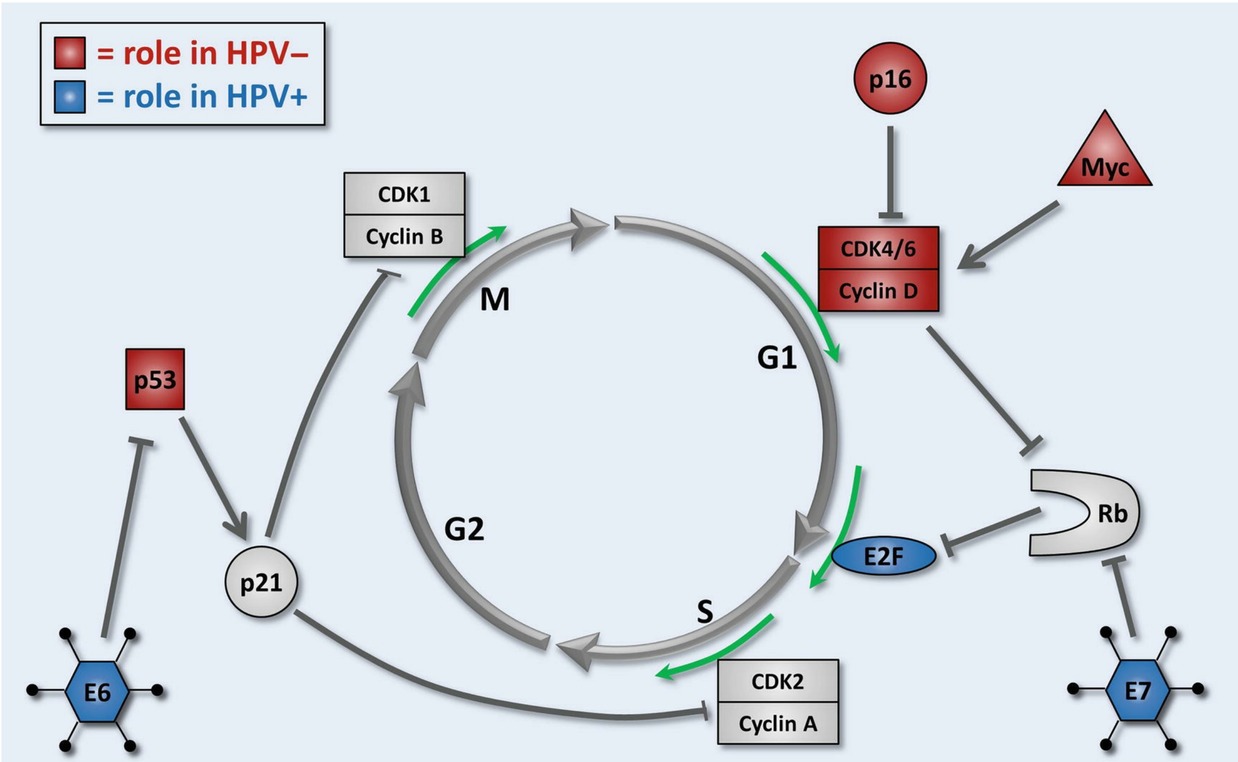

Figure 2.5. Cell cycle control. Progression through the cell cycle is tightly controlled in noncancer cells. In HNSCC, the regulators of cell cycle progression are ubiquitously altered by many different mechanisms. The most common defects in cell cycle regulators are shown for HPV− (*red*) and HPV+ (*blue*) HNSCCs.

As will be discussed later, p53 itself is mutated or deleted in roughly 70% of HNSCC. In most of the remaining 30% of cases, p53 is inactivated by the HPV E6 oncoprotein. Similarly, Rb activity is diminished through a variety of mechanisms in HNSCC. Although the Rb gene is mutated or deleted in only 5% of HNSCC, it is often directly inhibited by the HPV oncoprotein E7 or by alterations to its regulators (cyclin D1, p16^{INK4a}). The nearly ubiquitous, though heterogeneous, insults to the gatekeeper circuits indicate that this is one of the key requirements for development or progression of HNSCC.[69]

Abnormal Differentiation: Invasion and Metastasis

As part of their normal function, squamous epithelial cells express specific adhesion molecules in order to create a tightly packed functional sheet,

remain external to the basement membrane, and eventually terminally differentiate, senesce, and slough away. The normal maturation of epithelial cells involves orderly changes as they progress from the basal epithelial layer to become mature keratinocytes (Fig. 2.6). These changes are mediated by transcriptional changes driving increased or decreased expression of specific genes involved in epithelial differentiation. Disruption of this normal differentiation is thought to occur in HNSCC and other epithelial cancers, in which cell populations can attain properties and appearance of mesenchymal (connective tissue) cells. The resulting cells often lose their epithelial architecture, become less dependent on cell–cell contact, and possess increased motility, invasion, angiogenesis, and other mesenchymal-like properties. This phenomenon is referred to as epithelial–mesenchymal transition (EMT). The process of EMT is mediated by four major transcription factors: Snail, Slug, Twist, and Zeb 1/2. EMT is a normal process that is used during embryogenesis and wound healing but is hijacked during carcinogenesis.

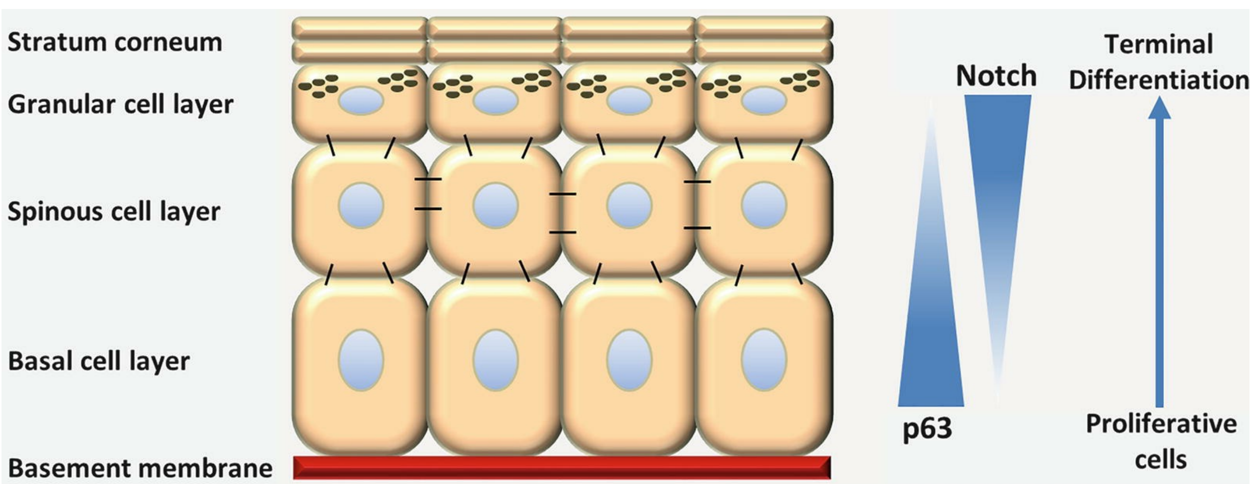

Figure 2.6. Maturation of keratinocytes. Epithelial cell proliferation is limited to the basal layer, and cells progressively differentiate as they migrate superficially before being sloughed from the surface. NOTCH and p63 play key roles in this differentiation process and are frequently disrupted during development of HNSCC.

Adherens junctions, a protein complex consisting of E-cadherin and α- and β-catenins, constitute a part of the normal cell–cell contacts between neighboring epithelial cells. They render the cells relatively immobile and

prevent cellular proliferation through a process known as contact inhibition. Compared to normal epithelium, cadherins are down-regulated in HNSCC.[70] Meanwhile, integrins, which help cells attach to the underlying extracellular matrix, are up-regulated in some HNSCC.[71] Beyond changes of adhesion properties, cancer cells have increased motility and invasion and possess matrix-degrading enzymes (matrix metalloproteinases—MMPs) (Fig. 2.7).[72,73] These changes are needed for the destructive invasive properties of HNSCC as well as for processes associated with lymphatic and hematogenous metastases.

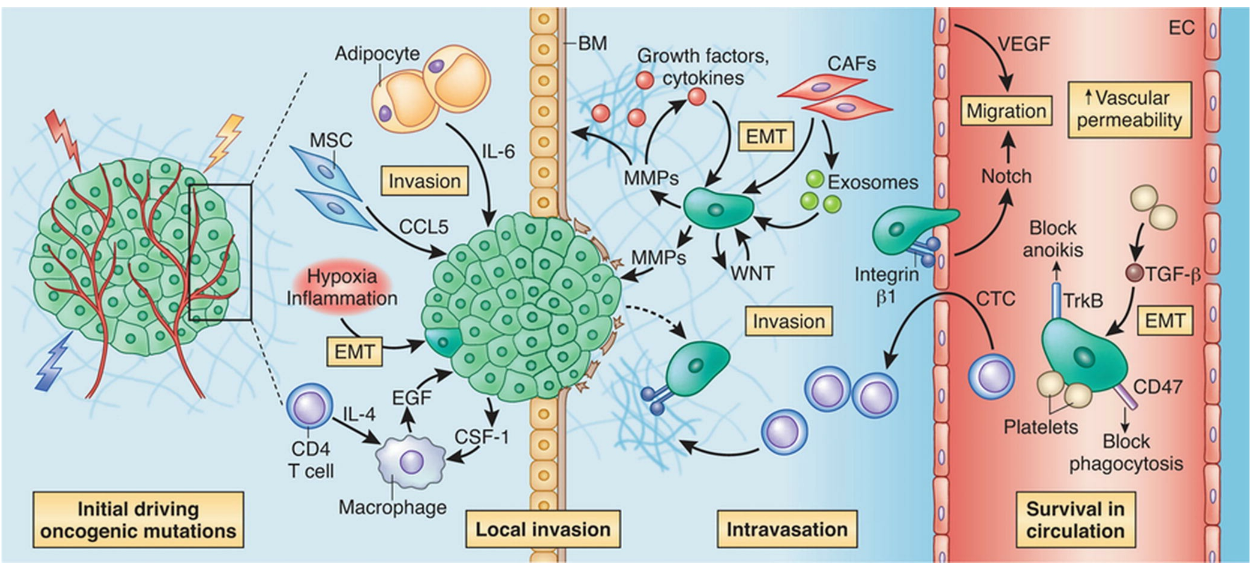

Figure 2.7. Tumor microenvironment, invasion, and metastasis. To disseminate, cancer cells acquire the capabilities to break down the basement membrane, invade into the stroma (local invasion), enter the blood circulation (intravasation), survive during dissemination, exit the blood vessel (extravasation, not shown) in a distant organ, and grow into clinically detectable metastases. In addition to cell autonomous mechanisms, cancer cells enlist a myriad of stromal cells to aid in each step during this invasion–dissemination cascade. BM, basement membrane; CAFs, cancer-associated fibroblasts; CTC, circulating cancer cell; EC, endothelial cells; EMT, epithelial–mesenchymal transition; MSC, muscle cells; MMPs, matrix metalloproteinases. (From Wan L, Pantel K, Kang Y. Tumor metastasis: moving new biological insights into the clinic. *Nat Med.* 2013;19(11):1450–1464, with permission.)

NOTCH is a family of transmembrane receptors that binds to the Delta and Jagged families of ligands on adjacent cells. When bound to its ligands, NOTCH is cleaved and the NOTCH intracellular domain (NICD) travels to the nucleus to affect gene transcription responsible for development and differentiation of a wide range of cell types, including epithelial cells. Although NOTCH was originally described as an oncogene, NOTCH signaling is down-regulated in HNSCC[74] as it is in several other squamous cancers.[75] Nineteen percent of HNSCCs possess a loss of function mutation in NOTCH1,[50,51] and a smaller percentage have loss of function in family members NOTCH2 and NOTCH3. In addition to its role in abnormal differentiation of HNSCC, aberrant NOTCH1 signaling simultaneously produces unchecked proliferation in many tumors. It is an elegant example of the interconnected nature of the "Hallmarks of Cancer." Another important gene involved in the differentiation of epithelial cells, p63, is overexpressed or mutated in 23% of HNSCCs.

Induction of Angiogenesis

As in normal tissues, cancers require oxygen, nutrients, and the removal of waste. A growing cancer demands high levels of energy and reducing capability, which can quickly outstrip nutrients and oxygen provided by the local blood supply. Hypoxia, as well as oncogene signaling, have been shown to drive the production of vascular endothelial growth factor (VEGF) and other factors that promote angiogenesis (Fig. 2.8). The neovasculature produced by tumor angiogenesis is characterized by excessive branching, erratic flow, and leakiness. Many HNSCCs overexpress VEGF or its receptors[76] resulting in a relatively high vessel density in HNSCC tumors.[77] Although not unique to HNSCC, the high density of leaky neovessels also provides a route of the spread of the cancer cells elsewhere in the body and can be considered an enabling factor for hematogenous metastasis. The cancers high requirement for nutrients also provides the basis for future antiangiogenic therapies, which have been tested in early clinical trials.[78]

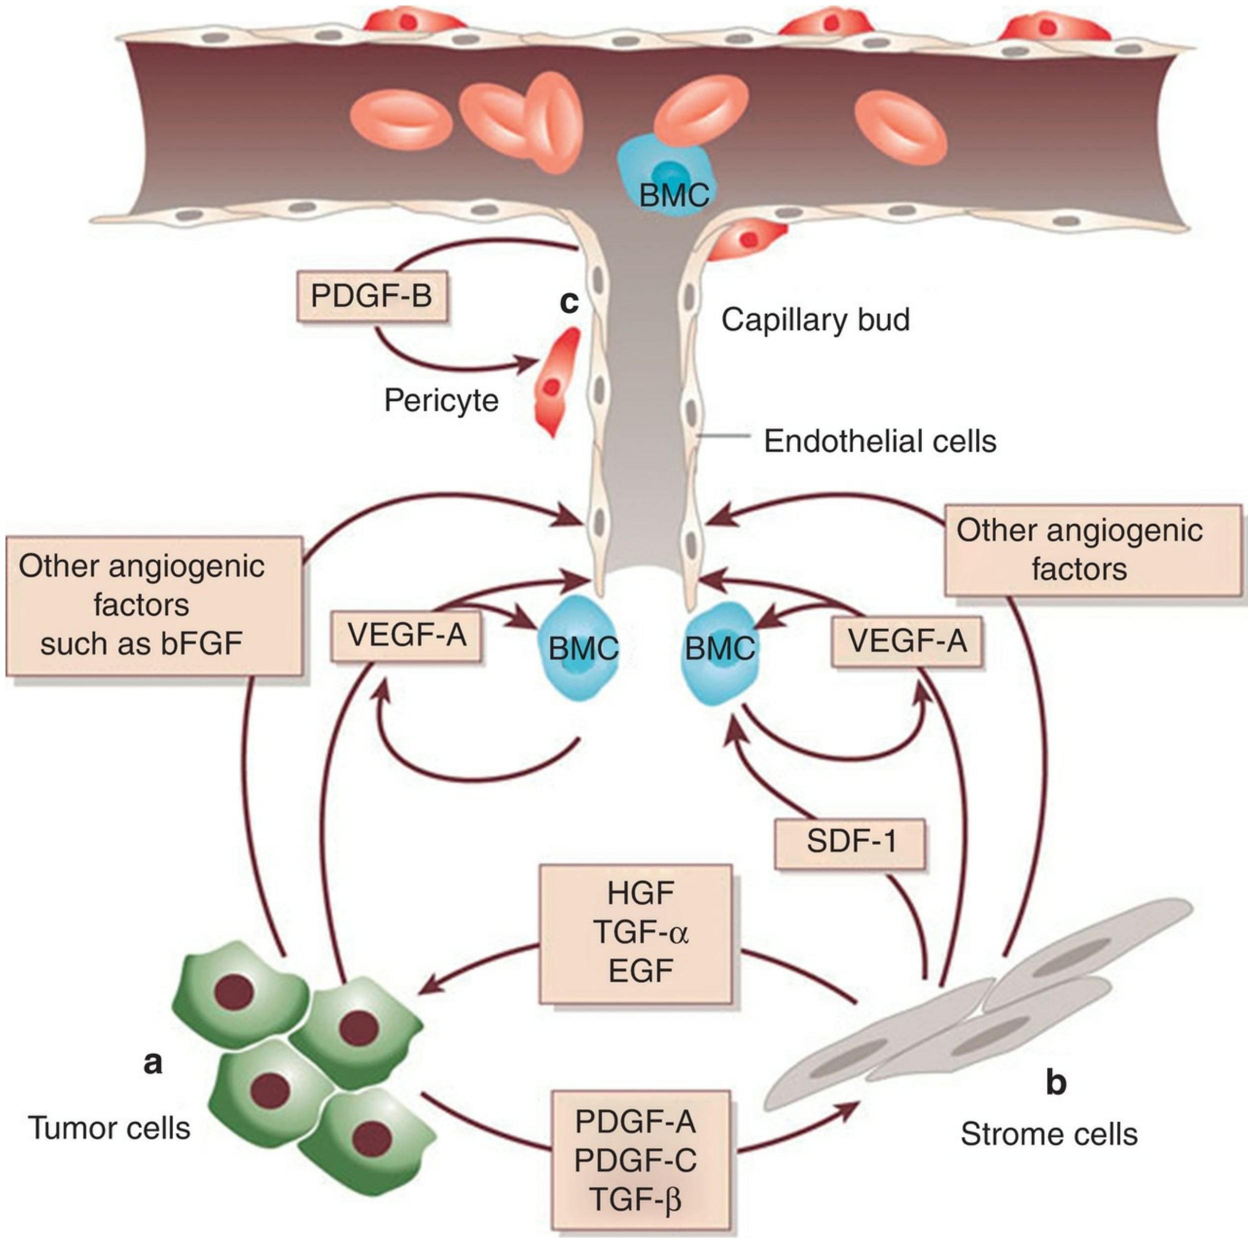

Figure 2.8. Angiogenesis. Cancer cells (a) produce VEGF and other angiogenic factors, which stimulate resident endothelial cells to proliferate and migrate. Stromal cells (b), such as fibroblasts, inflammatory, and immune cells, provide an additional source of angiogenic factors. Endothelial cells (c) produce PDGF-B, which promotes recruitment of pericytes in the microvasculature. Many of these angiogenic factors are being investigated as therapeutic targets. BMC, bone marrow–derived angiogenic cells; EGF, epidermal growth factor; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; PDGF, platelet-derived growth factor; SDF, stromal cell-derived factor; TGF, transforming growth factor; VEGF, vascular endothelial

growth factor. (From Ferrara N, Kerbel RS. Angiogenesis as a therapeutic target. *Nature*. 2005;438(7070):967–974, with permission.)

Resisting Cell Death

Apoptosis is a form of programmed cell death. Unlike necrosis, which consists of traumatic, acute cell death with the release of cell contents into the local environment, apoptosis involves an orderly, controlled process that results in fragments of the cell being phagocytized by neighboring cells. Apoptosis can be triggered through either the intrinsic pathway or the extrinsic pathway, which eventually converge on a common effector pathway (Fig. 2.9). In the intrinsic pathway, cell stresses such as DNA damage, decreased oxygen, or oncogene activation, activate p53 and result in transcription of various proapoptotic factors. A balance of proapoptotic (Bak, Bax) and antiapoptotic (Bcl-2, Bcl-xl) regulators determines whether the cell proceeds to apoptosis. When activated, proapoptotic factors migrate to the mitochondria and facilitate the release of cytochrome c, which in turn initiates the caspase cascade. The extrinsic pathway consists of external death signals in the form of specific ligands (e.g., Fas ligand), which bind to transmembrane receptors (e.g., Fas receptor) on the cells surface, which then recruits and activates caspase 8 to begin the caspase cascade. Both the extrinsic and intrinsic pathways converge on a common chain of effector caspases (3, 6, and 7), which initiate a proteolytic cascade resulting in a disassembly of organelles and consumption by neighboring cells.

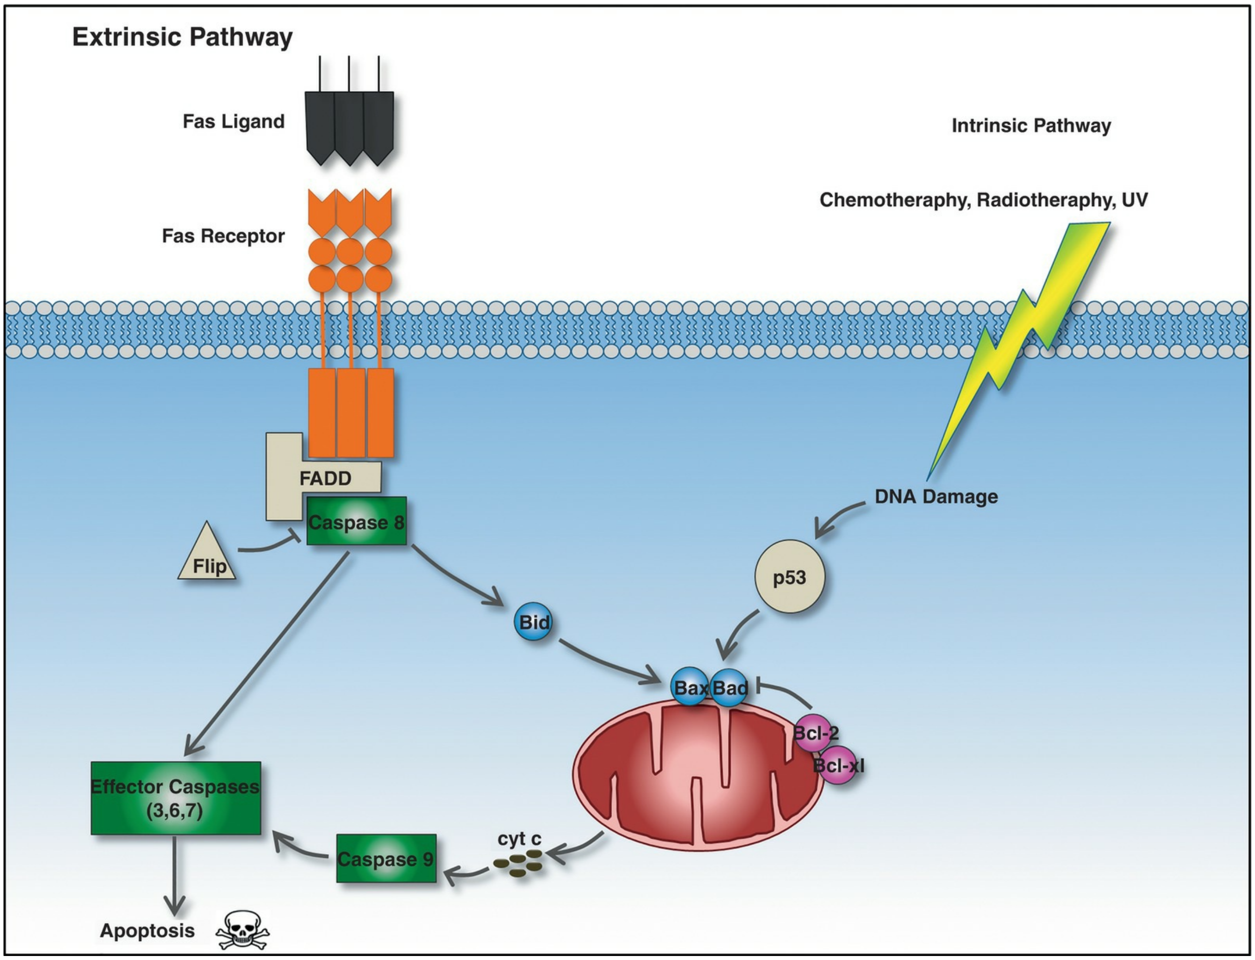

Figure 2.9. Apoptosis. The extrinsic and intrinsic pathways of apoptosis converge to activate controlled cell death. UV, ultraviolet radiation; Cyt c, cytochrome c.

Apoptosis serves as a major cell barrier to cancer.[79] As potential cancer cells acquire more and more molecular defects, these defects are more likely to be recognized and apoptosis triggered. There is always a balance between apoptosis and proliferation in tumors; however, for cancers, this balance must always favor survival and proliferation.[79,80] Thus, cancer cells usually evolve mechanisms to inhibit proapoptotic signals or up-regulate antiapoptotic signals. Loss of p53 activity is the most common defect limiting apoptosis in tumors, but increased expression or activity of antiapoptotic regulators (e.g., Bcl-2, Bcl-xL) or decreased expression or activity of proapoptotic factors is commonly found (e.g., Bax, Bak, caspases). Bcl-xL is up-regulated in 14% of HNSCC,[21] and caspase 8 (CASP8) is mutated or deleted in 10% of HNSCC. Interestingly, some cancers with CASP8 mutations maintain wild-type p53,

suggesting that CASP8 mutations may partially compensate for the presence of p53. As a prime example of the complexity of cancer signaling, proliferative pathways also inhibit apoptosis and promote cell survival. For example, EGFR signaling, PI3K/Akt signaling, and STAT3 activity have all been implicated in cell survival.[81,82]

As a mediator of chemotherapy- and cisplatin-induced cell death, apoptosis is targeted in order to increase efficacy of these treatments.[83,84] For example, inhibiting the antiapoptotic factor Bcl-xL has been shown to reduce cisplatin resistance.[85] Other studies targeting the p53 or survivin genes to increase apoptotic activity have also shown potential for synergistic antitumor activity with cisplatin.[86,87]

Replicative Immortality

With successive cycles of growth and division, normal cells eventually reach replicative senescence, a long-term state of viability without proliferation. Thus, normal, non–stem cells cannot multiply infinitely, and this poses yet another intrinsic barrier to cancer. It has been shown in the past few decades that telomere shortening and p16 expression contribute to this aging phenomenon.[88] Telomeres are repetitive nucleotide sequences at the end of chromosomes that protect the DNA ends from aberrant changes. However, telomeres shorten with successive generations, eventually becoming unable to prevent chromosomal damage such as end-to-end fusions. If unable to repair these telomere-associated chromosomal defects, the cell will die. Cancer cells must overcome this otherwise inevitable fate in order to secure immortality, and they do so by activating telomerase and inactivating p16 or Rb (Fig. 2.10). Telomerase is an enzyme that increases the length of telomeres, thereby reversing “aging” of the cell. Telomerase is nearly nonexistent in normal, mortal cells but expressed at high levels in the majority of immortalized cells in culture. As expected, increased telomerase activity is found in the vast majority of HNSCC tumors.[89,90] It remains unclear how telomerase activity or telomere length correlates to clinical features of the disease.

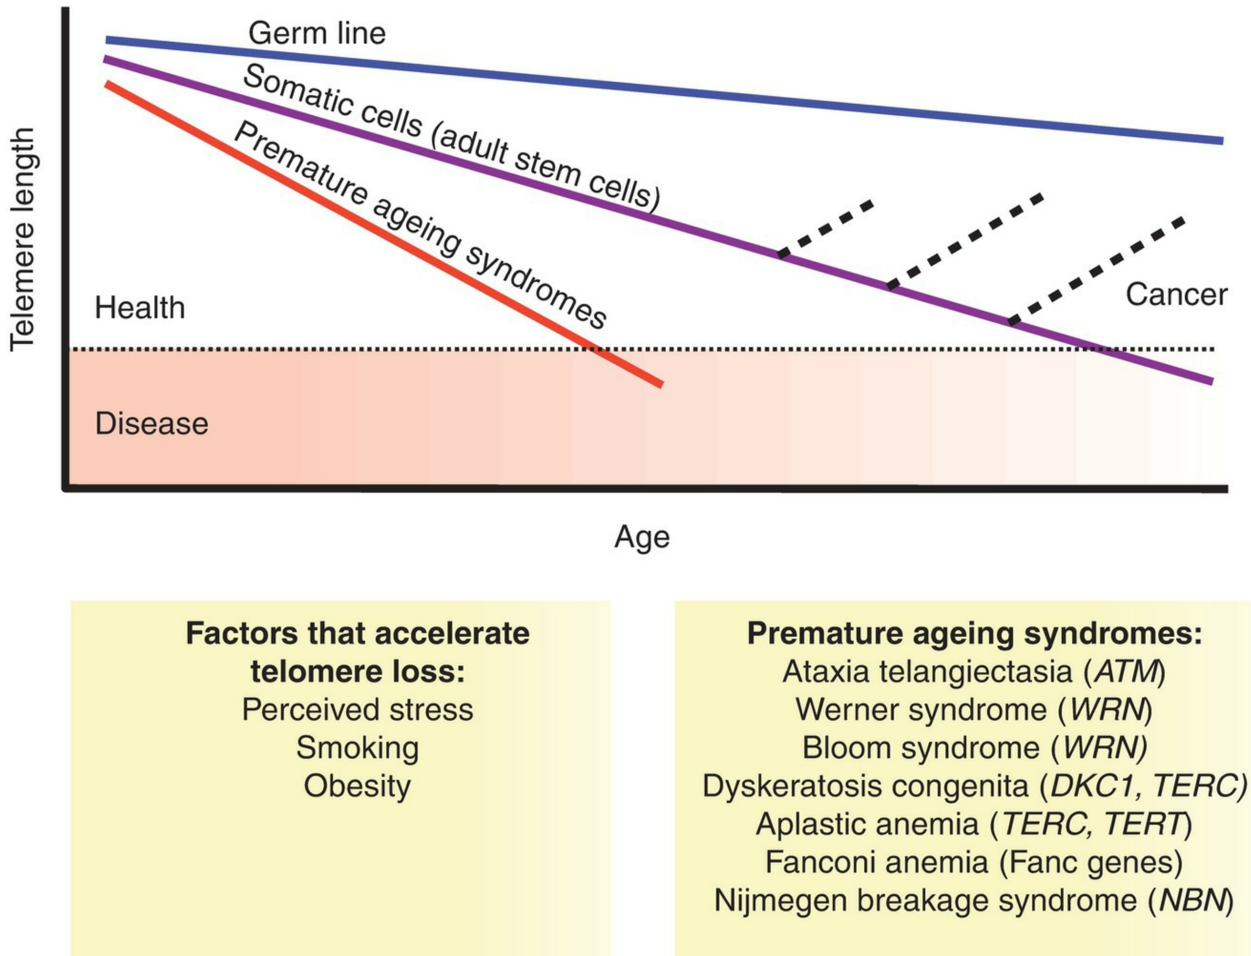

Figure 2.10. Immortalization. Normal somatic cells suffer progressive telomere attrition coupled to cell division or to increasing age of the organism. In germline cells, telomere shortening is attenuated owing to high levels of telomerase activity. By contrast, telomere shortening is accelerated in several human premature aging syndromes. In contrast, most immortalized cultured cell lines and human tumors aberrantly activate telomerase to achieve immortal growth. (Adapted from Finkel T, Serrano M, Blasco MA. The common biology of cancer and ageing. *Nature*. 2007;448(7155):767–774.)

Reprogramming Metabolism

As cancer cells proliferate, they must have a source of energy and building blocks for replication. It was discovered long ago that even in the presence of sufficient oxygen, cancer cells often preferred to utilize glycolysis as opposed to oxidative phosphorylation.[91] This was a curious finding, as glycolysis

represents a 20-fold reduction in efficiency compared to the Krebs cycle for producing ATP from glucose and is usually only performed out of necessity in the absence of oxygen. In order to fuel this “aerobic glycolysis,” cancer cells vastly increase glucose uptake by up-regulating glucose transporters, which is the basis for detection of HNSCC and many other cancers on PET-FDG (fluorodeoxyglucose) scans. Although less ATP is produced by glycolysis, the other by-products of glycolysis provide the building blocks and reducing capacity necessary for cell growth.[92] In addition, glycolysis results in production of lactate and acidification of the cancer environment, which in turn stimulates migration, provides a growth stimulus for surrounding tumor cells, and inhibits local immune function.[93]

With their uncontrolled proliferation, cancer cells have the capacity to outgrow their blood supply. Thus, these cells have adapted to thrive in hypoxic conditions. In response to hypoxia, they activate the transcription factor hypoxia-inducible factor (HIF), which further induces glycolysis and increases glucose uptake. Similarly, certain oncogenes themselves have been shown to up-regulate HIF and glycolytic metabolism. Various studies have revealed that HNSCC is associated with increased hypoxia and anaerobic metabolism.[94] Additionally, hypoxia in HNSCC has been suggested as a marker of poor prognosis,[95] as well as resistance to chemotherapy and radiotherapy.[96,97] It is postulated that the lack of oxygen prevents formation of therapeutic free radicals during radiotherapy and that the relative lack of perfusion results in decreased drug delivery during chemotherapy. Tumor metabolism is a growing area of research and may someday help explain these questions as well as clarify the relationship between metabolism and the other “Hallmarks.”

Role of the Immune System in Carcinogenesis

Evasion of Immune Destruction

Under normal circumstances, the immune system plays a vital role in the multifaceted process of cancer surveillance and destruction, at least partly explaining the significantly higher rate of tumors (including HNSCC) in various immunodeficient states.[98,99] Circulating cells of the innate immune system (natural killer cells, macrophages, dendritic cells) recognize local

tissue damage and products of necrotic tumor cells. Cytokines (such as interferon-gamma, IFN-γ) released by these processes further stimulate immune cells and have antitumor properties as well. Meanwhile, the adaptive immune system (T lymphocytes) can detect and destroy cells bearing cancer-specific antigens presented by HLA molecules.

It appears critical that in order for cancer cells to survive, they must evade surveillance and/or destruction by the immune system. They may do this by down-regulating expression machinery involved in antigen presentation.[100,101] The selective destruction of highly immunogenic clones may also gradually generate a cancer that is full of cells best suited to evade immune destruction, a process known as immunoediting.[102] It has been shown that HNSCC cells also secrete various factors that trigger T-cell anergy and even apoptosis.[103–105] Interestingly, HPV(+) cancers secrete different factors, including PDL-1, to accomplish a similar task.[106] The case of HPV(+) HNSCC is a special consideration for immune evasion; in addition to the need for cancer cells to avoid detection and destruction by adaptive immune responses, the viral infection and persistence must prevent cellular and innate immune responses. In addition to local secretion, HNSCC and other cancers release widespread factors and cytokines throughout the body, possibly signaling to hijack the host immunologic resources for the tumor's benefit of the cancer. As we learn more about the interaction of the immune system and cancer, it is clear that the relationship is not as simple as once thought.

Tumor-promoting Inflammation

Cancers of nearly every type are infiltrated by varying numbers of innate and adaptive immune cells. Although they may have been attracted to eliminate the cancer, experiments have shown that immune cells may actually spur carcinogenesis.[107–110] For example, DNA-damaging ROS released by immune cells to destroy a threat have been shown to increase genetic instability in tumor cells.[108] Additionally, immune cells attracted to fight the cancer may incidentally provide the cancer with a variety of growth/survival factors, proangiogenic factors, extracellular matrix-degrading factors, and factors that induce EMT. Although developed to combat exogenous threats, each of these may paradoxically enable cancer progression as part of the cancer's microenvironment.

Cancer Microenvironment

The cancer and its local environment, which consists of blood vessels, the extracellular matrix, signaling molecules, fibroblasts, neighboring cells, and immune cells, interact constantly and heavily influence one another (Fig. 2.7). For example, cancer can induce fibroblasts to begin secreting factors, which then support tumor growth and functions. The cancer's interaction with neighboring cells has also been proposed as the reason that cancers may be selective in the tissues to which they commonly metastasize (i.e., "seed and soil" hypothesis). The complex nature of the microenvironment presents a challenge to properly model and study HNSCC in the laboratory. Cells may behave differently, and certain drugs may be more or less effective in vitro than in the cells' natural, three-dimensional habitat. Knowledge of these interactions may identify new therapeutic targets (e.g., VEGF) or aid in the proper delivery of drug to tumors.

GENES ALTERED IN BOTH HPV(−) AND HPV(+) HNSCCS

p53

Arguably, p53 is the most widely studied tumor suppressor in human cancer and is the most commonly implicated gene in HNSCC as well. Located on the short arm of chromosome 17, TP53 is a 393 amino acid protein that is evolutionarily conserved and is expressed in all tissues of the body. The first 75 amino acids of TP53 are involved in the activation of transcription of specific genes, whereas amino acids 120 to 290 are involved in the specific recognition of DNA sequences.[111] The carboxyl terminus is believed to be important for nuclear localization and oligomerization of TP53 into tetramers.

The biologic role of p53 is to protect cells from DNA damage caused by radiation, chemical carcinogens, or other mechanisms. TP53 activity results in cell cycle arrest, so that DNA repair can occur, or by induction of apoptosis (Fig. 2.11). It performs these actions through the positive or negative regulation of gene transcription. Analysis of the sites of mutation of the TP53 gene in human cancers has revealed certain "hot spots" that are believed to be important in carrying out these functions. The majority of

mutations (more than 92%) are found in five evolutionary conserved regions of the gene. Mutations within these regions impair a cell's ability to repair its DNA, predisposing to genomic instability and additional alterations in oncogene and tumor suppressor gene products. Mutations of TP53 also prevent apoptosis in response to DNA damage, which may make cancer cells resistant to treatment with irradiation or chemotherapeutic agents that act by damaging cellular DNA and triggering apoptosis. The role of this gene in the pathogenesis of HNSCC has been extensively studied, but therapeutic activation of mutant p53 remains a future goal.

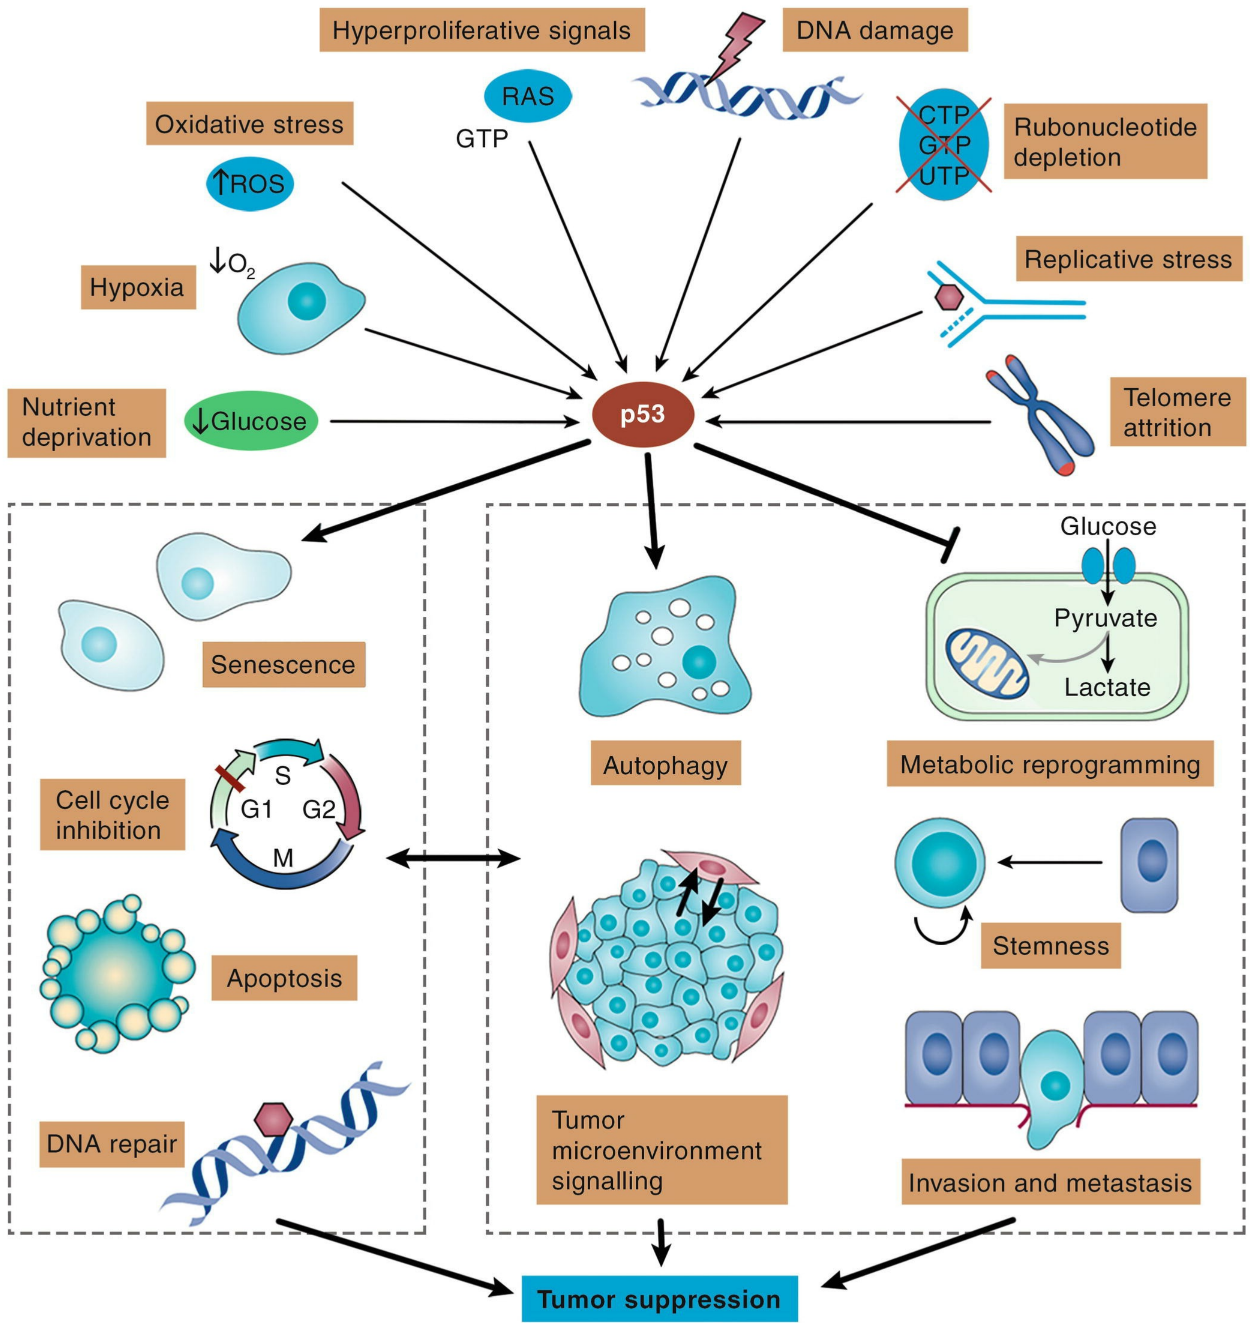

Figure 2.11. Functions of p53. Recent evidence demonstrates that a host of different stresses can activate p53 in the context of tumor initiation or progression (shown at **top**). P53 activation by these signals can consequently promote diverse responses that lead to tumor suppression (shown at **bottom**). (Adapted from Bieging KT, Mello SS, Attardi LD. Unravelling mechanisms of p53-mediated tumor suppression. *Nat Rev Cancer*. 2014;14(5):359–370.)

Early studies showed that aberrations in p53 were common in HNSCC

and increased in frequency during progression epithelium from normal, to hyperplastic, to dysplastic, to invasive cancer.[112,113] These studies also noted a correlation between p53 loss and genomic instability. P53 is now recognized as the most commonly mutated gene in HNSCC, with 84% of HPV(−) tumors having at least one mutation.[21] In the minority of HNSCCs expressing wild-type p53, there are alternative mechanisms for inhibition of p53 activity. First, in the roughly 20% of HNSCC that are HPV related, the HPV protein E6 binds to TP53, inactivates its function, and marks it for degradation, thereby abrogating the need for p53 mutation and accounting for the high incidence (97%[21]) of wild-type p53 in these cancers. Additionally, in the remainder (15% to 20%) of HPV(−) HNSCC with wild-type p53, it is proposed that the function of p53 is effectively inhibited by various (and potentially unknown) mechanisms. For example, the protein MDM2—which binds to the transcriptional domain of p53, blocks its activity, and marks it for degradation—is up-regulated in many cancers.[114] All told, these various insults to p53 occur in at least 95% of HNSCC, underscoring the importance of its pathway in the pathogenesis of the disease.

P53 mutation has been associated with poor patient survival in HNSCC, though early studies did not account for HPV status that may have confounded results.[115] More recent examination of HNSCC revealed that p53 mutations predicted to be disruptive were associated with increased local and regional recurrence.[116] Following knockdown of p53 expression, oral keratinocytes have increased ability to become immortalized.[117] Meanwhile, in addition to inactivation of its normal functions, some p53 mutations are associated with gain of function, as demonstrated by unique tumor phenotypes in genetically engineered mice.[118]

Because p53 is the most frequently mutated tumor suppressor across all human cancer types, restoring activity to mutant p53 has drawn much attention. Direct reactivation of mutant p53 using peptides to enhance normal conformation has shown biologic activity and therapeutic potential.[119] More recently, targeting compensatory proteins needed for cell survival in the absence of p53, such as WEE1[120] and aurora kinase,[121] have shown promise as targets for tumors with p53 mutations.

p16-Cyclin D1-RB

As with p53, inactivation of retinoblastoma (Rb) function is thought to be a requirement for human tumor formation. While defects in Rb are not common in HNSCC, its functional activity is diminished through a variety of other mechanisms (Fig. 2.5). In HPV(−) HNSCC, the most common defect inhibiting retinoblastoma is loss of activity of the tumor suppressor, $p16^{INK4a}$. $P16^{INK4a}$ is the most well-studied member of a family of INK4 (inhibitor of CDK4) proteins. $P16^{INK4a}$ binds and inhibits the G1 CDKs, CDK4 and CDK6, with resultant Rb activation and G1 cell cycle arrest.[122,123] Loss or mutation of $p16^{INK4a}$ results in excessive CDK activity and inactivation of Rb. All told, with 26% of tumors harboring $p16^{INK4a}$ mutations, 32% of tumors having homozygous gene deletion,[21] and 27% having expression lost through promoter hypermethylation,[124] down-regulation of the protein probably exists in the vast majority of HNSCC. The $p16^{INK4a}$ gene, CDKN2A, is also unique among human genes in that distinct first exons are spliced to a common second exon, but translation occurs in different reading frames resulting in two distinct proteins. Interestingly, protein products of the CDKN2A gene, $p16^{INK4a}$ and $p14^{ARF}$ (ARF, for alternate reading frame), are activators of RB and p53, respectively.[125,126]

The cyclin family of cellular proteins along with their partners, the CDKs, is responsible for driving the cell through the cell cycle. Of the many cell cycle regulators implicated in the development of cancers, cyclin D1 is among the most prevalent.[127] In HNSCC, CCND1, the gene that encodes cyclin D1 on the 11q13 locus, is amplified or overexpressed in up to 64% of tumors.[128] Studies have also correlated cyclin D1 expression with poor survival, invasion, locoregional recurrence, and the presence of lymph node metastases.[129–133] Aside from being a possible biomarker for disease phenotype, cyclin D1 has been extensively studied for therapeutic targeting.[134] Drugs that inhibit CDK 4/6 are showing promise for some cancer types, but primarily when combined with other agents.[134] Combinatorial therapy with CDK inhibition may be useful for HNSCC, because deregulation of G1 progression is nearly universal, but RB is still functional.

It is fascinating that the HPV oncoprotein E7 directly binds and inhibits Rb. While the details of this interaction will be explored later, this clearly obviates the need for genetic insults to the Rb pathway, as only ~5% of

HPV(+) cancers possess a defect in either p16 or cyclin D1. Overall, the extremely high rate and diverse nature of the alterations in the Rb pathway underscore the absolute necessity to bypass the G1 cell cycle checkpoint in order for cells to progress to HNSCC.

Pik3CA–PTEN–Akt

The PIK3CA gene encodes the catalytic subunit of the phosphatidylinositol 3-kinase (PI3K) protein, which adds phosphates to phosphatidylinositol, a membrane-associated lipid, producing phosphatidylinositol (3,4,5)-triphosphate that attracts proteins containing pleckstrin homology domains.[135,136] The major signaling pathway activated by PIK3CA is the protein kinase B (PKB = AKT) and mammalian target or rapamycin (mTOR) pathway, which supports cellular survival and growth. Normally, PIK3CA activity is stimulated by G proteins and RTKs. However, when mutated, PIK3CA remains active in the absence of upstream signaling.

Interestingly, PIK3CA is the oncogene most frequently mutated in HNSCC. Alterations in the PIK3CA gene have been discovered in 56% of HPV(+) and 34% of HPV(−) tumors. The majority of mutations (73%) are found in E542K, E545K, and H1047R/L hot spots and result in activation of the kinase, and the PIK3CA gene is located on the large 3q22-ter amplicon. Given that aberrations in other oncogenes occur less frequently in HNSCC, PIK3CA or downstream PI3K pathway components are perhaps the most promising therapeutic targets for both HPV(+) and HPV(−) HNSCC. Interestingly, in HPV(+) HNSCC, signaling of mutant PIK3CA activated mTOR more than AKT due to inhibition by E6, but in HPV(−) HNSCC, AKT and mTOR are both activated.[24]

Mutations in other components of the PIK3CA/AKT/mTOR pathway are common in other cancer types; however, mutations of PTEN and AKT are rare or not described in HNSCC. Given the importance of the pathway, drugs that target PIK3CA, AKT, and mTOR are excellent theoretical targets and are being tested for safety and efficacy in HNSCC.

COMMONLY AFFECTED GENES IN HPV(−) HNSCC

These are the individual genes most commonly implicated and extensively studied within HNSCC, and unless otherwise stated, these data specifically represent HPV(−) HNSCC. Each of the genes plays an important role in one or more of the "Hallmark pathways" introduced above, though the complex and interconnected nature of their functions often makes compartmentalization into a single pathway difficult. We present the data for each individual gene, integrating the various lines of evidence available in order to provide a comprehensive view of their role in HNSCC pathogenesis and/or progression. In addition to their critical roles in HNSCC carcinogenesis, many also represent avenues for targeted therapeutics and personalized treatments.

Tumor Suppressors in HPV(−) HNSCC

The most common defects in HPV(−) HNSCC are disruptions to tumor suppressor genes and are associated with defects in the regulation cellular proliferation, survival, and differentiation. Tumor suppressors have been difficult to directly target for therapy, because pharmacologic activation of mutant and inactive tumor suppressors is more difficult than inhibition of activated oncogenes. Recently, synthetic lethality schemes have been emerging for some defective tumor suppressors.

ARF

The ARF protein binds and inhibits MDM2, which is the major inhibitor of p53. MDM2 binds p53 inhibiting its transcription and marking it for proteasomal degradation. Inhibition of MDM2 by ARF stabilizes and activates p53.[125] The role of ARF in cancer development is clear in mice,[137] but is more questionable in humans.[138,139] Inactivating mutations of the CDKN2A gene selectively alter p16 activity; however, deletions of CDKN2A are common and result in loss of both p16 and ARF. Deletions of CDKN2A occur in HNSCCs with p53 inactivated by mutation, suggesting that the target of deletion is likely p16, not ARF.

NOTCH

NOTCH proteins are required for neural progenitor cell maintenance, and NOTCH is activated by chromosomal translocation in T-cell leukemias,

resulting in proliferation and survival.[140,141] On the other hand, NOTCH signaling is also required for epithelial differentiation,[142] and these dual roles suggest that NOTCH can serve as an oncogene or tumor suppressor depending on cellular context. In HNSCC, inactivating mutations in NOTCH1, NOTCH2, and NOTCH3 are observed in 31% of HPV(−) tumors.[50,51] NOTCH inactivation is also a common feature in lung and bladder squamous cancers, suggesting that loss of NOTCH is key for squamous carcinogenesis, possibly through inhibition of differentiation.[57] Targeting of NOTCH for cancer therapy is being explored for many cancer types but is currently limited to cancers where NOTCH acts as an oncogene.

Keap1/Nrf2

Keap1/Nrf2 are master regulators of cellular response to oxidative stress. Keap1 binds to Nrf2 and maintains Nrf2 in the cytoplasm in an inactive state. When exposed to oxidative stress, Nrf2 is released, translocates to the nucleus, and drives expression of many survival genes.[143] Interestingly, Nrf2, Keap1, and another critical component of the complex, Cul3, are altered in ~25% of HPV(−) HNSCC. The fact that defects are only observed in HPV(−) tumors suggests that cellular survival in high oxidative stress environments (e.g., tobacco smoke) promotes tumorigenesis.

Caspase 8

Caspase 8 is member of a family of enzymes responsible for triggering and executing apoptosis. Although there is cross talk between the intrinsic and extrinsic apoptotic pathways, caspase 8 is the final and critical step of the extrinsic pathway that is triggered by activation of the FAS receptor upon binding the FAS ligand. Caspase 8 cleaves and activates the executioner caspase 3 that leads to apoptotic cell death. Mutations of caspase 8 are found in 8% of HPV(−) HNSCC and remarkably ~1/3 of caspase 8 mutations are associated with mutations in the HRAS oncogene and occur in the absence of p53 mutations.[21] This subset of p53 wild-type tumors with simultaneous mutations of caspase 8 and HRAS is potentially targetable using apoptosis activators.

Oncogenes in HPV(−) HNSCC

Although activation of oncogenes is not as frequent in HNSCC as is disruption of tumor suppressors, they are of particular interest because of their therapeutic implications. In general, activating mutations or amplification of oncogenes has been easier to target with drugs to inhibit the abnormal activity. The successful targeting of the fused and activated ABL oncogene (Philadelphia chromosome) in chronic myeloid leukemia (CML) by imatinib opened the door for targeting of mutant oncogenes such as BRAF in melanoma, EGFR in adenocarcinoma of the lung, and others.

EGFR/RTKs

The EGFR and other members of the RTK family, such as human epidermal growth factor receptor 2 (HER2), have been as heavily studied as any oncogene in HNSCC. Extensive research and clinical trials resulted in approval of EGFR-targeting antibodies for therapy.[144] EGFR is amplified in 10% and overexpressed in many more HPV(−) HNSCCs, while HER2 is amplified in 3%.[21] Overexpression of RTKs is not seen in HPV(+) HNSCC. Interestingly, activating mutations of EGFR are relatively rare in HNSCC (5%), and drugs that have been effective in EGFR-mutated adenocarcinoma of the lung have not shown the same activity in HNSCC. How to appropriately target the EGFR family remains a focus of research, including combinatorial therapy and simultaneous targeting of other RTK family members such as the human epidermal growth factors 2 and 3 (HER2 and HER3).

The FGFR subfamily of RTKs is also frequently activated in HPV(−) HNSCC by amplification and overexpression. Members of the FGFR family, FGFR1, FGFR2, and FGFR3, are amplified in 10%, 2%, and 2% of HPV(−) HNSCC, respectively, and cumulatively overexpressed in another 14%.[21] Drugs that have activity against FGFR family members are in clinical trials for patients whose tumors carry alterations in FGFR.

p63

The p63 gene is another example of a gene product that has both tumor-promoting and tumor-suppressing activities. P63 is a homologue of p53. However, unlike p53, it has two major expressed forms. Transcriptionally, active p63 (TAp63) is a tumor suppressor with activities similar to p53,

whereas delta N p63 (ΔNp63) is missing the transcriptional activating N-terminal region and has anti-p53 activity.[145] ΔNp63 is the major p63 form implicated in HNSCC and is coamplified with genes on the 3q22-ter amplicon. High expression of ΔNp63 is observed in HNSCC and correlates with amplification of the 3q region that occurs in 19% of HNSCC.[21] The 3q amplicon contains a large number of genes in addition to p63, including those involved in survival (PIK3CA) and stem cell maintenance (SOX2).

RAS

The RAS (rat sarcoma) family of oncogenes is commonly activated in human cancers but has been difficult to target with drugs. Although there are three members of the RAS family in humans, only Harvey RAS (HRAS) is mutated in HNSCC, occurring in 5% of HPV(−) tumors.[21] Hot spot mutations of HRAS stabilize its binding to guanosine triphosphate (GTP) resulting in constitutive activation and cellular proliferation and survival that is independent of upstream signals. Because of its importance in multiple types of cancer and its difficulty in targeting, the National Cancer Institute has recently allocated resources to improve targeting of mutant RAS in cancer.

SOX2

Transcription factors are notoriously difficult to target for therapy, and the sex-determining region Y-box 2 (SOX2) gene product is no exception. SOX2 is a key driver of pluripotency or stemness and self-renewal of cells, and overexpression of SOX2 has been shown to promote lung squamous cell cancer in mice and has been associated with poor survival in HNSCC.[146,147] In HPV(−) HNSCC, SOX2 is amplified along with the 3q22-ter region in 19% of cancers, is one of the key drivers of cancer stemness, and will be a valuable target to inhibit the stem population.

HPV(+) HNSCC

The Papillomavirus subfamily, together with Polyomaviruses, creates the Papovaviridae—a family of DNA viruses often associated with malignant transformation of mammalian cells. Human papillomaviruses[148] are

associated with benign (e.g., papillomas, warts) and malignant lesions of keratinized and mucosal epithelial surfaces. Based on their potential to induce malignant transformation, more than 100 viral genotypes are subdivided into low- and high-risk HPVs. High-risk (oncogenic) genotypes, most commonly HPV types 16 and 18, as well as the more rarely encountered types 31, 33, 35, 39, 45, 51, 56, 58, and 59, are causative agents of anogenital cancers[149–151] and the majority of OPSCC[152–154] with HPV 16 being responsible for the vast majority of HPV-related HNSCC.[17] The incidence of HPV-related OPSCC has dramatically increased over the last two decades and is now approaching the incidence of uterine cervical cancer in the United States.[155–157]

Viral Biology and Epithelial Transformation

Papillomaviruses are sexually transmitted, species-specific, nonenveloped, double-stranded DNA viruses that have a roughly 8,000 base pair circular genome coding for 6 early (E) and two late (L) proteins. The viral genome is protected by a 55 nm icosahedral capsid[158–161] consisting of 72 capsomers, with each capsomer being a pentamer of the L1 major capsid protein. The minor capsid protein L2 is required for efficient viral DNA encapsidation and the generation of infectious virions.

Papillomaviruses infect proliferating undifferentiated keratinocytes in the basal layer of stratified epithelia. Studies of cervical stratified epithelia revealed that papillomavirus infects basal cells following trauma to the superficial layers. Viral protein synthesis is tightly regulated by cellular differentiation, because capsid proteins are not expressed in basal cells. As infected cells migrate to the surface and differentiate into keratinocytes, the major L1 and minor L2 capsid proteins are produced and the viral genome replicates, resulting in up to 10,000 viral DNA copies per cell, allowing virion assembly and shedding of infectious viral particles as differentiated epithelial cells are sloughed from the surface.[158,162–164] HPV is cleared by the immune system in the majority of infections, but if persistent, HPV can remain latent and form benign or malignant epithelial lesions. The host and viral factors that determine the specific outcome of the HPV infection are not well understood. During the course of an infection, the virus is eventually sloughed with epithelial cells in order to infect other organisms and complete its life cycle. Figure 2.12 shows a timeline for the progression from an initial

infection to a malignant tumor.

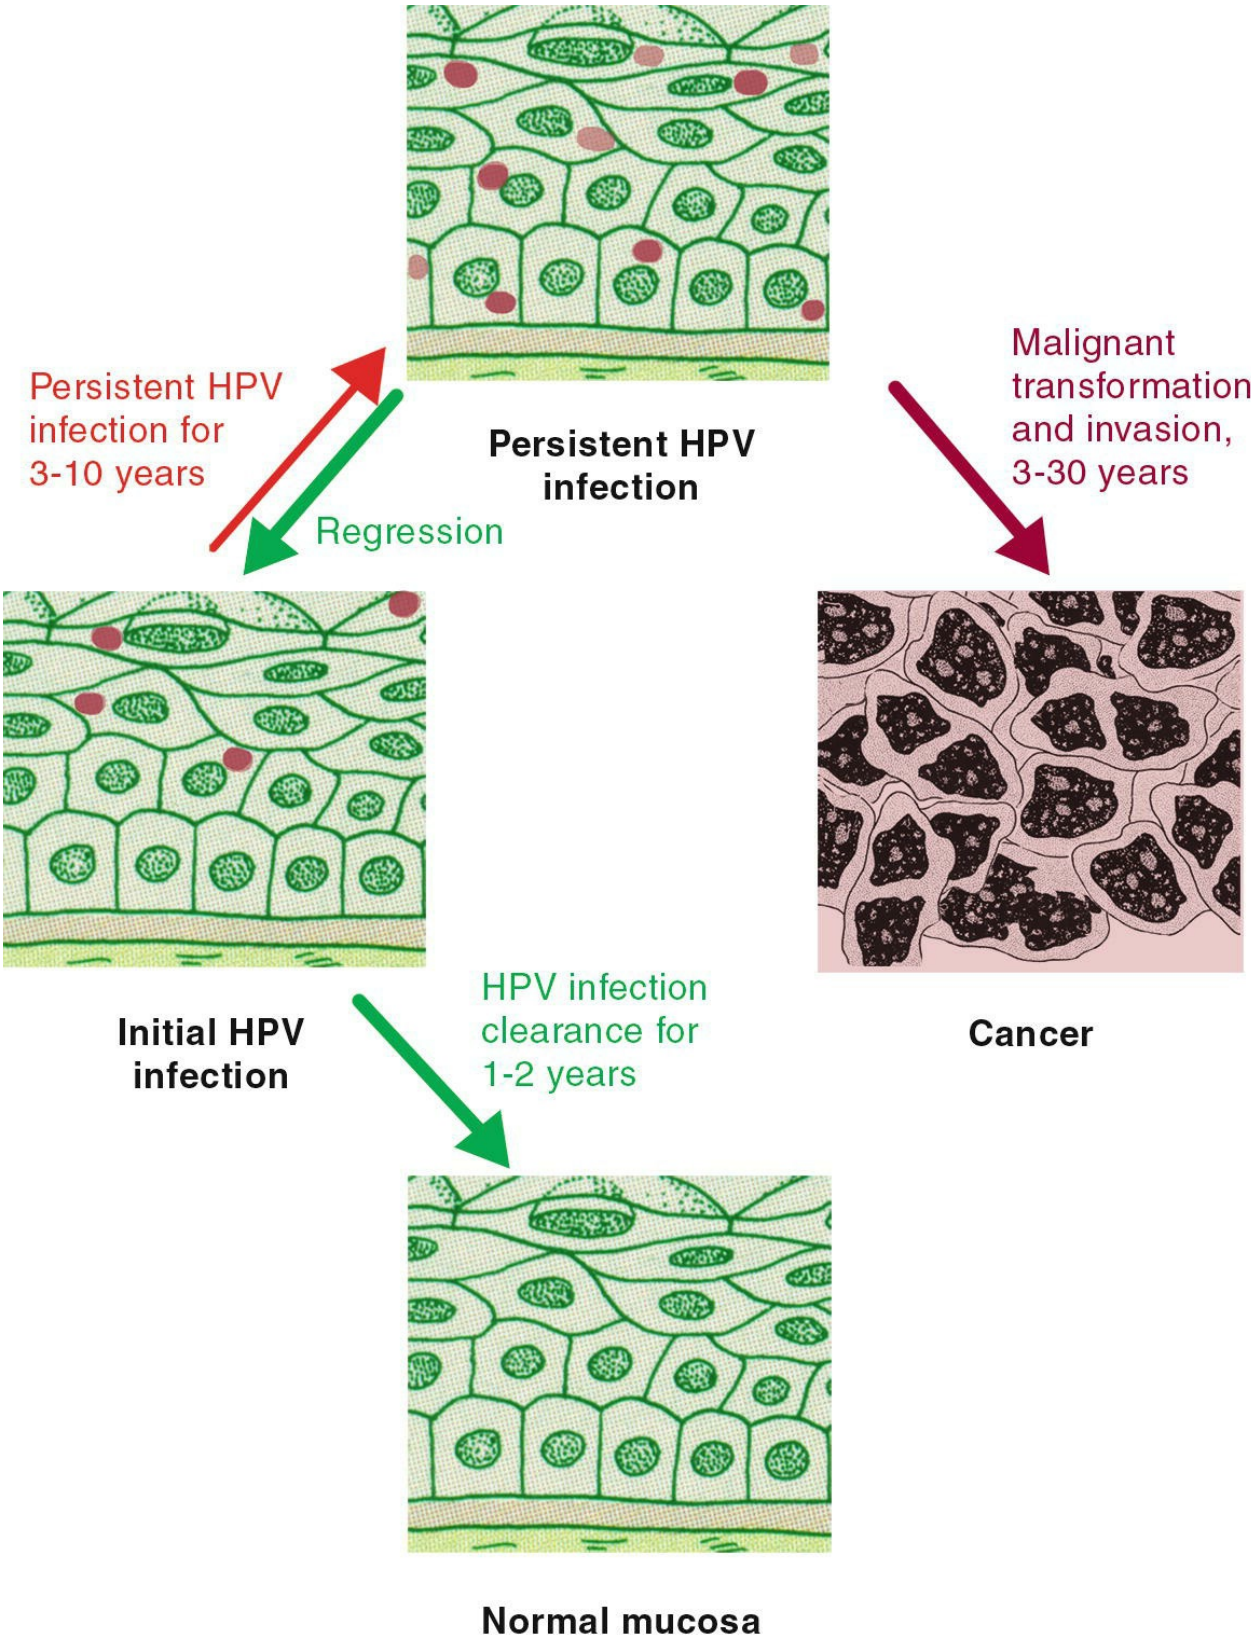

Figure 2.12. Timeline of HPV infection. An initial HPV infection can either be cleared or progress to a persistent infection lasting for years. Malignant transformation can result, usually many years after the initial infection. The host-, environmental-, and viral-related factors that determine the outcome of the HPV infection are not well understood.

Although great strides have been made to unravel the mechanisms by which high-risk HPV transforms normal cells, our knowledge of HPV-related carcinogenesis is incomplete. Nearly all studies examining HPV carcinogenesis have focused on cervical keratinocytes or the genital epithelia, with few examining oropharyngeal tumorigenesis. Development of uterine cervical cancer requires persistent viral infection and includes a well-described progression from precancerous lesions to invasive cancer. In early lesions, the HPV genome remains in an episomal state, but with advancement to high-grade lesions, HPV DNA frequently integrates into the host genome—a step that facilitates cancer development.[165,166] Integration is believed to accelerate carcinogenesis through frequent disruption of the HPV E2 gene, which normally suppresses expression of the major HPV oncogenes, E6 and E7.

The oncogenic properties of E6 and E7 are primarily explained by their abilities to inactivate two main human tumor suppressor proteins that are disrupted in virtually all human cancers: p53 and Rb. Inactivation of these targets deregulates cell cycle progression and inhibits apoptosis. E6, after forming a complex with cellular E6-associated protein (E6-AP), binds p53 and targets it for ubiquitination and subsequent proteasomal degradation. Several other E6 targets, including catalytic subunit of telomerase (hTERT), also contribute to E6-mediated transformation. E6 promotes cellular immortalization by up-regulating transcription of hTERT and can directly bind the hTERT protein to increase telomerase activity. Similar to E6, the HPV E7 protein functionally inactivates Rb via direct binding, ubiquitination and proteasome-dependent degradation. This results in the release and permanent activation of transcriptional factor E2F, driving expression of S-phase genes and promoting cellular replication. Interestingly, overexpression of another tumor suppressor, CDK inhibitor $p16^{INK4a}$, which is commonly observed in HPV(+) human cancer and is considered to be a surrogate marker for HPV positivity, is also linked to E7-mediated inactivation of Rb. In

human cancers, Rb inactivation is often reciprocal with p16 expression levels, indicating that down-regulation of Rb function is equivalent to loss of p16.[167]

Growing evidence suggests that the E5 protein in HPV types 16 and 18 also contributes to carcinogenesis. In transgenic mouse models, E5 alone induces cervical cancer and its tumorigenic effect synergizes with E6 and E7.[168] Although the exact mechanistic contribution of E5 to cancer development is not known, the role of HPV E5 in proliferation, migration, and invasion of cancer cells has been anticipated.[169]

Following HPV genome integration, E6 and E7 genes are consistently retained, whereas other HPV early and late genes are variably lost.[170] Due to integration and loss of part of the HPV genome, cervical malignant lesions are not thought to support an active HPV infection. However, some OPSCCs possess both integrated and episomal HPV DNA, whereas other tumors contain only one or the other.[171–174] Recent comprehensive whole-genome and transcriptome analysis of 35 HNSCC identified HPV integration in 25 cases (~71%),[175] confirming that HPV infection can drive development and progression of cancer of the head and neck independent of integration.

Syndromes Predisposing to HPV(+) HNSCC

As discussed previously, some familial syndromes caused by inherited mutations in genes involved in DNA repair and other vital cellular functions dramatically increase the relative risk of cancer of the head and neck (Table 2.2). Whether these genetic disorders predispose specifically to HPV-associated HNSCC remains inconclusive, with conflicting data reported by different research groups. In 2003, Kutler and coworkers[38] found HPV 16 in 83% of cancer of the head and neck in FA patients, as compared to 36% in the control population. In addition, an increased prevalence of HPV infection was found in the oral cavity of FA patients.[176] In contrast, several groups failed to detect HPV in HNSCCs from FA patients.[177–179]

Genomics of HPV(+) HNSCC

Expectedly, some specific molecular features arise as a result of expression of functional HPV oncogenes. As discussed, the HPV oncoproteins E6 and E7

inactivate p53 and Rb, respectively, and, therefore, HPV(+) head and neck tumors nearly universally harbor wild-type p53 and highly express the Rb upstream regulator p16^{INK4a} (CDKN2A). In addition, HPV(+) and (−) cancers are easily distinguished by gene expression profiling.[180–182] The great majority of genes differentially expressed in HPV(+) versus HPV(−) HNSCCs act in cell cycle, including CDK inhibitors 1B and 1C (CDKN1B/C), p15^{INK4b} (CDKN2B), transcriptional factors E2F1 to E2F4, and G1/S phase–specific kinase CDC7, as well as in DNA replication and DNA repair (DNA polymerases, minichromosome maintenance proteins 2 to 7, MCM2 to MCM7; X-ray repair cross-complementing protein, XRCC1; and replication protein A, RPA2).[180–182] Notably, all these genes are overexpressed in HPV(+) tumors compared to HPV(−) HNSCC.

In addition to genes, several miRNAs are up-regulated (miR-9-5p, miR-20b-5p) or down-regulated (miR-193b-3p) in HPV(+) OPSCC.[183,184] The contribution of these miRNA alterations in HPV-associated tumorigenesis are not well described, but are also seen in HPV-associated cancers of the urogenital tract.[184]

Losses of 3p and 8p, and gains of 3q and 8q chromosomal regions, are common in HNSCC, irrespective of HPV status. The 3q26/28 amplicon contains several genes that control epithelial cells differentiation and survival, including the TP53 homologue, TP63, SOX2, and the oncogene PIK3CA.

Notwithstanding chromosomal amplifications and deletion shared with HPV(−) HNSCC, HPV(+) cancers also possess a distinct signature of chromosomal gains and losses. Massive genome-wide analysis of HPV integration revealed a direct link between HPV integration and genomic rearrangements, including amplifications, deletions, and translocations. Interestingly, in the cohort of 25 HPV(+) HNSCC, no HPV integration sites were recurrent,[21,175] which may suggest a random mechanism of the integration event. Although not mechanistically linked to HPV integration, a recently discovered recurrent deletion of the TNF receptor-associated factor 3 (TRAF3) gene was identified in 14% of HPV(+) head and neck tumors, and truncating mutations of TRAF3 were also found in 8% of HPV(+) HNSCC. Remarkably, neither mutations nor deletions of TRAF3 were found among 243 analyzed HPV(−) HNSCC.[21,175] Exclusive alterations of TRAF3 in HPV-associated HNSCC along with the known role of TRAF3 in cellular

antiviral response strongly suggest that inhibition of TRAF3 function is critical for tumorigenesis driven by HPV in the head and neck. Interestingly, inhibition of TRAF3 is also observed in Epstein-Barr virus (EBV)-associated malignancies, but in this case, the EBV oncogenic protein, LMP1, interacts with TRAF family members. Further, TRAF3 deficient mice are predisposed to squamous cell carcinomas of the tongue and salivary gland tumors with an incidence as high as 50%.[185]

Another important genomic feature that differentiates HPV(+) from HPV(−) HNSCC is focal amplification of E2F1—a transcriptional factor driving cell cycle progression—found in 19% of HPV(+) head and neck tumors. The reason for E2F1 amplification in the face of HPV E7-driven inhibition of Rb and Rb-family members is unknown. E2F1 and its family member E2F2 have been implicated in amplification of the HPV genome, but the role of E2F1 in HPV(+) HNSCC remains speculative.[186]

The most common genetic events found in HPV(+) HNSCC are summarized in Table 2.3. Several previous studies have shown significantly fewer somatic mutations and fewer chromosomal abnormalities in HPV(+) as compared to HPV(−) HNSCC[22,23]; in contrast, recent TCGA analysis found that mutation rates did not depend on HPV status.[21] However, HPV(+) tumors showed specific global mutation signature enriched for the APOBEC-associated mutations. APOBEC is a family of cytidine deaminases that convert cytosine to uracil during RNA editing and retrovirus and retrotransposon inhibition. Recently, APOBEC family members have been shown to induce specific mutation clusters in a number of human tumors, including bladder, cervical, breast, head and neck, and lung cancers.[187]

Epigenetics of HPV(+) HNSCC

Epigenetic changes play an important role in cancer development and progression. Just as with mutations or copy number changes, up-regulation of oncogenes or down-regulation of tumor suppressors via epigenetic changes can aid carcinogenesis. In cancer, epigenetic silencing of tumor suppressors through methylation occurs at least as frequently as mutations or deletions. Genome-wide gene expression profiling highlighted several hundred genes that are differentially expressed in HPV(+) and HPV(−) oropharyngeal cancers.[188] The majority of studies examining gene promoter methylation in

HNSCC are substantially descriptive without functional significance between methylation, gene expression, and clinical behavior. However, promoter hypermethylation of ALDH1A2, OSR2, GATA4, GRIA4, and IRX4—genes coding for proteins involved in retinoid metabolism—was found to correlate with decreased transcript expression, HPV gene expression, and improved survival.[189] Our findings indicated that SMG-1, a PI3K-related kinase family member, involved in the nonsense-mediated RNA decay process and maintenance of genome integrity, has low expression in HPV(+) OPSCC due to promoter hypermethylation, which may contribute to the enhanced radiation sensitivity of HPV(+) cells and tumors.[190] Interestingly, several genes from cadherin superfamily, including cadherins (CDH8, CDH13, CDH18, CDH19, CDH23) and protocadherins (PCDH10, PCDH15, PCDHB1, PCDHB4, and PCDHB15) that are all targets of polycomb repressive complex 2 and potential players in metastatic process, were selectively hypermethylated in HPV(+), but not in HPV(−) HNSCC.[191] In addition, higher DNA methylation in genic and LINE-1 regions, which most likely indicate a global hypermethylated phenotype, has been found in HPV(+) versus HPV(−) head and neck cancer cell lines.[52] However, recently it has become clear that the distinct gene expression and methylation signature of HPV(+) HNSCC (global hypermethylation) are found only in cancers harboring episomal HPV, whereas methylation and gene expression profiles of tumors with “integrated-only” HPV are very similar to HPV(−) tumors and normal tissue.[175] This finding hints at distinct carcinogenic mechanisms for cancers with integrated and nonintegrated HPV and heralds epigenetic changes as a major driver of cancer development in HNSCC with episomal HPV; however, more detailed and focused studies are needed to clarify this hypothesis.

Proteomics of HPV(+) and HPV(−) HNSCC

Gene expression and mutational analyses reveal clear differences between HPV(+) and HPV(−) HNSCC, but examining protein expression and activation has increased identification of pathways that are differentially activated based on HPV status. Comparing HPV(+) and HPV(−) tumors, proteomics studies have found differences in proteins primarily involved in metabolism, adhesion, differentiation, and keratinization.[192] However, the continued search for targetable signaling pathways prompted a recent

examination of protein and phosphoprotein expression, focusing on tumor-associated signaling cascades. Remarkably, 30% (41/127) of proteins or phosphoproteins involved in these pathways were differentially expressed.[24]

As expected, both cyclin D1 expression and Rb inhibitory phosphorylation were relatively increased in HPV(−) HNSCC compared to HPV(+) cancers. Differential expression and phosphorylation of these cell cycle genes is likely explained by HPV E7-dependent down-regulation of Rb, with resultant increased transcriptional activity of cell cycle driver E2F1. Consistent with previous reports, EGFR, STAT3, MYC, and insulin pathway proteins were also expressed at higher levels in HPV(−) HNSCC.[144,193,194] Surprisingly, HPV(−) HNSCC had increased activation of Akt as measured by phosphorylation of downstream targets.[24] Increased Akt activation in HPV(−) versus HPV(+) cancers was even more remarkable given the high percentage of HPV(+) cancers with activating mutations of PIK3CA and the absence of similar mutations in HPV(−) cancers. Together, these results suggest that both HPV(+) and HPV(−) HNSCC are dependent on Rb inhibition, albeit by different mechanisms. E2F1 amplification in HPV(+) tumors suggests that these tumors are particularly dependent on E2F1 activity. On the other hand, HPV(+) HNSCC seems to be less dependent on activation of RTK signaling compared to HPV(−) cancers.

Interestingly, high expression levels of several DNA repair proteins segregated to HPV(+) versus HPV(−) tumors. Additionally, elevated levels of apoptotic markers, including cleavage of caspases 3 and 7, were found in HPV(+) tumors. Finally, mechanistic studies revealed that activating mutations of PIK3CA in HPV(+) HNSCC preferentially stimulated mTOR, as opposed to the Akt pathway, suggesting that HPV(+) tumors rely on activation of PI3K, but not on downstream Akt activation.[24]

Treatment of HPV(+) HNSCC

Despite the dichotomous patient population, treatment response, and prognosis, and the fundamental molecular differences between HPV(+) and HPV(−) HNSCC, the presence of HPV alone does not currently play a role in treatment decisions. For advanced stage patients, treatment minimally includes platinum drugs concurrent with high doses of radiation. However, ongoing clinical trials are currently testing whether HPV(+) HNSCC may be

effectively treated with de-escalated therapy and less invasive surgery, in order to limit the serious side effects associated with traditional therapies.[195–197] In addition, cetuximab, an anti-EGFR antibody, which is currently used as a radiation sensitizer, is currently being investigated as another means of treatment de-escalation.[198]

Recent data that women vaccinated against HPV had a lower prevalence of oral HPV infection[199] suggest that both currently available HPV vaccines, Gardasil and Cervarix, protect against oral HPV infection and potentially HPV(+) HNSCC. Using a therapeutic HPV vaccine following the development of an infection or cancerous transformation in order to stimulate an immune response against cells harboring HPV and expressing HPV genes is another interesting area of scientific and clinical interest,[200,201] as are other immune-related therapies.[202]

The increasing knowledge of the molecular pathogenesis of HPV(+) HNSCC is driving discovery of newer, targeted, less toxic therapies. Several drugs, including demethylating agents, cyclin-dependent kinase inhibitors, mTOR inhibitors, WEE1 inhibitors, and PARP inhibitors, have been investigated in our laboratory and elsewhere. Many of these potential therapies have shown selective cytotoxicity for HPV-associated HNSCC in preclinical studies and thus represent acceptable candidates for clinical trials.

SUMMARY

The genetic and epigenetic alterations central to tumorigenesis of HNSCC are being uncovered with new technologies, building on prior knowledge in molecular biology. This chapter provides a framework for organizing and understanding the wealth of information being produced. Understanding the pathogenesis of HNSCC will be an essential foundation for discovery of new therapies. Importantly, it is becoming clear that HNSCC is not a single entity, but is rather a similar manifestation of a heterogeneous collection of etiologies and insults. Our approach to treatment of this cancer requires sophistication to match the complexity of the processes that were responsible for its creation.

Progress in advancing new targeted drugs has proven incremental and onerous since the relatively recent unlocking of the human genome, but many

new therapies are on the horizon (Table 2.4) and should allow us to treat HPV(+) and HPV(−) HNSCC in a more sophisticated, targeted, and personalized fashion. We are at the beginning of a journey to understand molecular defects that are drivers of HNSCC. As an indicator of progress in this venture, trials are already in place using molecular data to guide therapy. We are moving from relatively stagnant treatments based on histology, stage, and site to treatments based on individual defects in the tumor or the ability of the immune system to respond. As these therapies emerge, the next major advance will be in design and delivery of rational combinatorial therapies.

Table 2.4 Current Therapeutic Targets in HNSCC

Target	Functional Pathway	Drug Mechanism	Drug Name(s)	Stage(s) of Development
p53	DNA damage response, cell cycle/ apoptosis	Adenovirus gene therapy	Advexin	Phase 3
			ONYX-015	Approved in China
		Wee-1 inhibitors	MK-1775	Phase II
		Aurora kinase inhibitors	ZM447439, hesperadin, VX-680	Phase II
pRb	Cell cycle	CDK inhibitor	P276-00	Phase 2
EGFR	Growth signaling	Monoclonal antibody	Cetuximab	In clinical use
			Panitumumab, zalutumumab, nimotuzumab	Phase 2-3
Tyrosine kinases (EGFR, VEGFR, PDGFR, HER2, ErbB4, cKIT, RET)	Growth signaling	Tyrosine kinase inhibitors	Gefitinib, erlotinib, lapatinib, afatinib, sorafenib, sunitinib, vandetanib, pazopanib,axitinib, nilotinib	Phase 1-3
MEK	Growth signaling	MEK inhibitor	Trametinib	Phase 1
PI3K	Proliferation, resisting apoptosis	PI3K inhibitor	PX866, BKM120, BYL719, rigosertib	Phase 2
AKT	Proliferation, resisting apoptosis	AKT inhibitor	MK2206	Phase 2
mTOR	Proliferation, resisting apoptosis	mTOR inhibitor	Rapamycin, everolimus, temsirolimus, CC-115	Phase 1-2
JAK	Proliferation, resisting apoptosis	JAK inhibitor	Ruxolitinib	Phase 1
MET or MET/VEGFR	Angiogenesis, invasions/metastasis, proliferation	MET inhibitor or MET/VEGFR inhibitor	LY2801653, foretinib, E7050/ golvatinib	Phase 1-2
PDK	Cancer metabolism/ hypoxia	PDK inhibitor	Dichloroacetate	Phase 1
AMPK	Cancer metabolism	AMPK activator	Metformin	Phase 2

3 Pathology of the Head and Neck: Basic Considerations and New Concepts

Elizabeth G. Demicco Bruce M. Wenig

The role of the modern surgical pathologist is to identify tissue-based lesions and describe their known theranostic characteristics in order to accurately inform patient prognosis and clinical therapy. As such, the pathologist is an integral member of the multidisciplinary team responsible for the management of cancer of the head and neck. In the modern era, the creation of a pathologic diagnosis goes far beyond the straightforward “naming” of an entity based on histologic appearance, and may require close correlation with the gross specimen, clinical, radiographic, or molecular characteristics in order to evaluate and convey relevant information for appropriate patient care.

This chapter provides an overview of pathologic issues related to cancer of the head and neck and is divided into three sections. In the first, a general overview of the role of pathology in head and neck neoplasia is provided. “Histopathologic Parameters” section addresses histopathologic parameters evaluated by pathologists, with focus on those relevant in the assessment of mucosal squamous cell carcinoma. “Ancillary Studies (Pathologic Toolbox) and Applications” section provides an update of the diagnostic tools used by pathologists in routine clinical analysis, as well as a look at emerging technologies.

Basics of Pathology

Pathology Reporting

The pathology report provides the basis for all tissue-based clinical decisions. As such, it is a vital part of the patient's medical record. At the most basic level, the pathology report contains a description of the tissue examined by the pathologist, at both the gross and microscopic levels. If a lesion is present, the pathologist is responsible for establishing the general type of process (inflammatory, infectious, benign neoplastic, or malignant) and subclassifying it as specifically as possible with a name that conveys the lineage of the cells involved and the etiology of the process. In addition, adequate diagnosis of malignant tumors requires further specification as to cellular differentiation. Where evaluable, the extent of tumor is reported, including whether it is in situ or invasive, its size, presence or absence of vascular/lymphatic invasion, perineural invasion, or presence at surgical margins. Lymph nodes must be identified and examined for metastases and extranodal extension. Ancillary testing required for diagnosis or therapeutic applications may also be contained within the surgical pathology report.

The Surgical Pathology Specimen

Pathology specimens come in a variety of forms, ranging from cyst contents or solid tumor aspirations, to needle core biopsies and incisional or excisional biopsies, to radical, complex resections. Each specimen type must be properly labeled and promptly submitted to ensure that it is appropriately processed for subsequent evaluation. Pathologic examination begins with examination of the gross surgical specimen. Note is made as to the type of specimen, for example, biopsy (shave, core, punch, incisional, excisional), resection, or lymph node dissection, and the overall size.

Gross examination of biopsy specimens may be relatively simple. The tissue biopsied should be noted, if identifiable, as epithelial/mucosal, bone, cartilage, or soft tissue, and the specimen should be submitted entirely, with or without additional sectioning, depending on specimen size.

For excisions and resections consisting of large, complex specimens, as frequently results from head and neck resections, the gross examination may be more involved. The intricate anatomy of the head and neck requires the surgical pathologist to be aware of the normal structures and their relationships to one another, in order to properly assess tumor involvement. Correct orientation is key to the establishment of the status of the surgical margins and requires a close working relationship between the pathologist

and the surgeon. In many cases, surgeons can ensure proper orientation using sutures or ink to indicate critical margins. In complex cases, or those where nonmargin tissue has been disrupted, personal orientation of the pathologist to the specimen by the surgeon may be required.

After specimen orientation, the pathologist documents the structures present, sections the specimen, and records the size, appearance, and extent of the tumor. Sections submitted for histologic evaluation must represent areas requiring special attention, for example, surgical margins, lymph nodes, or bone invasion, that may impact the patient's prognosis and future management. Failure to properly evaluate and section the gross specimen can have significant adverse effects on patient care.

Subsequent to appropriate fixation of the specimen in formalin or other agents, the tissue is further mechanically processed, dehydrated, and infiltrated with paraffin. Depending on the type of tissue, the length of time needed for proper fixation varies; for instance, adipose tissue requires a longer processing time. Calcified specimens such as bones must be decalcified in acid or chelating agents prior to processing. Decalcification can take from hours to weeks, based on the specific agent used, the density of bone, and the thickness of the section. Processed tissue is embedded by hand into paraffin blocks, sectioned into 4- to 5-μm sections, and stained with hematoxylin and eosin (H&E) or other histochemical stain for routine histologic evaluation. Typically, specimen processing for routine formalin-fixed, paraffin-embedded (FFPE) tissues may take from a few hours to a day for small biopsies rapidly processed in specialized processors, to many days for complex bone resection specimens.

The surgical pathologist is completely dependent upon the tissue procured by the surgeon. Without appropriate or adequate material, an accurate diagnosis cannot be rendered. In general, biopsies should avoid necrotic tissues near the center of lesions. Transitional areas showing the interface between normal and abnormal tissue are preferred, such as the edge of an ulcer or the line of demarcation between a verrucous proliferation and flat epithelium. Superficial biopsies are rarely helpful; invasion of epithelial lesions cannot be determined without evaluation of the epithelial–stromal interface, in a full-thickness section. Failure to provide an adequate biopsy results in diagnostic and therapeutic delays as well as frustration for the patient, clinician, and pathologist alike. Repeat biopsies may be distorted by

postbiopsy inflammatory changes and degenerative artifact, further adding difficulty to appropriate interpretation.

It is also necessary to consider the differential diagnosis before placing biopsy tissue in fixative and sending it to pathology. Although in most circumstances, immediately placing tissue in fixative at the time of surgery is preferred, because tissues undergo ischemic changes and progressive autolysis the longer they remain unfixed, fresh tissue may be required by the pathology laboratory in certain circumstances. Ancillary studies such as flow cytometry or cytogenetics, which are frequently utilized in diagnosis of hematolymphoid proliferations, require fresh viable tissue, which must be sent directly from the operating room without delay for processing. Some laboratories may wish to save a portion of tissue in fixatives other than formalin for lymphoid biopsies for better preservation of cellular morphology.[1] If ancillary studies such as electron microscopy, molecular studies, or cytogenetics are anticipated, it is also recommended that fresh tissue be sent without transport delay and the pathologist be notified that special handling is required.

The use of frozen tissue biorepositories established from fresh tissue after minimal ischemic time is encouraged for preservation of neoplastic and uninvolved tissues. However, gross specimen dissection is best handled by the pathologist, and incision or sectioning of the specimen by the surgical team is discouraged, as it may create difficulties in appropriate pathologic evaluation of margins, or sectioning for microscopy.

Cytology

Cytologic preparations may be obtained from bodily site washings, cyst fluid aspirations, or solid tumor aspirations or may be made directly from the surgical specimen. Touch imprints, squash preparations, and scrape cytology specimens prepared from surgical specimens are commonly used as an adjunct technique to frozen section evaluation, particularly for evaluation of thyroid nodules, lesions of the central nervous system, or hematolymphoid lesions. Touch imprints are prepared by pressing a glass slide against the cut surface of tumor and are best used for lymphoid or hematopoietic processes, where cells easily transfer from tissue to glass. Squash preparation involves cutting minute portions of tumor (<1 mm^3) and pressing it between two slides to spread out cells. Squash preparations are best reserved for very soft tissues

that spread easily under pressure. To harvest cells for scrape preparations, a scalpel blade is used to scrape the cut surface of a lesion, and the material is then smeared onto a glass slide.

Fine needle aspiration (FNA) biopsies are performed by inserting a thin needle attached to a syringe into the mass of interest. Cells are harvested by using light suction applied to the syringe while the needle is rapidly moved back and forth through the tissue to loosen cells and obtain a sample from different regions. Material collected may be smeared directly on slides or saved in fluid for paraffin-embedded cell block preparation or for fluid-based cytologic preparations created using filtration or centrifugation. Smeared slides are rapidly fixed or allowed to air dry and stained for histologic evaluation with H&E, Papanicolaou stain, or Diff-Quick preparation. Additional unstained preparations can also be set aside for immunohistochemistry or molecular studies.

FNA is a reliable and safe method to obtain cytology specimens from cystic lesions, lymph nodes, and many types of solid tumors. Early concerns about nerve damage and biopsy tract seeding by tumor cells were largely unfounded,[2,3] with the most frequent complications being hematoma and infection. FNA biopsy is easily performed on palpable masses and may be used in conjunction with ultrasound imaging to improve accuracy and to target deep lesions.[4,5] Because it is relatively cost- and labor-effective when applied to the readily accessible structures of the head and neck, FNA biopsy has become the preferred screening diagnostic modality for clinically concerning neck masses, including lesions arising in the parotid, thyroid, or lateral neck. As with all techniques in medicine, FNA biopsy and interpretation is highly dependent on experience, with higher diagnostic accuracies reported by high-volume academic centers,[6] and improved rates of biopsy adequacy when performed or screened on-site for adequacy by cytopathologists.[7–10] FNA biopsy has proved invaluable in presurgical planning and patient counseling, particularly in regard to defining the need for procedures with higher risk of morbidity, such as nerve sacrifice or neck dissection.[11,12] FNA also allows for serial follow-up if a lesion continues to grow over time. Many surgeons do, however, prefer to verify cytologic diagnoses at the time of surgery with intraoperative frozen section (further discussed below).

Salivary Glands

Diagnosis of salivary gland neoplasms by FNA biopsy can be challenging. Many tumors are composed of a mixture of cell types, and even cytologically bland tumors can demonstrate an infiltrative growth pattern definitive for malignancy on final pathology.[13] Common sources of diagnostic error include cellular pleomorphic adenoma, low-grade carcinomas such as low-grade mucoepidermoid or papillary cystadenocarcinoma, lymphoepithelial cysts, and lymphoproliferative disorders.[14] Fortunately, the majority of tumors of the major salivary gland are benign, with pleomorphic adenoma and Warthin tumor representing the most common subtypes,[15] resulting in a high pretest probability of benign diagnoses. FNA biopsy of lesions of the major salivary glands has a high specificity for malignancy, with reported sensitivity, specificity, and accuracy for malignant diagnosis ranging from 73% to 92%, 94% to 100%, and 90% to 98%, respectively.[11,16–18]

Because FNA biopsy allows for the creation of cell block tissues, diagnostic accuracy may be improved by incorporating immunohistochemical or molecular analyses into final pathologic interpretation. In most instances, salivary tumors will undergo resection for definitive therapy, regardless of the FNA interpretation as benign or malignant. However, because FNA biopsy is largely comparable in accuracy to frozen section,[11,19,20] prior knowledge of the likely malignant potential enables the surgeon to better counsel the patients and prepare them in advance as to the necessity of wide resection, possibly including sacrifice of the facial nerve, or elective neck dissection. Discussions may also be entered into about postsurgical management and adjuvant therapy options, if required.

Neck Masses

It may be difficult to distinguish a benign from a malignant mass in the neck on the basis of clinical and radiographic information alone. Lesions may represent reactive lymphadenopathy, primary lymphomas, enlarging developmental cysts, infection (lymphadenitis), metastases to the lymph nodes, or benign or malignant mesenchymal tumors arising in soft tissue of the neck. Fortunately, ultrasound-guided FNA is one of the most accurate modalities for confirming the presence of metastatic disease in enlarged cervical nodes, with reported sensitivity for squamous cell carcinoma in solid

lymph nodes ranging from 80% to 90%.[21,22] FNA is less sensitive for malignancy in cystic neck masses, with sensitivity as low as 33%.[23,24]

Sensitivity and accuracy of FNA biopsy diagnosis of lymphoproliferative lesions is enhanced by concurrent immunocytochemistry, flow cytometry, and/or cytogenetic analyses. Dedicated FNA passes in addition to those needed for smear and cell block preparations may be required to obtain adequate material for these studies. In the absence of ancillary immunophenotyping studies or flow cytometry, the ability of FNA to correctly identify and classify lymphoma has been reported to be as low as 52%.[25] Immunocytochemistry increases accuracy to 70% and flow cytometry to 75% to 81%.[25,26] Flow cytometric analysis improves the ability to distinguish reactive lymphadenopathy from non-Hodgkin lymphoma, although it has little effect on identification of Hodgkin lymphoma. In other contemporary analyses, overall diagnostic accuracy of FNA biopsy of cervical lymphadenopathy reaches 82%,[27] with highest overall accuracy (up to 100%) reported for identification of metastatic carcinoma and lowest (~75%) for diagnosis of Hodgkin and non-Hodgkin lymphomas.[26,27] Sensitivity and specificity of FNA biopsy for lymphoma is user dependent, and some series have noted no benefit to FNA biopsy of cervical lymphadenopathy.[28] In the vast majority of cases, however, FNA biopsy interpretation by an experienced cytopathologist is an acceptable screening tool to triage management of a mass in the neck. Diagnoses of metastatic carcinoma in a cervical node appropriately trigger further evaluation to identify primary site or tumor-specific management protocols, while lesions concerning for lymphoma should undergo excisional biopsy for definitive diagnosis and subtyping. Benign or reactive lesions may be followed or rebiopsied depending on the level of clinical suspicion for malignancy.

Thyroid Lesions

Thyroid nodules are one of the most common indications for neck FNA. Palpable nodules are identified in ~5% of the adult population,[29,30] with between 20% and 75% of the population having clinically unrecognized nodules.[31,32] Reported incidence of thyroid carcinoma averages 5% in solitary nodules and 3% in multinodular goiter.[33] Presurgical diagnosis via FNA biopsy prevents unneeded surgery for benign, nonprogressive lesions

and helps to triage patients with a neoplasm for the appropriate procedure. Diagnostic accuracy of FNA biopsy of the thyroid is well established, with both specificity and sensitivity for malignancy of over 90% in large historical series.[34–37]

Standardization and interpretation of thyroid cytology has been greatly improved by the widespread adoption of systems such as the Bethesda reporting system, which classifies biopsies in a 6-tiered system as: Bethesda Class 1—nondiagnostic or unsatisfactory, Bethesda Class 2—benign, Bethesda Class 3—atypia of uncertain significance or follicular lesion of uncertain significance, Bethesda Class 4—follicular neoplasm or suspicious for follicular neoplasm, Bethesda Class 5—suspicious for malignancy, and Bethesda Class 6—malignant (Table 3.1).[38–40]

Table 3.1 Bethesda Classification of Thyroid Cytology

Bethesda Classification	Frequency of Diagnosis	Risk of Malignancy	Recommended Management
1. Nondiagnostic, Unsatisfactory	<15%	N/A	Repeat FNA with ultrasound guidance
2. Benign	30%–75%	<2%	Clinical follow-up
3. Atypia of undetermined significance, Follicular lesion of uncertain significance	<10%	20%–40%	Repeat FNA
4. Follicular neoplasm, Suspicious for follicular neoplasm	~5%	40%	Lobectomy
5. Suspicious for malignancy	<5%	70%	Thyroidectomy or lobectomy
6. Malignant	~5%	>95%	Thyroidectomy

Nondiagnostic biopsies occur in 3% to 14% of thyroid FNA,[41,42] with higher percentages resulting from procedures performed by less experienced clinicians in the absence of immediate pathologic assessment of adequacy and a lower incidence when performed and assessed in FNA clinics by trained cytopathologists.[8,9,43] Ultrasound guidance further increases diagnostic success rates for difficult-to-palpate nodules.[43] Benign lesions, for example, nodular hyperplasia or chronic thyroiditis, are identified on cytology in approximately 30% to 70% of aspirated nodules,[41,44] with reported false-negative rates as low as 0% to 2%.[44,45]

The most challenging cases to manage are those diagnosed as Bethesda 3, as final diagnosis may range from benign nodular hyperplasia to papillary or follicular thyroid carcinoma. Initially, lesions with atypia of uncertain significance were predicted to run a 5% to 15% risk of malignancy.[38] In

practice, studies have reported malignancy rates ranging from 20% to 38%, not including incidentally discovered second lesions in the resected specimen.[41,42,46] Moreover, the Bethesda category 3 is intended to account for no more than 10% of cases in a given practice.[38] Overusage of the category can lead to additional management dilemmas. Although the Bethesda guidelines recommend repeat FNA for indeterminate lesions, and studies have shown that 40% to 50% of indeterminate lesions can be classified as benign on repeat FNA,[42,46] other consensus guidelines recommend surgery as the next step.[47] Triage of cytologically indeterminate lesions to reflex mutational analysis or commercial propriety gene expression analyses to more clearly delineate benign from malignant based on molecular signature has become increasing popular and is discussed in greater detail in “Ancillary Studies (Pathologic Toolbox) and Applications” section.

Lesions diagnosed as suspicious for follicular neoplasm on resection are found to be hyperplasias, adenomas, follicular carcinomas, and less frequently, papillary carcinoma, with malignancy rates of up to 40% to 46%.[45], [48] Determination of malignancy in an encapsulated follicular nodule requires identification of capsular or vascular invasion, features for which neither FNA nor frozen section is sensitive. Thus, appropriate management for Bethesda 4 lesions is lobectomy with evaluation of the entire capsule of the lesion on paraffin section. Oncocytic or “Hürthle cell” features are seen in nonneoplastic conditions as well as both benign and malignant neoplasms and have little diagnostic significance when reported on FNA.[49,50]

Approximately 70% of thyroid nodules reported as suspicious for malignancy on FNA (Bethesda 5) turn out to be malignant after definitive excision,[48] and the vast majority of these are papillary thyroid carcinoma (PTC), whereas >95% of lesions with cytologic diagnosis of malignancy are confirmed after resection.[51,52]

FNA biopsy of the thyroid does elicit biopsy site changes in the thyroid gland, including hemorrhage, necrosis, cystic degeneration, fibrosis, inflammation, and nuclear cytologic atypia of adjacent tumor cells as well as squamous or oncocytic metaplasia. Capsular disruption by biopsy tract and subsequent entrapment of follicular cells may simulate capsular invasion. Such changes may be mistaken as evidence of malignancy on subsequent FNA biopsy or resection[53–55] and must be interpreted with caution in

postbiopsy resection specimens.

Orbit

FNA is sometimes used to diagnose deep unresectable posterior orbital tumors or those for which access would require large, complex craniofacial surgery. Reported success rate (defined as being diagnostically helpful or accurate) approached 80% in older studies,[56,57] with the majority of lesions being lymphoproliferative or inflammatory conditions. FNA is rarely used in this location, due to the rarity of orbital masses and the technical skill required for the procedure. In the modern era, endoscopic surgery with direct visualization of the lesion is preferred to procure tissue for histopathologic evaluation.[58,59] FNA has also been proposed as a diagnostic tool for uveal melanomas and other intraocular tumors,[60,61] with sensitivity and specificity for malignancy reported as 100% and 98%, respectively. Complications include intraocular hemorrhage and rarely retinal detachment or tumor seeding.[62]

Intraoperative Consultation (Frozen Section)

During the course of surgery, it may be necessary to send a specimen for immediate pathologic examination, to help guide surgical decision making. Intraoperative consultation may take the form of gross specimen examination; cytologic preparations, as discussed above; or frozen section. Specimens may also be sent to the frozen section laboratory for rapid processing for biorepository or for tissue harvesting for cytogenetics, microbiology studies, flow cytometry, diagnostic mutational screening, or gene expression assays. Because the frozen section laboratory works in a time-sensitive fashion and may have multiple cases waiting for results before surgery may proceed, “curiosity frozens,” the result of which will not affect the procedure under way, but which may cause harm to the diagnostic material or delay other waiting cases, are strongly discouraged. It must be clearly understood that the frozen section interpretation is a preliminary diagnosis, intended only to provide immediate actionable information to the surgeons at the time of surgery, and is not meant to be the basis for postsurgical treatment or patient management. Decisions about adjuvant therapy must therefore be deferred until a definitive final diagnosis is rendered on FFPE tissues.

Appropriate uses of intraoperative consultation include establishing biopsy adequacy, triage of tissue for ancillary studies such as flow cytometry, or to make a preliminary diagnosis that will affect the extent of surgery. Margins are evaluated for adequacy of clearance, and additional margins may be sent until tumor clearance is achieved. Specimens may also be sent for tissue confirmation, such as confirmation of parathyroid glands in need of preservation during thyroidectomy.

Frozen section analysis requires that tissue be rapidly examined at the gross level, oriented, and inked if indicated and sections cut for histologic analysis. These tissue sections are embedded in gel matrix and rapidly frozen at –20°C to –30°C. Thin, 4- to 7-μm sections are cut using a microtome, and the tissue is stained with H&E for evaluation. Different tissues have varying water and lipid contents causing them to freeze at different rates, which may lead to tissue and cellular distortion. Sectioning frozen tissue may be technically difficult, particularly for adipose or dense fibrous tissue, and may not produce satisfactory sections for interpretation. Heavily calcified tissues, such as bone, often cannot be sectioned at all. Air-drying artifact may also be introduced if sections are not fixed rapidly enough after being cut. Some tumors, in particular melanocytic lesions, should not be sent for frozen evaluation, as frozen artifact precludes sufficiently accurate identification of malignant cells.

Due to the above technical limitations of the technique combined with the rapid turnaround time required (within 20 minutes from receipt as recommended by the College of American Pathologists), frozen section may be less accurate than paraffin sections. Reported overall error rates for frozen section vary, based on both specimen type and experience. In large studies of general surgical cases, accuracy of frozen section reaches 98%, with deferral rates of 2% to 3%.[63–65] Overall, historical concordance rates are similar for head and neck surgeries,[66,67] which are among the services most heavily reliant on intraoperative consultation.[65] Discrepancy rates on surgical margins are much higher than those for any other specimen type[68–72] and are further discussed below.

In addition to specimen-, technical-, and sampling-related errors, frozen section "errors" also include misinterpretation or miscommunication of results.[73] Read-back verification by the surgeon is required to ensure proper diagnosis communication between the interpreting pathologist and treating

surgeon.[74]

Margins

Negative surgical resection margins with complete clearance of malignancy are required for local cancer control.[75] Margins are therefore frequently sent for frozen section during the course of resection of mucosal squamous cell carcinomas and may be a point of controversy for both pathologists and surgeons. Factors impacting on proper evaluation of margins include the type and complexity of surgical specimen, orientation of the specimen, adequate sectioning and gross evaluation, and correct interpretation of histologic findings. Despite best efforts, all frozen section diagnoses carry the risk that permanent section will reveal tumor not diagnosed at the time of frozen section. In general, accuracy of frozen section in the diagnosis of margins ranges from 89% to 99%,[76–78] with specificity >95%, but low sensitivity. Many groups report that approximately half of the cases with positive final margins were not identified on frozen (range of missed positive margins, 15% to 83%).[68–72,77] False-negative margins on frozen section most frequently result from sampling error, in which carcinoma is absent on the frozen section slide but is found on permanent sections after deeper sectioning.[76] False negatives also occur when the area sampled on frozen section did not truly represent the closest extent of tumor to margin.[68,79] Less frequently, false negatives result from diagnostic misinterpretation of tissue present on the slide, a source of error that may depend on the specimen type, case volume, degree of experience with head and neck tumor evaluation by involved surgical pathologists, and presence of altered tissue states after adjuvant therapy. Frozen section evaluation of margins is particularly problematic in tumors that have been previously irradiated.[69,77]

Historically, the value of frozen section margin evaluation in improving survival was based on the observation that patients with negative margins at the time of frozen section had local recurrence rates of 14%, compared with 20% in patients who required additional supplementary margins to be taken for clearance and 80% in patients for whom adequate clearance was not achievable.[75]

Some authors have questioned the value of frozen section evaluation on local disease control and survival.[69,70,80] Gerber et al.[68] recently reported

that, in a retrospective series of 178 patients undergoing primary resection of oral cavity squamous cell carcinomas with curative intent, frozen section was performed in 111 patients, with positive final margins in 20% of cases, compared with 28% of those who did not undergo intraoperative consult. This difference was not statistically significant.[68] DiNardo and coauthors[69] had similar results and suggested that, after taking into account both accuracy and cost-effectiveness, frozen section evaluation was best used judiciously and largely reserved for patients in whom subsequent margin revision would have the highest chance of success. Effect of frozen section on margin status is also dependent on other factors, such as tumor size,[68] site,[67] and the skill of both the surgeon and the pathologist. Studies have reported widely varying rates of positive margins on final pathology, from between 4% and 53%,[71,72,81–87] suggesting that individual institutions should establish their own quality assurance parameters for when to perform margin frozen section and how those results should affect patient management.

Diagnosis

Masses of every conceivable anatomic site pass through the frozen section laboratory for intraoperative diagnosis on a regular basis. In the head and neck, salivary tumors, thyroid nodules, parathyroid lesions, lymph nodes, and mucosal biopsies form the bulk of this material. FNA has made inroads in diminishing the use of frozen section diagnosis in many of these lesions, but some surgeons prefer a cautious approach with review of tissue-based diagnostic material prior to embarking upon an aggressive surgical procedure.

Frozen section has been reported to have sensitivity and specificity as high as 98.5% and 99%, respectively, for diagnosis of malignant lesions of the parotid, although it is less accurate at distinguishing between different types of benign or malignant tumor.[88–90] Frozen section can also distinguish true salivary gland processes from metastatic tumor in periparotid lymph nodes and can triage lymphoid proliferations to appropriate ancillary studies. Compared to cytology, frozen section is reported to have a lower false-negative rate for detection of salivary gland malignancy.[91]

Thyroid lesions are frequently sent for frozen section to confirm malignant diagnoses made on FNA or to attempt a definitive diagnosis of

lesions with indeterminate or suspicious cytology. Not all such frozen sections are appropriate. FNA diagnosis of PTC (Bethesda 6) has a <5% false-positive rate,[92–94] and frozen section is not warranted prior to proceeding with total thyroidectomy. Likewise, frozen section of nodules with a benign diagnosis on FNA is unwarranted[95–97] and provides no additional diagnostic information unless a clinically suspicious second nodule that was not previously biopsied is detected during the course of the operation. Frozen section is insensitive for malignancy in tumors with an FNA diagnosis of "follicular neoplasm," which may include hyperplasia, follicular adenoma, non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP), follicular carcinoma, or follicular variant of papillary carcinoma in the differential diagnosis.[98,99] Follicular carcinoma requires identification of vascular and/or capsular invasion for diagnosis, features that are often focal and unlikely to be serendipitously present on frozen section, whereas the follicular variant of papillary carcinoma may present with subtle nuclear features that cannot be recognized in frozen tissue.[100,101] Frozen section has a variable sensitivity of 17% to 70% and specificity of 100% in malignant diagnosis of follicular pattern neoplasms, but a deferral rate of over 50%.[102–107]

Frozen section, in conjunction with intraoperative touch or scrape preparations, is best used to evaluate lesions diagnosed as atypical or suspicious for malignancy and can usually detect PTC; medullary carcinoma, poorly differentiated; and anaplastic carcinoma, among other malignancies, with an 84% sensitivity for malignancy, 100% specificity, and 57% likelihood of diagnosing PTC in cases with a preoperative diagnosis of Bethesda 5 lesion.[93,108] Cytologic preparations are recommended as an adjunct study to better examine nuclear details for characteristic features of PTC. It is estimated that frozen section consultation alters the surgical procedure in <1% of cases with preoperative benign diagnosis on FNA,[96] ~5% of those with follicular diagnosis,[109] and 20% to 57% of those with cytologically suspicious diagnosis.[96,110]

Although lymphoid proliferations are rarely diagnosed on frozen section, frozen section of lymph nodes is valuable in intraoperative diagnosis of lymph nodes metastases[111] and has been suggested as a methodology for sentinel lymph node evaluation in squamous cell carcinomas of the head and

neck[112] (discussed in greater detail in “Histopathologic Parameters” section below).

Histopathologic Parameters

Tissue lesions can be characterized by a number of different parameters. At the most basic level, histologic review determines if the sampled tissue is normal or atypical. Atypical conditions include reactive, inflammatory, and neoplastic conditions among others. For neoplastic lesions, one critical distinction is benign or malignant. However, classifying a tumor simply as malignant conveys insufficient prognostic and therapeutic information. To this end, the art of pathology has developed multiple systems of tumor classification and subclassification to more precisely delineate behavior.

Tumor Classification

Lineage

Tumors are typically classified based on the histologic line of differentiation (commonly referred to as the cell of origin) as epithelial, mesenchymal, hematopoietic/lymphoid, or neural/neuroectodermal. Within lineage, there exists a myriad of more specific subtypes, which can generally be identified based on histologic, immunophenotypic, and/or molecular characteristics. By far, the most common malignant tumors affecting the head and neck arise from mucosal or glandular epithelium. Non–glandular-derived epithelial malignancies are carcinomas, with squamous cell carcinoma being the most common subtype. Gland-forming epithelial malignancies are adenocarcinomas. Malignant mesenchymal tumors are termed sarcomas, whereas lymphoproliferative malignancies are lymphomas. Neuroectodermal structures give rise to a variety of benign and malignant tumors, including melanoma, olfactory neuroblastomas, malignant peripheral nerve sheath tumors, and others.

Squamous Cell Carcinoma.

Squamous cell carcinoma is the single most common type of carcinoma affecting the head and neck. Tumors arise within stratified squamous

epithelium, both cutaneous and mucosal, including oral cavity, pharynx, larynx, and nasal cavity. Squamous cell carcinoma may be further classified into conventional type or as one of several uncommon subtypes, each with its own distinctive clinicopathologic characteristics and behaviors (Table 3.2).

Table 3.2 Classification of Squamous Cell Carcinoma Variants of the Head and Neck

Conventional squamous cell carcinoma
Keratinizing
Nonkeratinizing (frequently HPV associated)
Variants
Acantholytic
Adenosquamous
Basaloid
Spindle cell
Verrucous
Nasopharyngeal carcinoma
Basaloid
Keratinizing
Nonkeratinizing (EBV-associated)
Differentiated
Undifferentiated
Sinonasal undifferentiated carcinoma
NUT midline carcinoma

EBV, Epstein-Barr virus; HPV, human papillomavirus.

Within the category of conventional squamous cell carcinoma, a further distinction is made between keratinizing and nonkeratinizing or hybrid tumors (Table 3.3).[113–117] Keratinizing squamous cell carcinomas historically represent the bulk of squamous cell carcinomas arising in the oral cavity and larynx and are associated with a history of alcohol consumption,

smoking, or chronic epithelial inflammatory conditions. Histologically, keratinizing squamous cell carcinomas are characterized by stratified malignant epithelium with distinct cell borders and intercellular bridging. Keratinization may be represented as cytoplasmic eosinophilia in more poorly differentiated cases or more typically by the presence of anucleate keratinocytes or "pearl" formation in well-differentiated tumors (Fig. 3.1). Keratinizing squamous cell carcinomas are, in general, highly aggressive, and advanced disease responds poorly to therapy.[118,119] Five-year survival rates depend on TNM stage and site and vary from up to 85% for glottic tumors to ~50% for supraglottic, hypopharyngeal, or buccal tumors.[119,120]

Table 3.3 Distinction Between HPV-Positive and HPV-Negative Squamous Cell Carcinoma

	HPV Positive	HPV Negative
Age	<60 y	>60 y
Gender	M > F	M > F
Site	Oropharynx (lingual and palatine tonsils)	All mucosal sites of oral cavity, pharynx, larynx, nasal cavity
Risk factors	Number of sexual partners, Immunosuppression	Tobacco, alcohol, chronic inflammatory conditions
Histology	Nonkeratinizing	Keratinizing
P16 expression	Positive (strong nuclear and cytoplasmic expression in >70% of cells)	Negative to patchy weak expression
Stage at presentation	Early metastasis with small primary tumor (pT1N2)	Larger primary tumor, but later metastasis. (pT1-2, N0-1)
Morphology of metastases	Cystic	Solid
Prognosis	5-year survival 70%–80%	5-year survival 25%–85%

HPV, human papillomavirus.

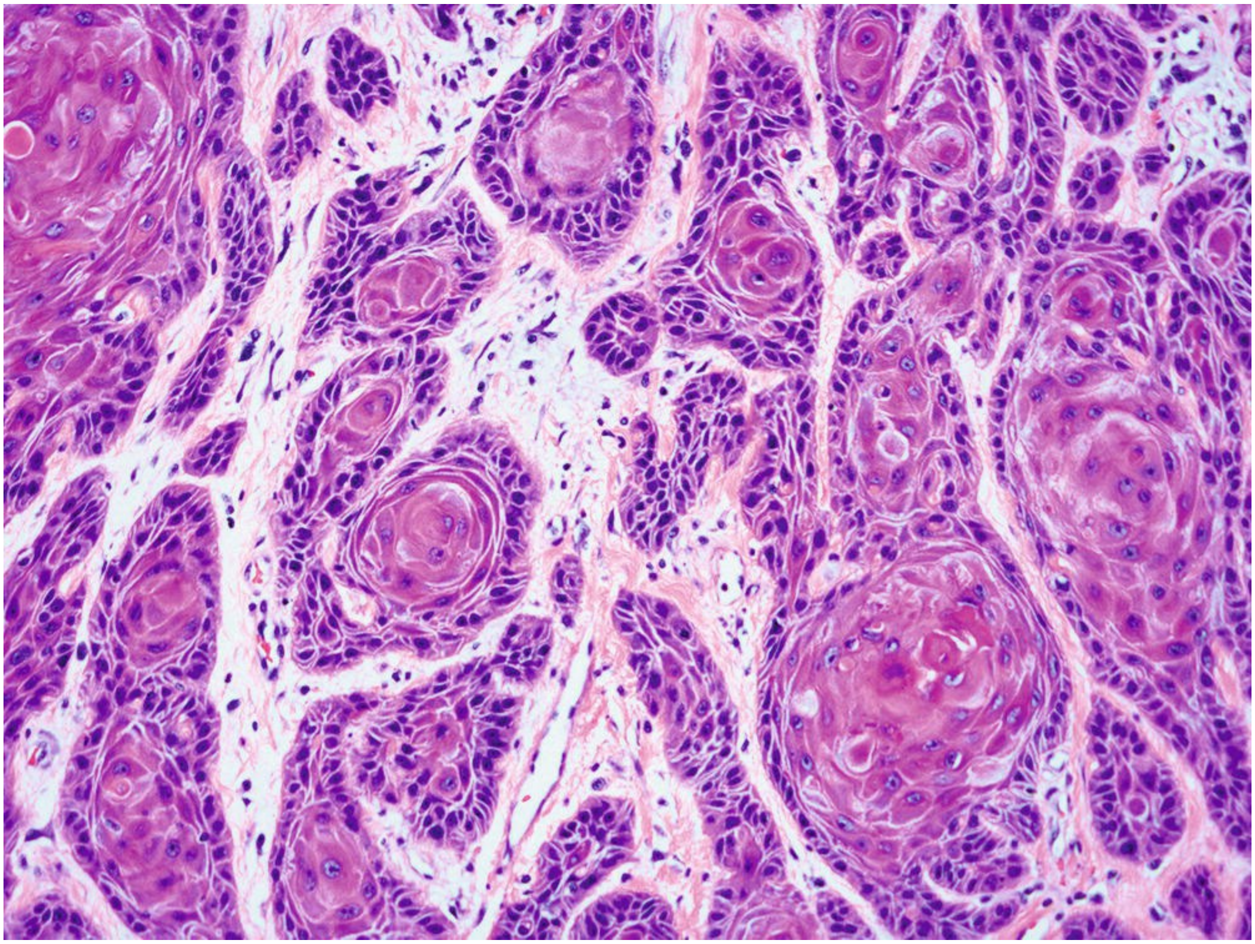

Figure 3.1 Invasive keratinizing squamous cell carcinoma characterized by cells with prominent cytoplasmic eosinophilia (keratinization) and clear spaces in between cells (intercellular bridging).

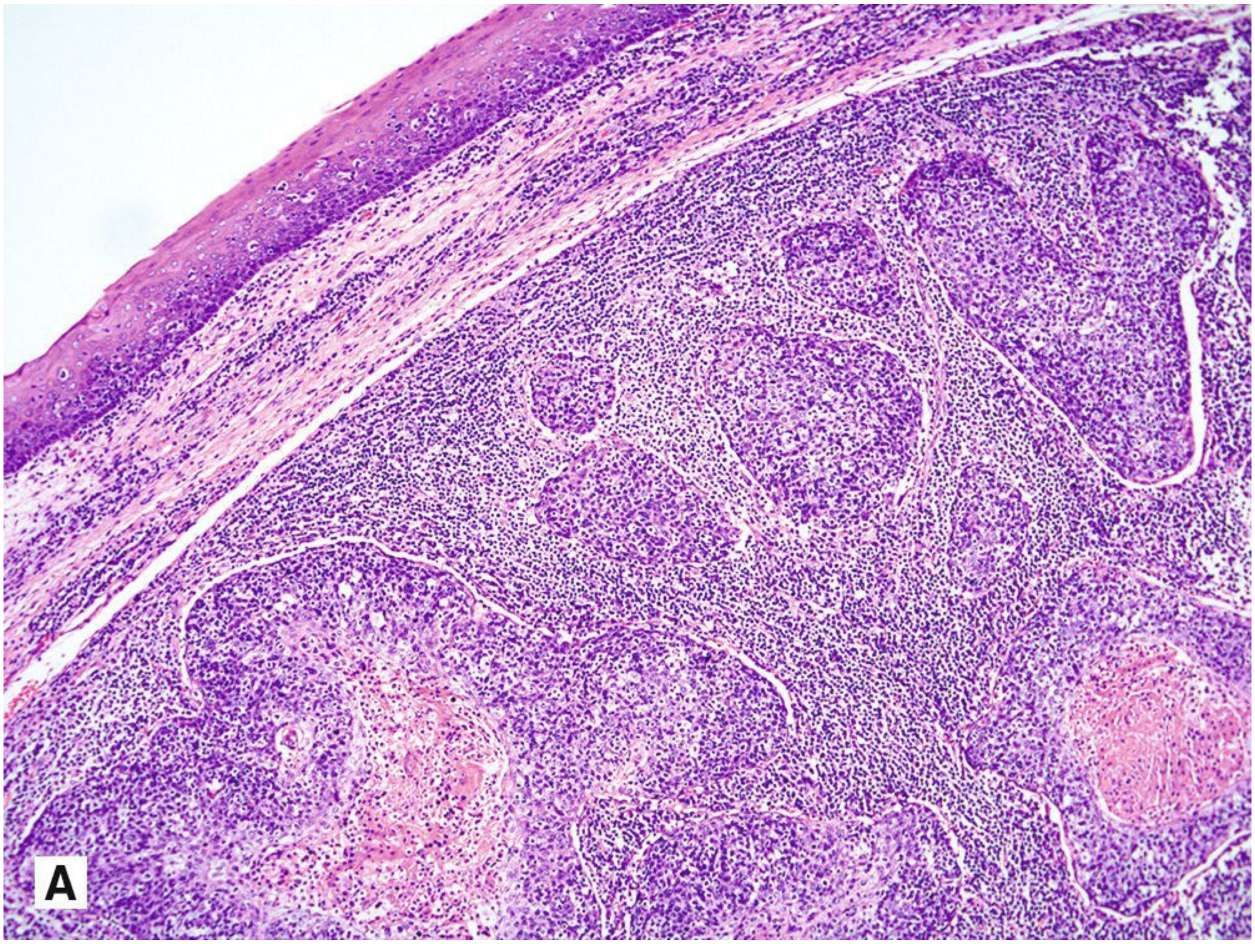
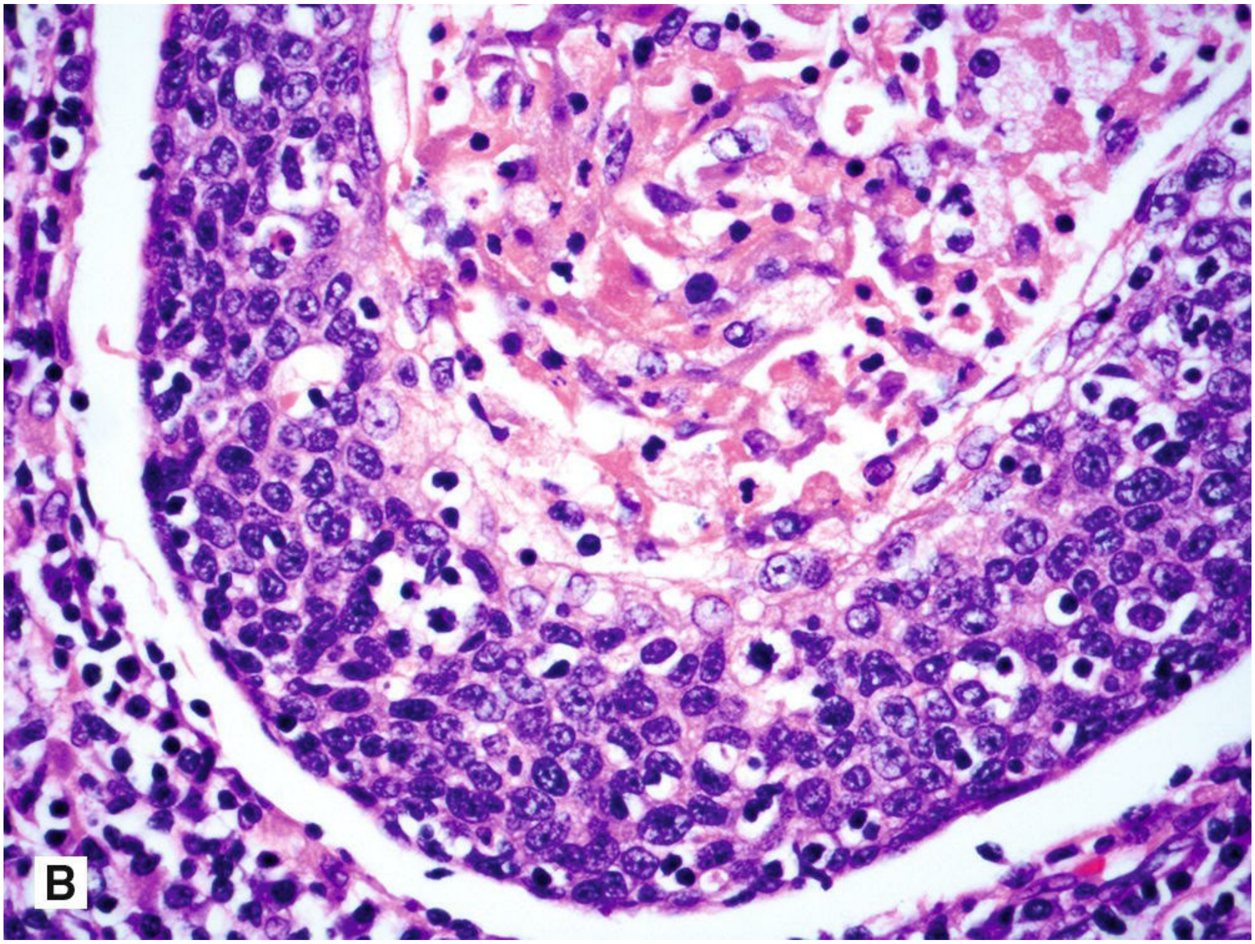
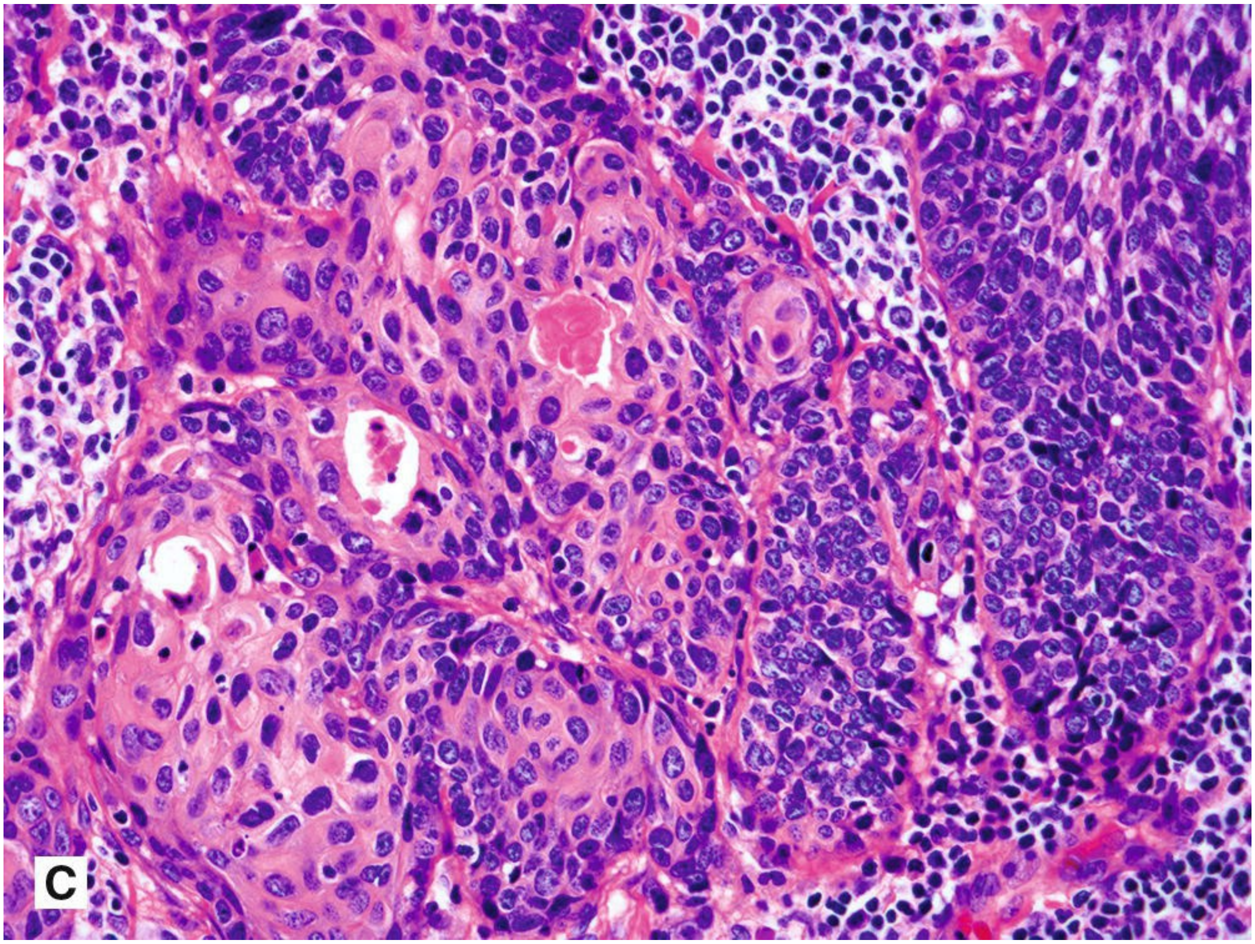
Nonkeratinizing and hybrid (focally keratinizing) squamous cell carcinomas are characterized by the complete/near absence of keratinization or by the admixture of nonkeratinizing and keratinizing cells, respectively. These tumors arise nearly exclusively in the oropharynx in association with tonsillar crypt epithelium and are most often associated with infection by high-risk human papillomavirus (HPV) genotypes, mainly HPV16, 33, 35 or 18 (Fig. 3.2).[121,122] As keratinizing squamous cell carcinomas have shown declining incidence in the past decade with decreased smoking prevalence, the proportion of HPV-associated carcinomas has increased.[123–125] These tumors possess a distinctive pathophysiology, with early lymph node metastasis, but superior outcomes compared to conventional squamous cell carcinoma, even in advanced disease.[113,126,127] Five-year relative survival rates are estimated

to be ~75% compared to 24% to 40% for non–HPV-associated oropharyngeal cancers.[128]





B



C

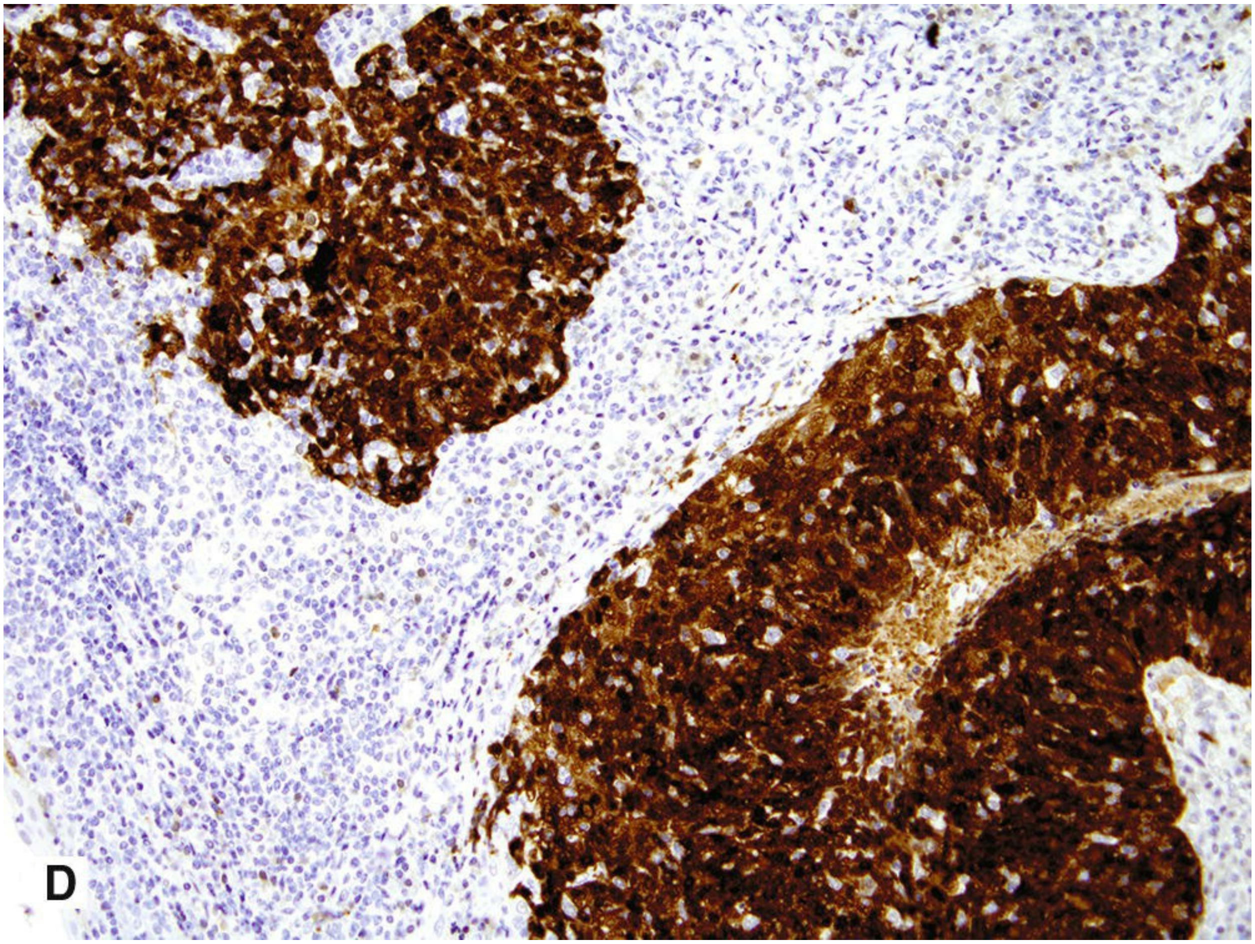


Figure 3.2 Oropharyngeal HPV-associated carcinoma. **A:** Low magnification of a submucosal infiltrative solid and cystic neoplasm. **A:** At higher magnification, the lesional cells are devoid of keratinization (i.e., nonkeratinizing). **C:** Hybrid carcinoma showing an admixture of nonkeratinizing and keratinizing malignant cells. **D:** Diffuse and strong p16 immunoreactivity (nuclear and cytoplasmic) represents a surrogate marker for HPV16 confirms the neoplasm as HPV associated; reflex in situ hybridization and PCR analysis identified the presence of high-risk HPV (not shown).

Nonkeratinizing squamous cell carcinoma often presents with neck metastasis and clinically occult primary lesion. Deep biopsy of lingual and pharyngeal tonsils or tonsillectomy may be required to locate the primary tumor, as microscopic tumors often arise deep within tonsillar crypts and are not detectable by superficial biopsy.[129] Nonkeratinizing tumors are variously described as having “immature,” “transitional,” “basaloid,” or “poorly

differentiated" histologic features, although they are now thought to represent relatively well-differentiated tumors recapitulating the phenotype of tonsillar crypt epithelium. Tumors characteristically express strong and diffuse nuclear and cytoplasmic p16 protein as a side effect of oncogenic viral protein inhibition of RB-mediated cell cycle arrest.[130] The presence of p16 immunoreactivity in a cervical nodal metastasis without a known primary cancer is strongly correlated to an oropharyngeal primary cancer.

Basaloid squamous cell carcinoma was initially described as a highly aggressive subset of squamous cell carcinoma that occurred in older males with a peak incidence from 60 to 80 years and showed malignant differentiation toward a phenotype similar to that of basal cells.[131] Basaloid squamous cell carcinoma may arise in a variety of mucosal sites in the upper aerodigestive tract including the larynx, hypopharynx, oropharynx, and sinonasal tract. Irrespective of site of origin, the histologic findings are similar, and tumors are characterized by multilobular, nested growth pattern with frequent comedonecrosis, foci of abrupt keratinization, and stromal hyalinization (Fig. 3.3). The overlying mucosa shows only limited foci of intraepithelial dysplasia. Unfortunately, nonkeratinizing, HPV-associated carcinomas have a similar-appearing cellular differentiation, and the term basaloid squamous cell carcinoma has been subverted by many authors to include both the highly aggressive "true" HPV-negative basaloid squamous cell carcinomas and the less aggressive nonkeratinizing HPV-associated variant.[132,133] Communication between pathologist and treating clinician is essential to ensure that the appropriate prognostic information is conveyed. When in doubt, HPV testing is essential.[132,133]

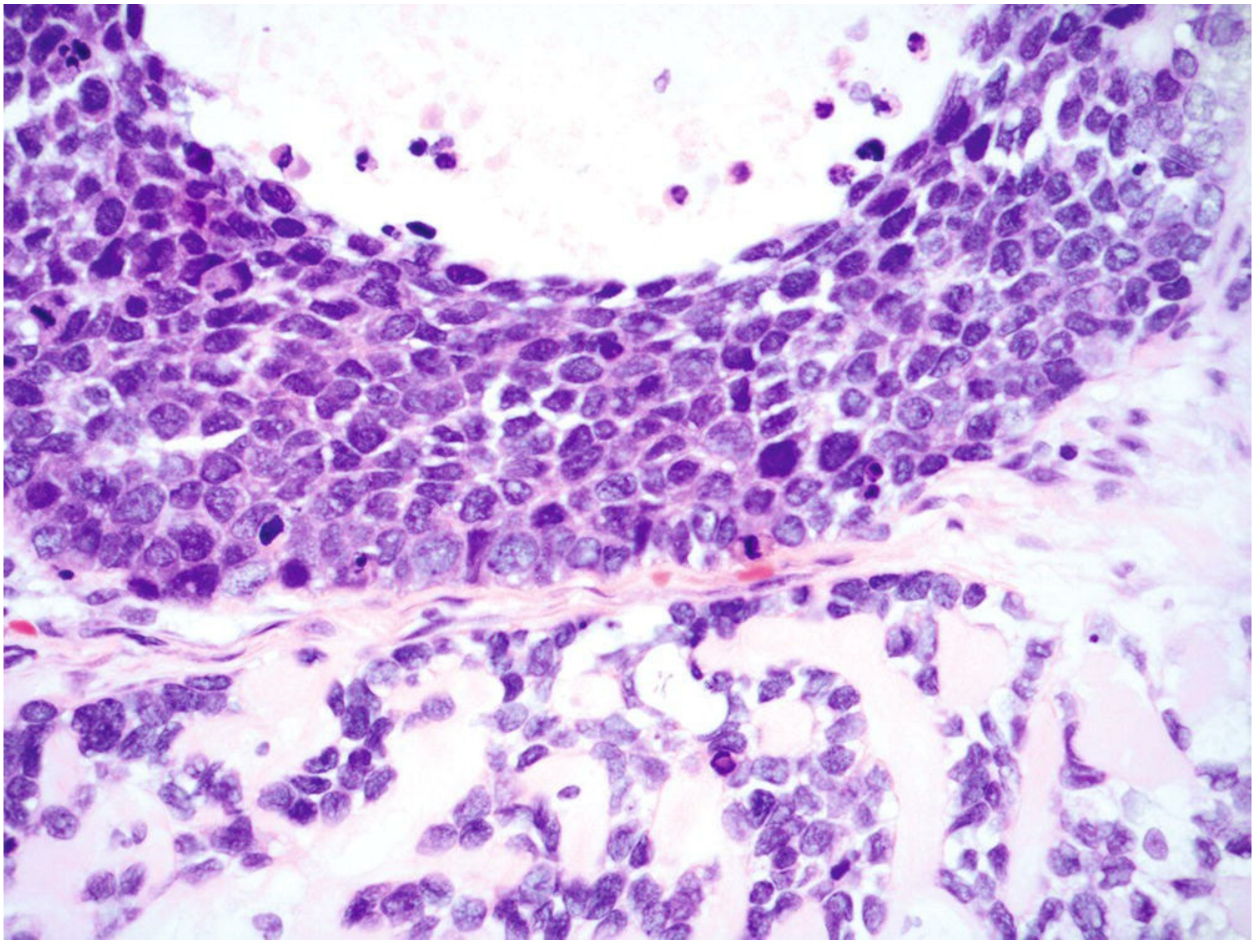

Figure 3.3 Basaloid squamous cell carcinoma composed of cells with hyperchromatic nuclei (basaloid cells), nuclear pleomorphism, and increased mitotic activity. The tumor nests include comedo-type necrosis **(top)** and associated stromal hyalinization **(bottom)** resembling the reduplicated basement membrane seen in salivary gland neoplasms. In areas not shown, there was evidence of squamous differentiation. This tumor was HPV negative.

Verrucous squamous cell carcinoma is a locally aggressive variant most commonly arising in the oral cavity of older patients and characterized by a markedly hyperplastic, filiform, warty architecture, and a broad, pushing invasive growth pattern (Fig. 3.4).[134,135] These tumors may be extremely difficult to diagnose on biopsy, as the large cell size and abundant keratinizing cytoplasm often make nuclear enlargement difficult to appreciate. Moreover, invasion is difficult to assess in the absence of infiltration. Proper diagnosis therefore relies on an adequate biopsy specimen.

Biopsy is best taken from the edge of the lesion to show the interface between tumor and normal mucosa and should be deep enough to reach underlying submucosa. Pure verrucous carcinomas do not exhibit any infiltrative growth and do not metastasize. The presence of infiltrative nests, "hybrid verrucous carcinoma," is associated with behavior akin to conventional squamous cell carcinomas. Verrucous carcinomas are associated with chronic inflammation and usage of smokeless tobacco.[136] Tumors may cause extensive local morbidity if left untreated, but in general, prognosis is good, with 5-year survival rates reported from 80% to 95%.[118,136]

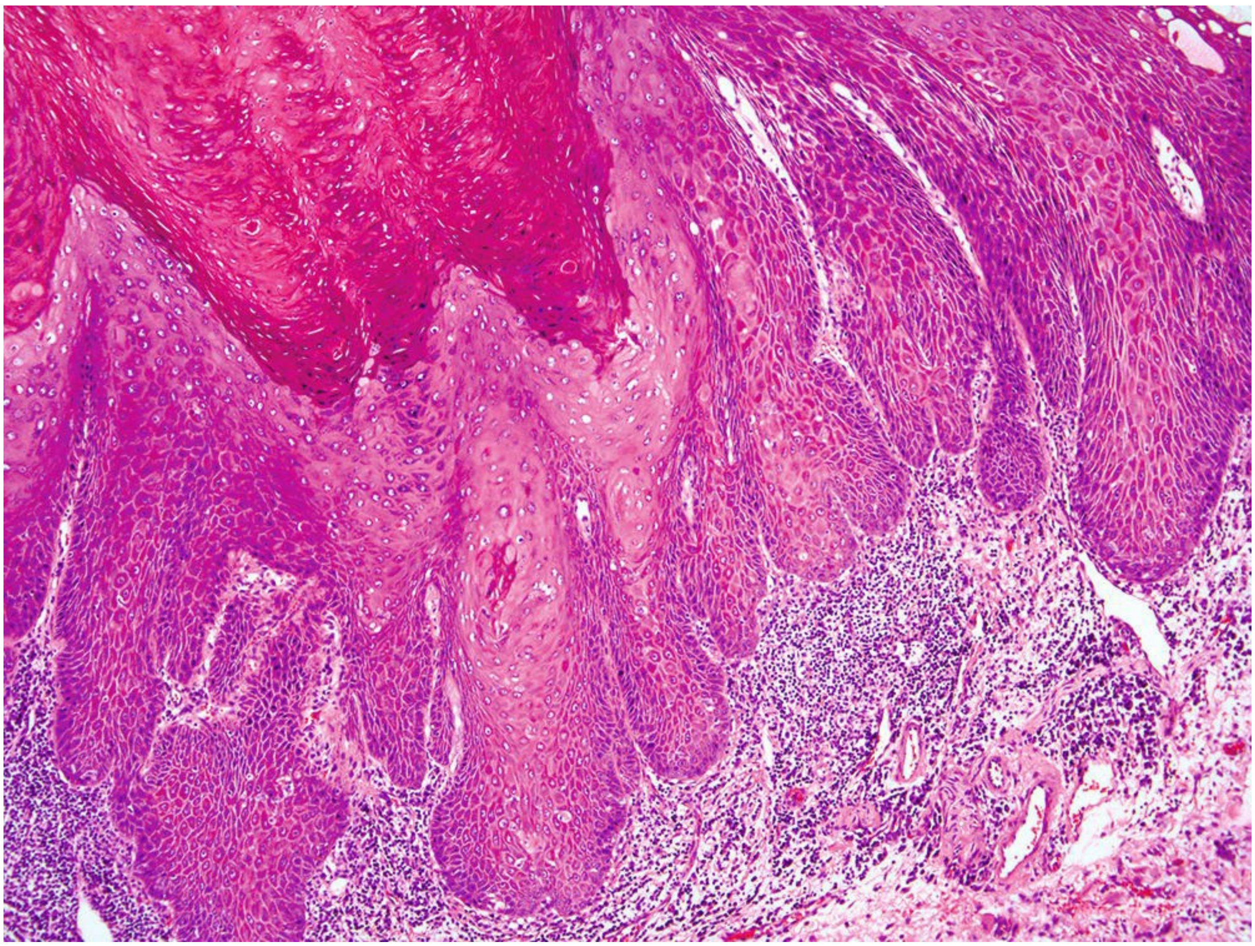

Figure 3.4 Verrucous carcinoma characterized by (tiered) keratosis of the surface and a bland epithelial proliferation with downward extending rete ridges (so-called pushing margin) and absence of epithelial dysplasia.

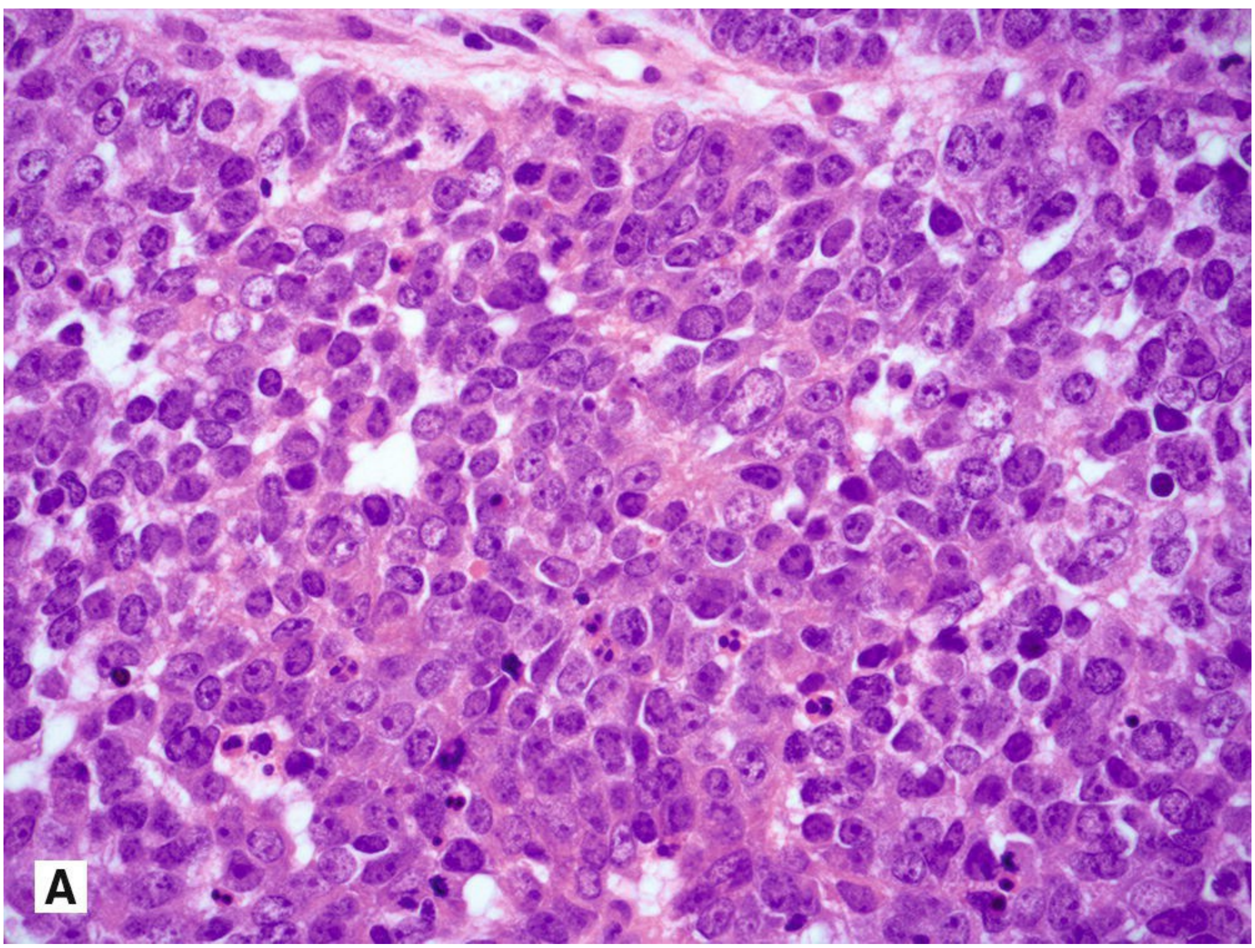
Sinonasal Undifferentiated Carcinoma.

Sinonasal undifferentiated carcinoma (SNUC) is a rare, aggressive

malignancy characterized by rapid local spread. Tumors are composed of nests, sheets, and trabeculae of malignant, poorly differentiated cells with scant cytoplasm, large nuclei, and, typically, prominent nucleoli (Fig. 3.5). Mitotic rate is high, and necrosis is frequently abundant. Malignant cells may express simple keratins and rarely neuroendocrine markers.[137] The etiology of SNUC is unclear; tumors are negative for Epstein-Barr virus (EBV) and HPV. Because of their rapid onset and extensive local involvement at presentation, SNUC have poor prognosis. The major differential diagnoses for SNUC include (in no particular order) rhabdomyosarcoma, olfactory neuroblastoma, nasopharyngeal undifferentiated carcinoma, small cell neuroendocrine carcinoma, poorly differentiated squamous cell carcinoma, and NUT midline carcinoma among others (Table 3.4). When the diagnosis is in question, correlation with the clinical and radiographic features is critical to making the correct diagnosis. Successful treatment is dependent on radical resection in conjunction with adjunct chemoradiation.[137]



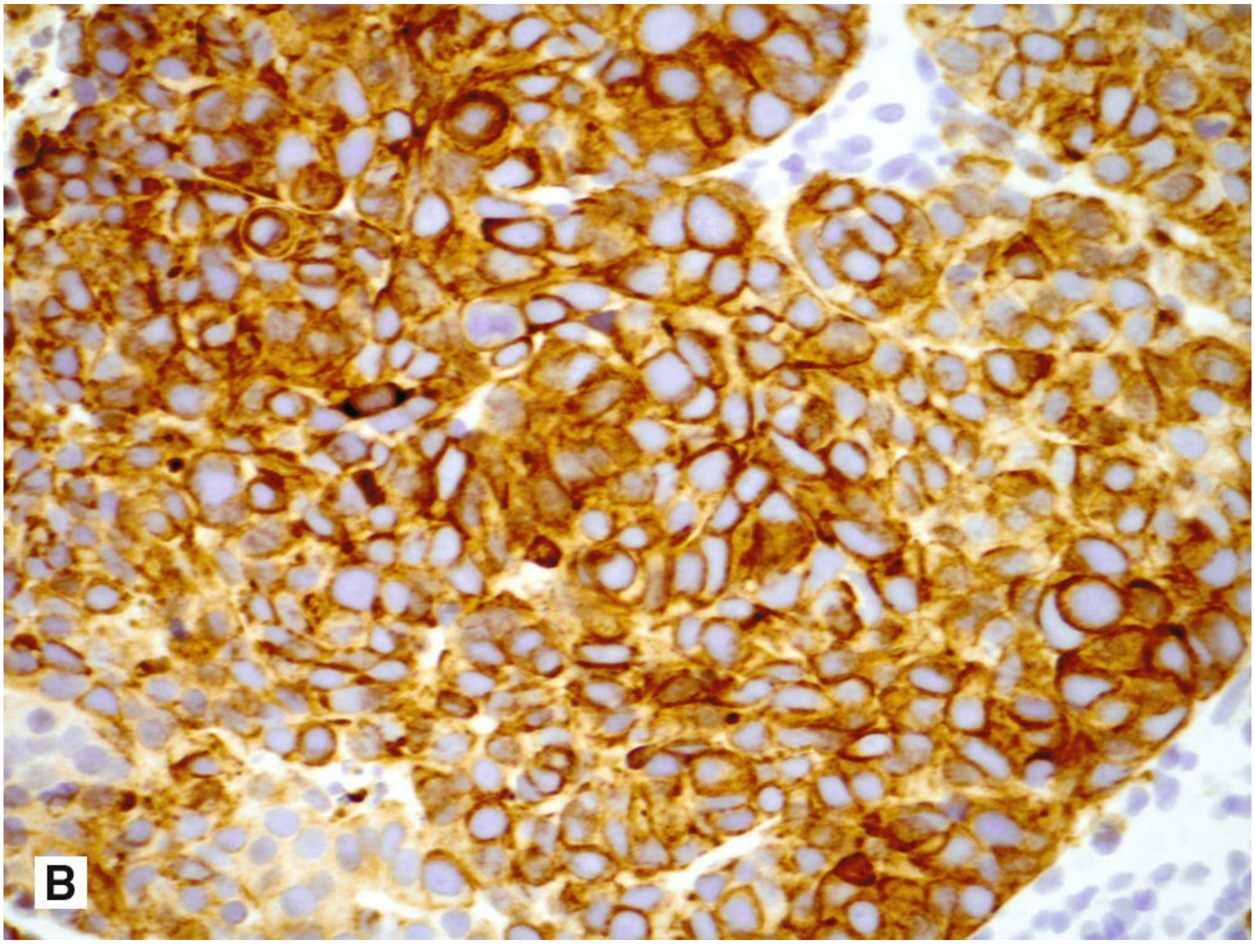


Figure 3.5 Sinonasal undifferentiated carcinoma (SNUC). **A:** Sinonasal high-grade malignant neoplasm characterized by cells with large nuclei, prominent nucleoli, scant cytoplasm, and increased mitotic activity lacking evidence of cellular differentiation. **B:** Cytokeratin (CAM5.2) immunoreactivity confirms the neoplasm as being of epithelial cell origin and in the absence of immunoreactivity indicative of any other tumor type as well as absence of EBV, the clinical findings, and location of the tumor coupled with the light microscopic findings would be diagnostic for SNUC.

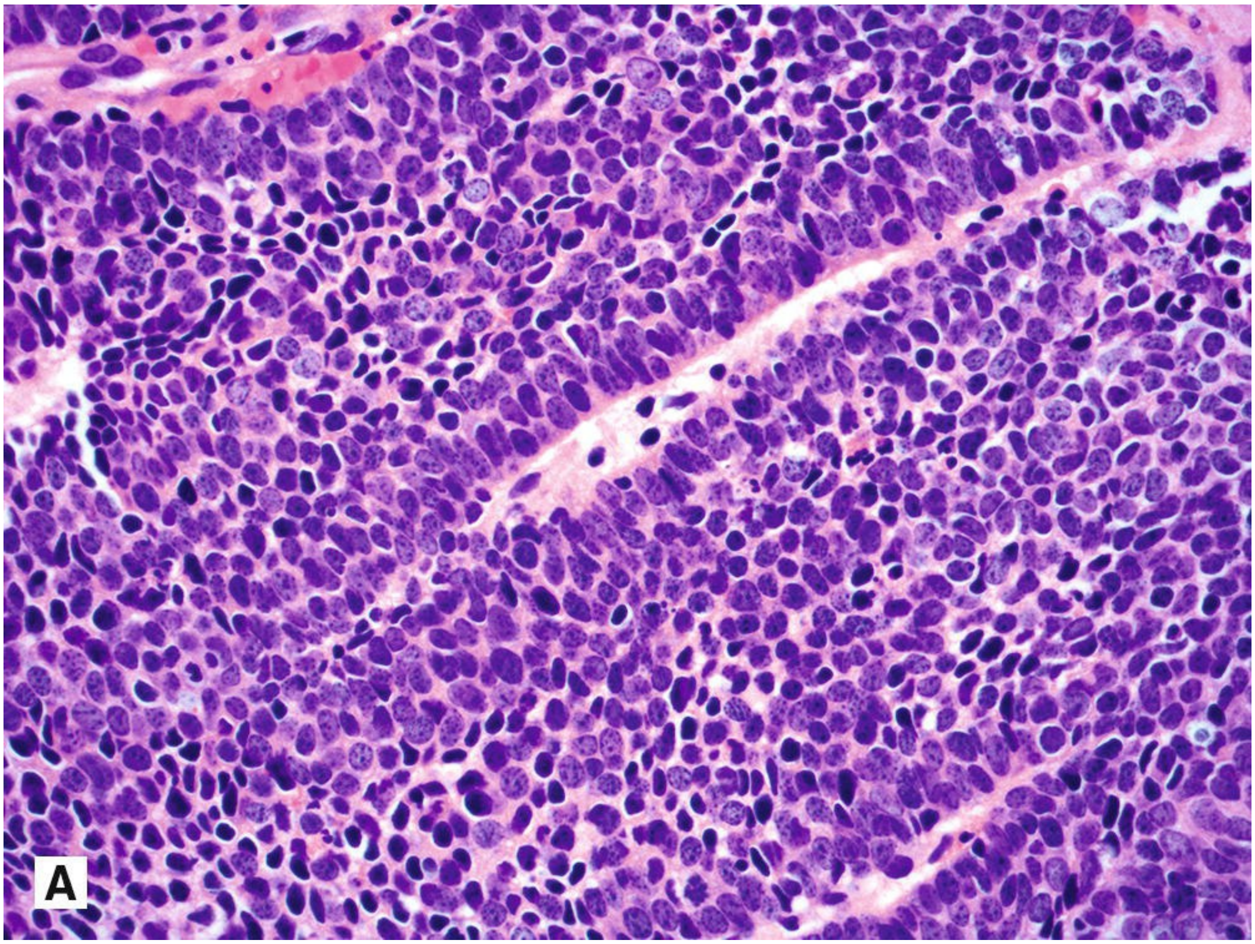
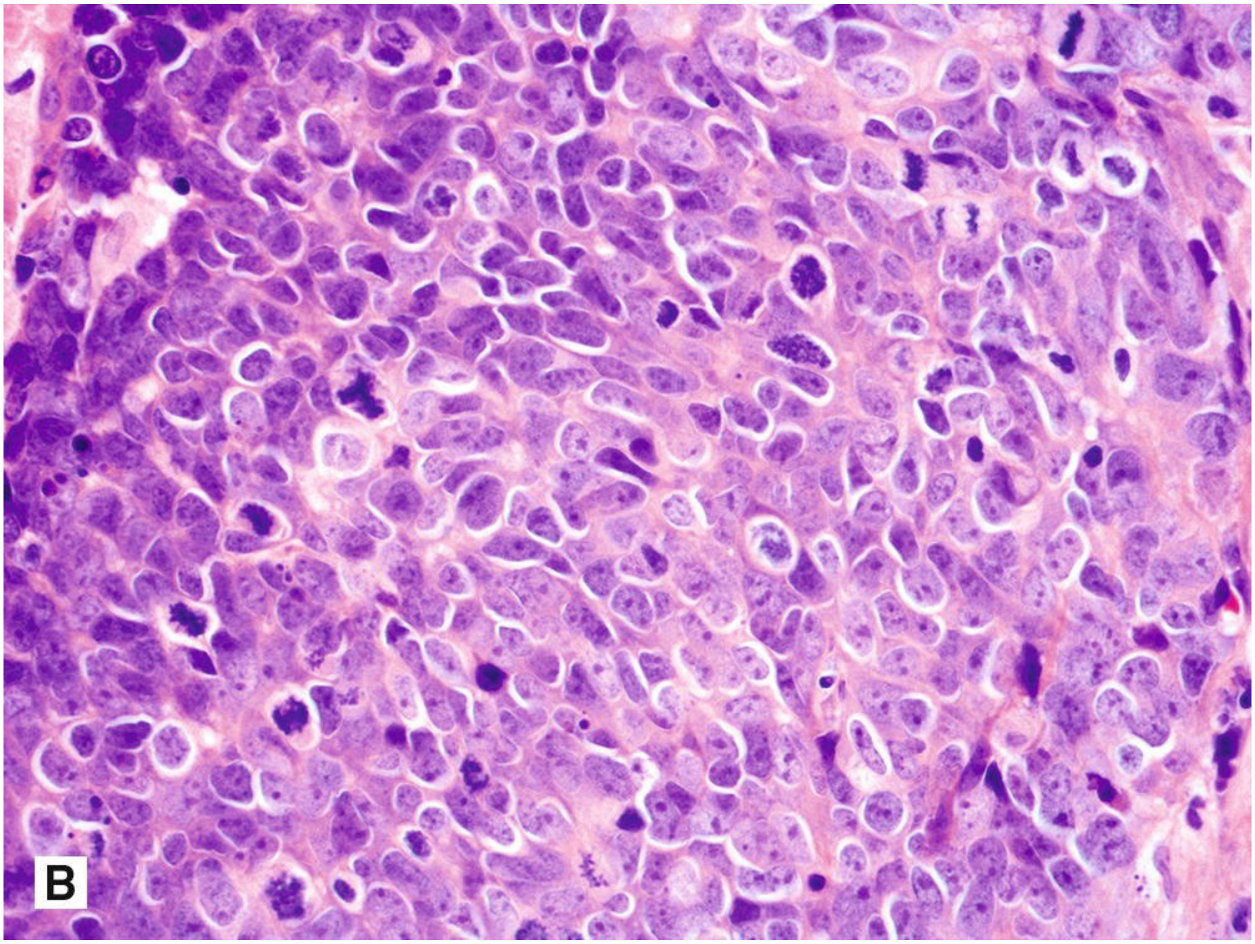
Lymphomas (i.e., NK/T cell lymphoma, nasal type)

Nasopharyngeal Carcinoma.

Nasopharyngeal carcinoma (NPC) represents a phenotypic spectrum of squamous cell carcinoma types, including keratinizing, nonkeratinizing, and basaloid morphologies. The nonkeratinizing type is most common and accounts for 75% of all cases of NPC. Nonkeratinizing NPC typically occurs in adults, with peak incidence between 40 and 60 years, and is two to three times more common in men than women. Tumors tend to have extensive local spread, early lymph node metastases, and the propensity for hematogenous metastases.[138] Nonkeratinizing NPC is subdivided into two morphologic types including differentiated (15% of all NPC) and undifferentiated (60% of all NPC). The differentiated subtype of nonkeratinizing NPC (formerly referred to as lymphoepithelioma) is characterized by the presence of stratification of malignant cells with well-defined borders (Fig. 3.6), whereas the undifferentiated subtype of NPC (NPUC) shows a syncytial growth pattern with crowding of cells and large,

vesicular nuclei with prominent nucleoli (Fig. 3.6). In some cases, the malignant cells may be spindle shaped. Clinically, there is no relevance to the distinction between differentiated and undifferentiated NPC. Both types are characterized by an associated nonneoplastic (benign) lymphoid proliferation that may overrun and obscure the malignant cells, resulting in the so-called lymphoepithelial morphology with tumor cells arrayed in plexiform nests interrupted by aggregates of nonneoplastic lymphocytes.





B

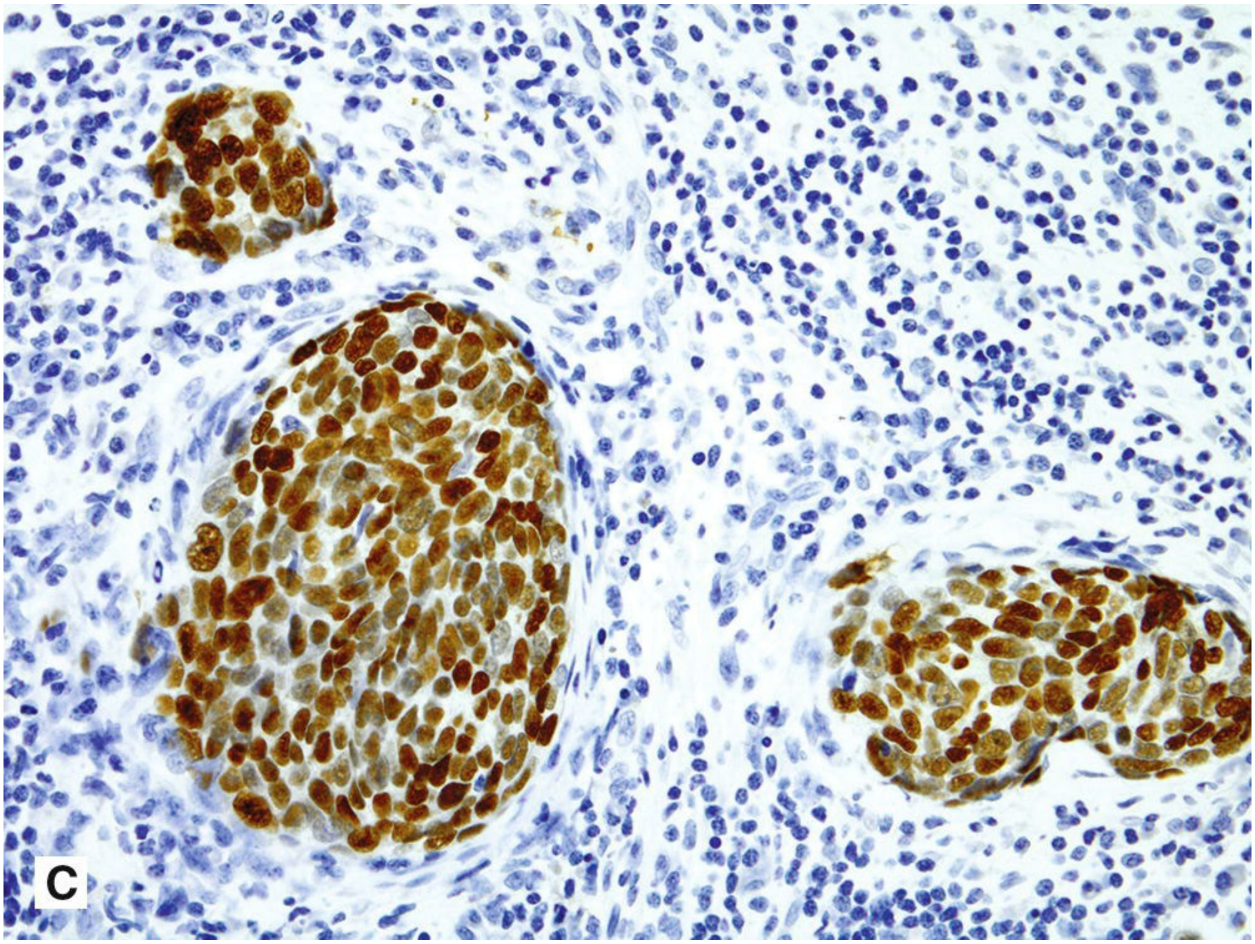


Figure 3.6 Nasopharyngeal carcinoma, nonkeratinizing types. **A:** Differentiated type characterized by cohesive cords, stratification of malignant cells with well-defined borders. **B:** Undifferentiated type shows syncytial growth pattern with crowded cells and large vesicular nuclei with prominent nucleoli. **C:** In situ hybridization for Epstein-Barr–encoded RNA (EBER) is diffusely positive (nuclear staining). Both subtypes of nasopharyngeal carcinoma, nonkeratinizing types, are associated with EBV.

Nonkeratinizing NPCs are frequently associated with Epstein-Barr virus (EBV), and the presence of diffuse (nuclear) positivity for Epstein-Barr encoded RNA (EBER) by in situ hybridization (ISH) is diagnostic (Fig. 3.6).[138] NPC is more common in regions where EBV is endemic (e.g., China) and is rare in the United States.[138] It is critical to make the distinction between nasopharyngeal nonkeratinizing carcinoma (associated with EBV) and oropharyngeal nonkeratinizing carcinoma (associated with HPV) as the behavior and prognosis are different, although both result from viral

infections. Another potential diagnostic dilemma given overlapping histologic features and presence of cytokeratin immunoreactivity includes differentiating NPC from SNUC. The presence or absence of EBV will allow the distinction between these tumors with NPC associated with EBV and SNUC negative for EBV. Keratinizing and basaloid NPC behave similarly to their counterparts arising elsewhere in the upper aerodigestive tract.

Of note, the use of the designation viral-associated carcinoma for NPC (EBV-associated) and oropharyngeal carcinoma (HPV-associated) may be adopted in future classifications of head and neck neoplasm.

NUT Midline Carcinoma.

NUT midline carcinoma is a rare, aggressive malignancy defined by chromosomal rearrangements, most commonly between 15q14 and 19p13.1, resulting in fusion of the *NUT* gene locus to *BRDU4* or *BRDU3*, among other partners, and subsequent overexpression of NUT protein.[139,140] Although NUT midline carcinoma may arise anywhere in the body, the majority of reported cases arise in the upper respiratory tract and mediastinum.[139] Histologically, NUT midline carcinomas appear poorly differentiated and may or may not exhibit evidence of squamous differentiation in the form of abrupt keratinization. The presence of immunoreactivity for NUT protein marker (nuclear staining) confirms the diagnosis. In the sinonasal tract, NUT carcinomas are thought to be frequently misdiagnosed as squamous cell carcinoma or SNUC. The distinction is important because NUT midline carcinomas may present at any age and have an average survival of less than a year.[139]

Carcinoma of the Salivary Glands.

Salivary gland carcinomas are rare, with reported incidence annual rates in the United States of only 1.3/100,000 individuals. The parotid gland is the most common site and accounts for up to 80% of cases, followed by the minor salivary glands, submandibular gland, and sublingual gland. Most malignant tumors arise in the superficial lobe of the parotid gland. The likelihood of a salivary gland tumor to be malignant also varies by site. Carcinoma is identified in <30% of parotid tumors, 40% of submandibular gland tumors, 50% of minor salivary gland tumors, and up to 90% of sublingual masses.[141]

Diagnosis of salivary gland neoplasia is made more complex by the number of described types of carcinoma, with over 20 malignant salivary gland carcinomas recognized (Table 3.5). The most common primary salivary gland malignancies, each accounting for 10% to 25% of cases, are mucoepidermoid carcinoma and adenoid cystic carcinoma (Figs. 3.7 and 3.8), with specific incidence rates showing geographic variation.[142,143] Precise histologic diagnosis of salivary gland tumors can be difficult, as many tumors are composed of a mixture of cell types or may show a spectrum of morphologic phenotypes. As a result, adenocarcinoma not otherwise specified (NOS) accounts for ~10% of cases.[142]

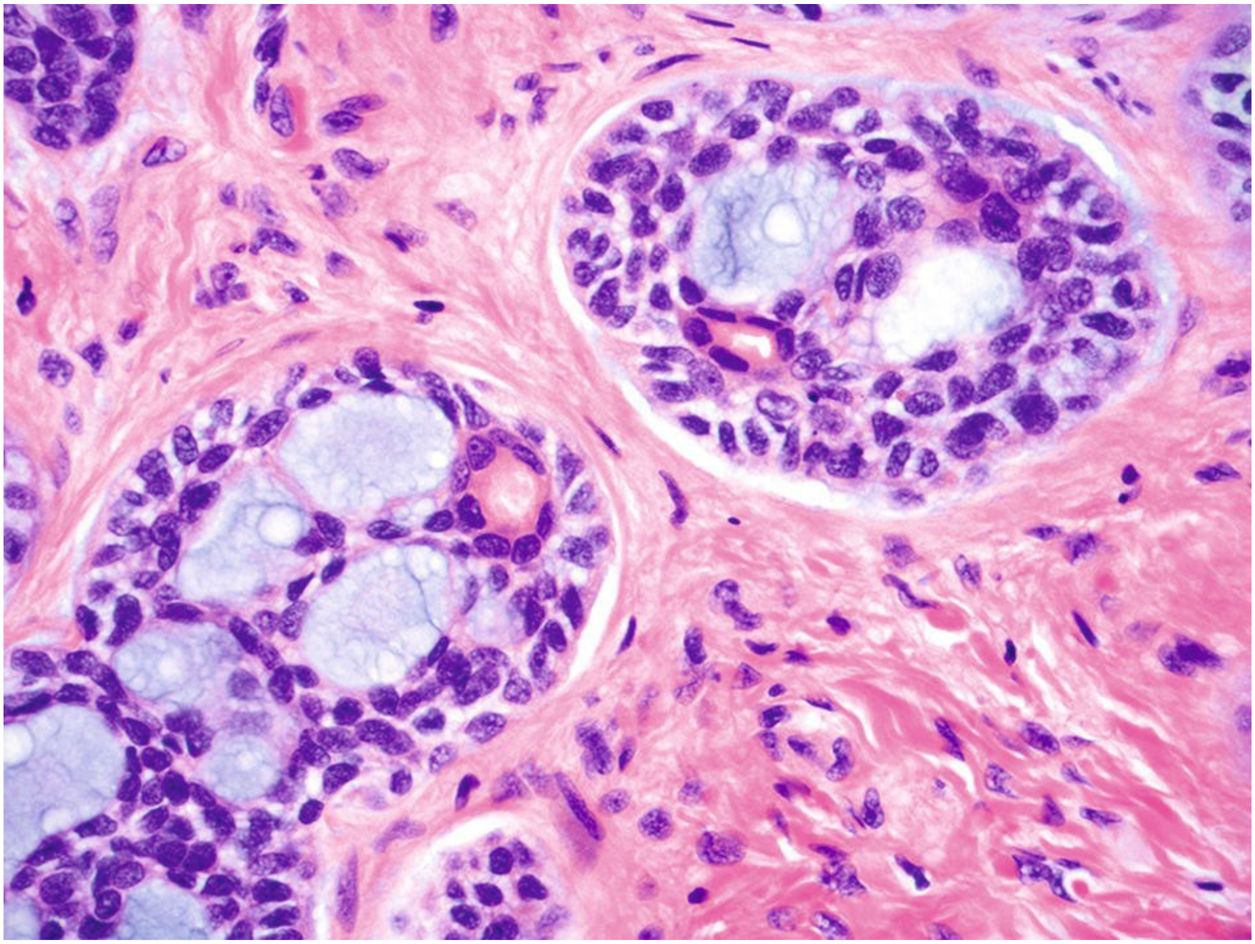

Figure 3.8 Adenoid cystic carcinoma with classic histology including the cribriform growth pattern ("Swiss cheese") predominantly composed of abluminal (myoepithelial) cells surrounding cystic spaces and less conspicuous but identifiable true glands surrounded by luminal (epithelial) cells.

The in-depth description of the many types of salivary gland carcinoma is beyond the scope of this chapter. However, recent studies have elucidated characteristic genomic alterations associated with several variants, which may enable improved diagnosis in future (Table 3.6).[144]–[159] Moreover, our improved ability to accurately segregate tumors by molecular alterations will enable more accurate prognostication.

Table 3.6 Chromosomal Rearrangements in Salivary Gland Neoplasia

	Chromosomal Rearrangement	Gene Fusion	Prevalence
Adenoid cystic carcinoma	t(6;9)(q22-23;p23-24)	*NFIB-MYB*	30%–50%

Thyroid and Parathyroid Carcinomas.

Thyroid carcinoma is the most common endocrine malignancy. Tumors arise from either the follicular epithelium (papillary, follicular, poorly differentiated, and anaplastic thyroid carcinomas) or parafollicular C-cells of neuroectodermal origin (medullary thyroid carcinoma [MTC]) and have been shown to demonstrate specific genetic mutations (Table 3.7).

Table 3.7 Common Genetic Alterations in Thyroid Neoplasia

Tumor Type	Affected Genes	Prevalence
Follicular adenoma	*RAS*	10%
Noninvasive follicular thyroid	*RAS*	30%
Neoplasm with papillary- like nuclear features (NIFTP)	*BRAF* *PAX8/PPARγ*	<5% 20%
Follicular carcinoma	*RAS* *BRAF* *PAX8/PPARγ* translocation	45% <10% 35%–45%
Papillary carcinoma	*TRK*	<5%
Follicular variant	*RAS* *BRAF* *PAX8/PPARγ* translocation *RET/PTC* translocation	40% 10% 10% 3%
Classical variant	*RAS* *BRAF* *RET/PTC* translocation	1% 70% 10%
Poorly differentiated carcinoma	*RAS* *BRAF*	20% 20%
Anaplastic carcinoma	*RAS* *BRAF*	45% 25%
Medullary carcinoma		
Sporadic	*RET*	50%
Familial	*RET,* germ-line mutation	>95%

PTC is by far the most common variant of thyroid carcinoma, accounting for ~86% of thyroid carcinomas, with a rising incidence over the past few decades.[160,161] Controversy exists as to the cause of this dramatic increase.[160] Whereas some authors cite the improved ability to detect disease, and more frequent discovery of incidental thyroid nodules on imaging studies undertaken for other reasons.[161,162] It is now thought that the reported increase in carcinoma is due to overdiagnosis of indolent disease.[163,164] In particular, the non-invasive, encapsulated follicular variant of papillary thyroid carcinoma has been determined to have low risk of aggressive behavior and has been recently renamed as non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP).[165] In addition, it is suspected that many incidentally discovered "microcarcinomas" found on resection for benign solitary nodule or multinodular goiter represent at best, premalignant change and, based on their benign behavior in recent series, should not truly be considered to be a true malignant disease.[166,167]

Classical papillary carcinomas are diagnosed based on their nuclear features on FFPE sections. These features include enlarged, pale to optically clear nuclei with peripherally located, small nucleoli and the presence of nuclear membrane irregularities typically visualized as longitudinal grooves and pseudoinclusions (Fig. 3.9). Clearing of the nuclei is an artifact of formalin fixation and is not seen in frozen sections, cytology preparations, or tumors fixed in other media.[101,168] Tumor cells often have abundant cytoplasm. The architecture of papillary tumors may be papillary or follicular; colloid is often scant. Intratumoral fibrosis and calcification is common. At the molecular level, classical PTC is characterized by a high frequency of mutations in the mitogen-activated protein kinase (MAPK) pathway, with activating *BRAF* mutations (most commonly n.T1796A (p.V600E)) accounting for nearly 70% of cases,[169–172] whereas *RET/PTC* gene rearrangements each account for 10% to 20% and *TRK* rearrangements for ~5%.[173] *RAS* mutations are rare in classical papillary carcinoma (Table 3.7).[172,174–179] Papillary carcinomas invade lymphatics early and spread to lymph nodes of the neck. Despite early nodal metastasis, papillary carcinomas have a relatively good prognosis. Survival is predicted by age and tumor size; younger patients have excellent long-term survival rates, whereas older patients and those with large primaries progress more rapidly.[180,181]

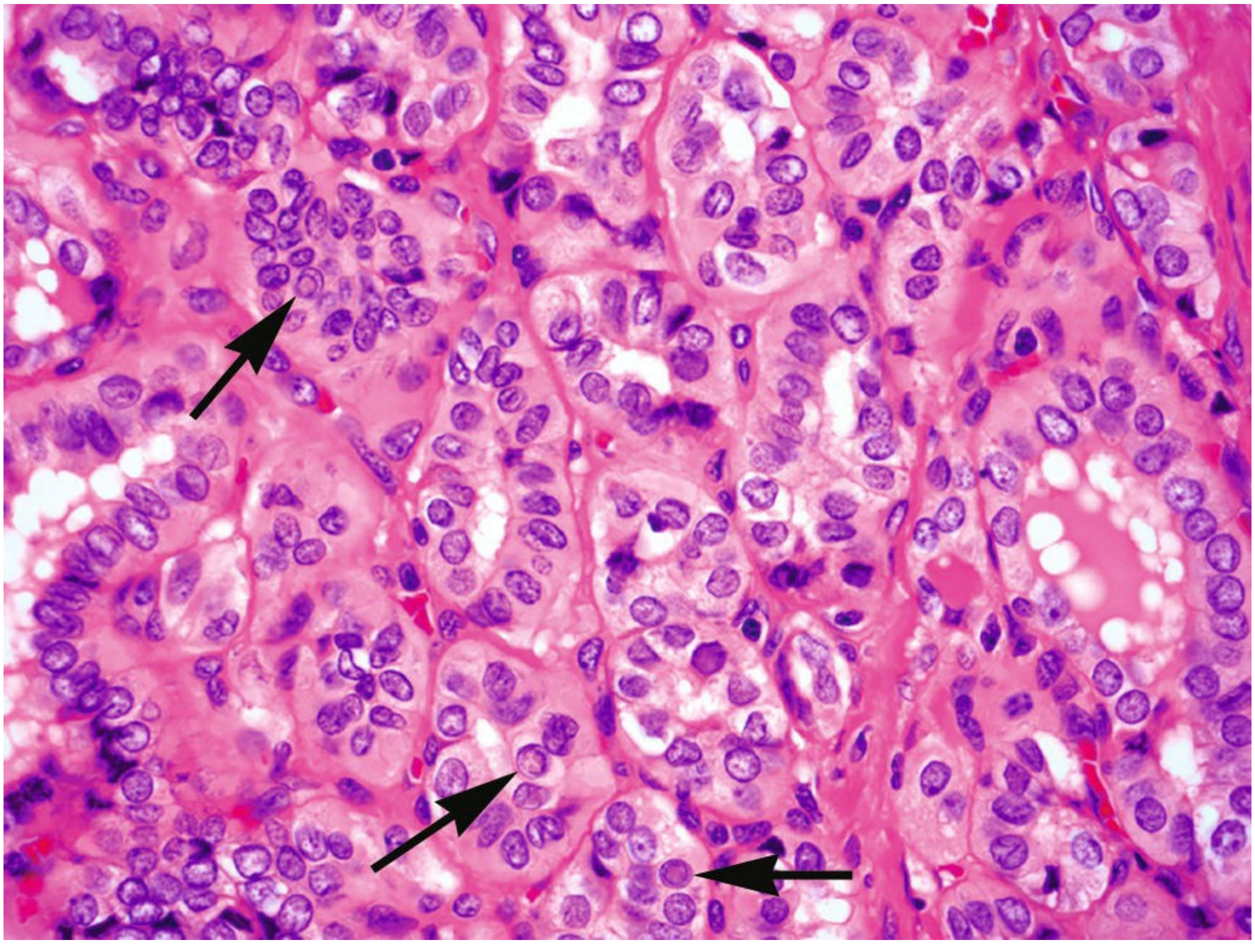

Figure 3.9 Papillary thyroid carcinoma. The diagnosis is predicated on the nuclear alterations including enlarged nuclei with variation in size and shape, very fine-appearing nuclear chromatin, overlapping, and crowding of nuclei, nuclear grooves, and nuclear (pseudo)inclusions (*arrows*).

Several variants of papillary thyroid carcinoma exist, the most controversial of which is the follicular variant papillary thyroid carcinoma (FVPTC). FVPTCs are distinguished by a lack of papillary architecture and subtle nuclear features of papillary carcinoma. The main differential diagnosis for invasive FVPTC is follicular carcinoma. Up until recently, encapsulated FVPTC without evidence of vascular or capsular invasion were also considered to be malignant despite low intraobserver agreement on the diagnosis.[182,183] However, increased recognition of the non-aggressive behavior of these tumors, and histologic and molecular similarity to follicular adenoma and carcinoma[175,184–186] has led to a new nomenclature of NIFTP. The new terminology was selected to reduce overdiagnosis of carcinoma and

overtreatment of a tumor which poses little risk to the patient.[166,187]

Follicular thyroid carcinomas constitute about 10% of thyroid malignancies.[160] Tumors typically have a microfollicular growth pattern and bland nuclear features, and are distinguishable from adenomas only by the presence of invasion. All solitary encapsulated nodules of the thyroid must have the entire capsule submitted for histologic evaluation, as the presence of either tumor invasion through the capsule into normal thyroid gland parenchyma or angioinvasion is diagnostic of malignancy (Fig. 3.10). Because they have a predilection for angioinvasion, follicular carcinomas spread hematogenously, generally bypassing regional lymph nodes to metastasize directly to the bone or lungs.[188] Subsequently, follicular carcinoma has a worse prognosis than does papillary carcinoma.[188] Follicular carcinomas have higher frequency of *RAS* mutations than do classical papillary carcinomas, with ~50% of tumors having activating mutation in *RAS* present. Another 35% or so are characterized by *PAX8/PPARγ* gene fusion.[189] Of note, *RAS* mutations are also seen in follicular adenomas and NIFTP and are not considered diagnostic for malignancy.[174]

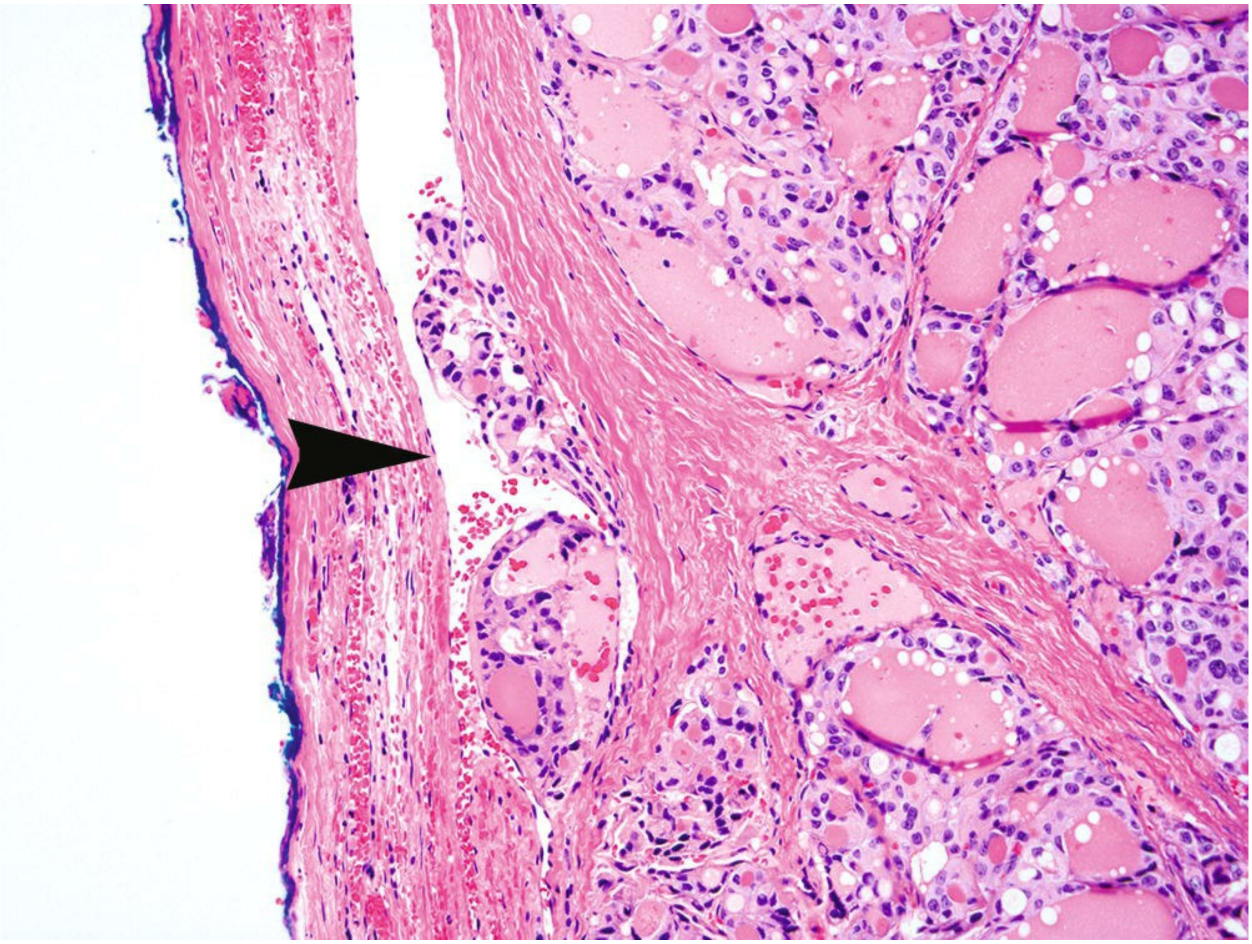

Figure 3.10 Follicular carcinoma. The tumor lacks nuclear features diagnostic for papillary carcinoma but shows an invasive growth pattern including invasion through the capsule and into an extracapsular endothelial-lined vascular space (*arrowhead*).

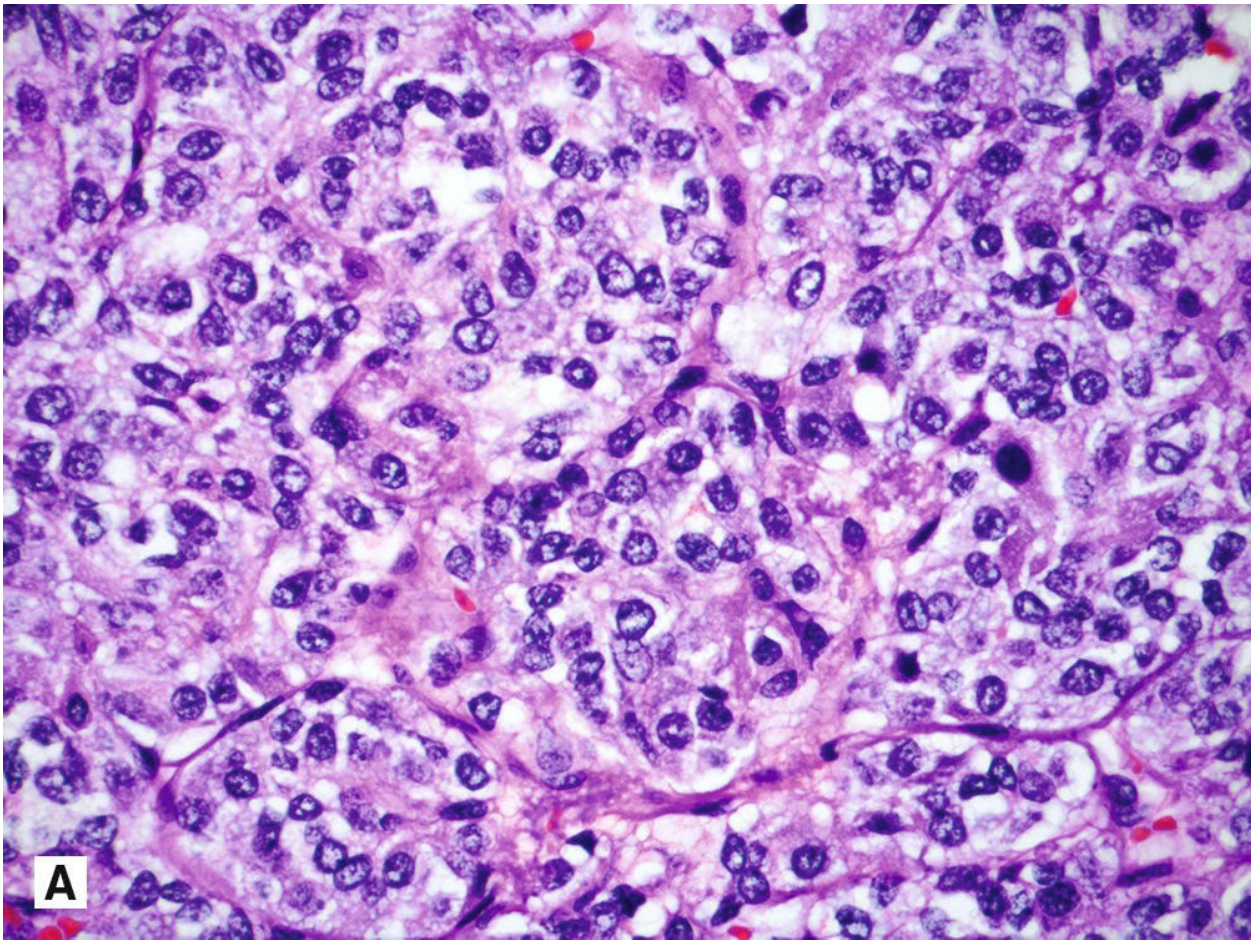
Anaplastic thyroid carcinoma is a rare, highly aggressive tumor, accounting for 1% of thyroid malignancies,[161] with a propensity to arise in elderly patients with long-standing thyroid disease. Anaplastic carcinoma presents as a rapidly growing mass in the neck, often with airway compromise, and by the time of presentation, is usually unresectable. One-year survival rates are as low as 35%,[190] and death is commonly due to local extension.[191] Histopathologic evidence of residual differentiated carcinoma suggests that anaplastic carcinomas arise in preexisting papillary or follicular carcinomas.[191] This theory is supported by molecular evidence of progressive genetic alterations as tumors advance from differentiated carcinoma to poorly differentiated carcinoma and anaplastic carcinoma.[176] Anaplastic carcinomas

display a variety of morphologies, from spindled, sarcomatoid cells, to large epithelioid cells, and some cases may show squamoid differentiation. One characteristic feature is a marked tumoral inflammatory response.

MTC constitutes about 2% of thyroid malignancies.[160] Whereas the majority of cases are sporadic, 20% to 40% are familial medullary thyroid carcinoma (FMTC).[192–194] Activating *RET* mutations are found in the majority of cases, with at least 39 different germ-line mutations described in familial cases (MEN 2A, MEN 2B, FMTC).[193,195,196] Familial tumors arise in younger patients (peaking in the fourth decade) and tend to be bilateral or associated with multifocal C-cell hyperplasia. Sporadic cases arise in the fifth to seventh decades and are usually solitary. Five-year survival rates approximate 85%.[196] Histologically, tumors have classical neuroendocrine appearance with abundant granular cytoplasm and round nuclei with “salt and pepper” stippled chromatin (Fig. 3.11A). Cells may be round, spindled, or plasmacytoid, whereas the stroma is frequently fibrotic and highly vascular. Calcitonin-derived amyloid deposition is a common feature (Fig. 3.11B).



A

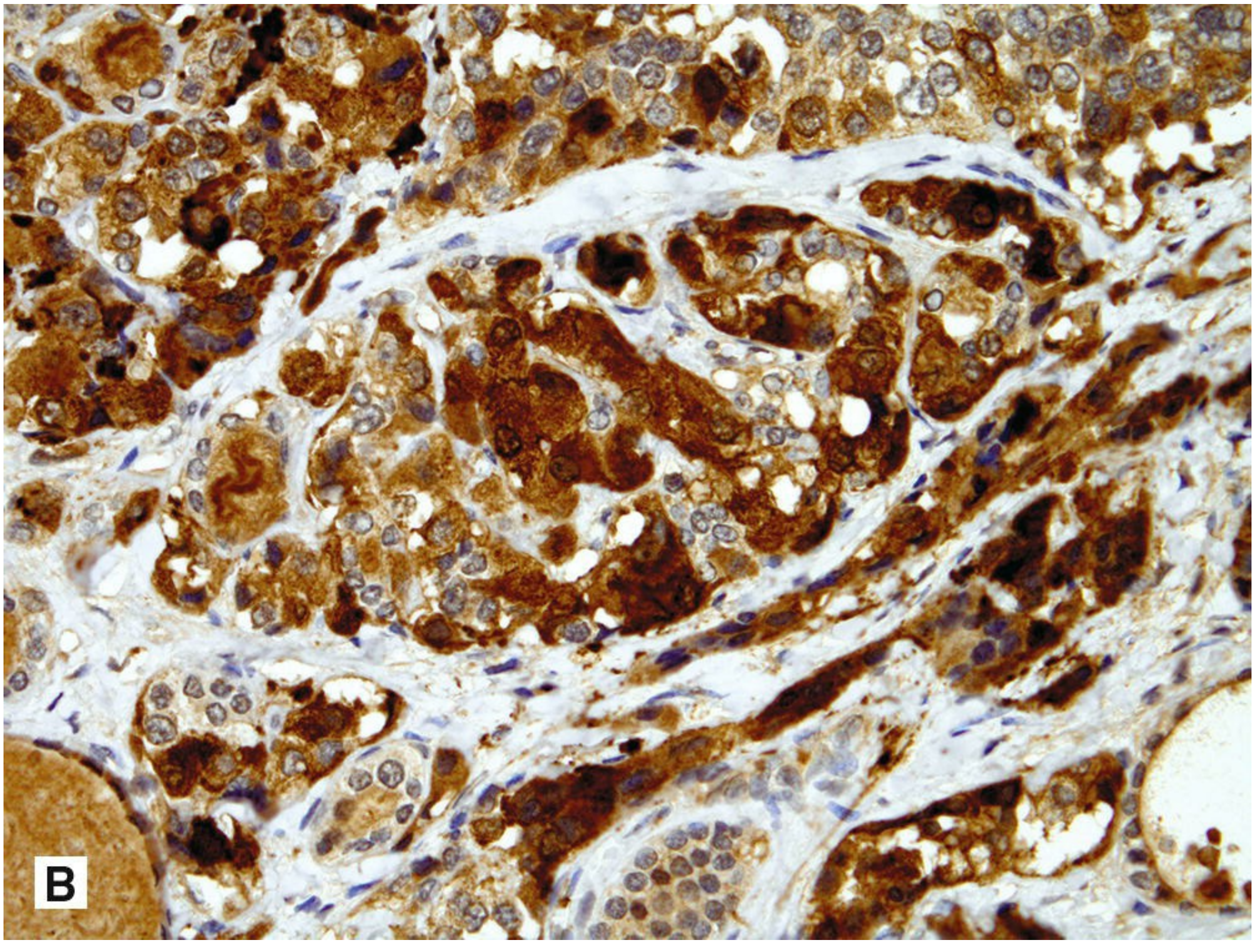


Figure 3.11 Medullary carcinoma of the thyroid. **A:** Intrathyroidal neoplasm characterized by organoid or cell nest growth pattern, absence of colloid formation, and presence of nuclei with stippled-appearing nuclear chromatin. **B:** Diffuse calcitonin immunoreactivity confirms the diagnosis; note the absence of calcitonin staining in residual thyroid follicular epithelial cells **(lower left)**.

Parathyroid carcinomas are very rare, accounting for <1% of parathyroid tumors.[197] Diagnosis requires close communication between the resecting surgeon and diagnosing pathologist. Parathyroid carcinomas produce very high elevations of parathyroid hormone to levels greater than typically seen in cases of hyperplasia or adenoma.[198] At the time of surgery, tumors are found to be densely fibrotic and may be difficult to resect from adjacent structures. This fibrotic reaction may be an indicator of invasion of thyroid or skeletal muscle, which, along with lymph–vascular invasion (LVI), are the only reliable histologically diagnostic features of parathyroid carcinoma (Fig.

3.12). In isolation, solid tumor growth, the presence of fibrosis, mitotic activity, and necrosis all suggest malignancy but are usually not adequate to make the diagnosis. Mutations in *CDC73 (HRPT2)*, the gene encoding parafibromin protein, are frequent in both sporadic and familial parathyroid carcinomas.[197] Presence of mutation is often reflected in the absence of parafibromin protein, a feature that may be detected by immunohistochemistry. Absence of parafibromin expression in borderline lesions possessing some, but not all of the features of carcinoma (atypical adenomas), may help support a diagnosis of malignancy.[199,200] The prognosis of parathyroid carcinomas depends on the success of resection, with lower recurrence rates (~30%) associated with preoperative diagnosis and complete en bloc resection.[197]

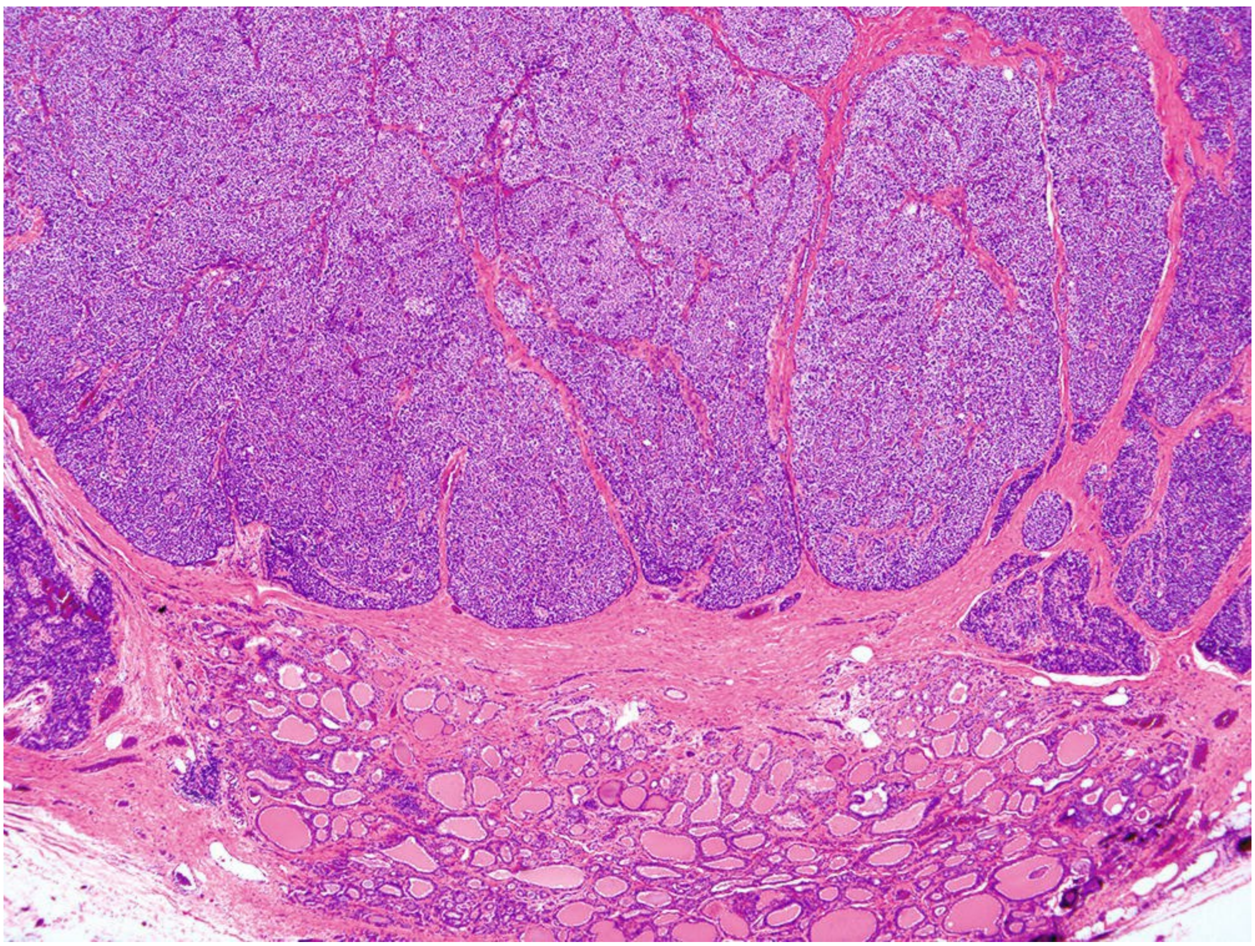

Figure 3.12 Parathyroid carcinoma. Clinically, the tumor was adherent to the thyroid gland necessitating ipsilateral lobectomy (inferior) and was histologically characterized by the presence of intralesional fibrosis creating a

nodular-appearing proliferation extending to the thyroid parenchyma.

Neuroectodemal and Neuroendocrine Malignancies.

Neural crest cells migrate throughout the body during development and are thought to be precursors to melanocytic cells, receptor and endocrine cells of perivascular glomus bodies, the olfactory sensory apparatus, and Merkel cells associated with cutaneous mechanoreceptors, among others.

Malignancies arising from sensory apparatuses, including paragangliomas and olfactory neuroblastoma, share similar histologic features with other neural crest–derived tumors such as MTC and pheochromocytoma. Tumors have a nested, highly vascular growth pattern, with balls of neoplastic cells surrounded by S100 protein–positive sustentacular cells. Malignant cells may display a wide spectrum of neuroendocrine differentiation, from bland cells with round nuclei and abundant granular cytoplasm, as in most paragangliomas, to aggressive-appearing small cells with scant cytoplasm, necrosis, and high proliferative index, as in high-grade olfactory neuroblastoma. Most tumors express neuroendocrine markers (e.g., chromogranin, synaptophysin), at least focally and typically lack immunoreactivity with epithelial-related markers (e.g., cytokeratins).

Neuroendocrine tumors of mucosal or salivary origin, while no longer thought to be of neural crest origin, demonstrate similar histologic and immunophenotypic features, although sustentacular cells are not present. Merkel cell carcinoma is a neural crest–derived small cell malignancy with a distinctive, perinuclear dot-like pattern of cytokeratin 20 expression,[201] as well as immunoreactivity with neuroendocrine markers (e.g., synaptophysin, others). Tumors arise in older individuals with a history of sun exposure and are commonly associated with immunocompromise, a finding explained by the discovery of the role of polyoma virus in Merkel cell carcinogenesis.[202] Immunoreactivity with the Merkel cell polyoma virus (MCPyV), a nuclear marker, is confirmatory of the diagnosis.

Mucosal melanoma is a rare, highly aggressive malignancy with poor survival rates. The head and neck is the most common site for mucosal melanoma, with tumors arising from melanocytes lining mucosal epithelium anywhere in the upper aerodigestive tract. Definite risk factors have not been

identified, and *BRAF* mutations are rare, although *KIT* mutations have been reported.[203] Thus, mucosal melanoma is considered a clinical entity distinct from cutaneous melanoma. Nevertheless, histologic and immunophenotypic features are similar, with many tumors displaying melanin pigment or antigenic evidence of melanogenesis.

Clinicopathologic correlation on small biopsy specimens is key in determining the correct workup for the diagnosis of small cell malignancy with neuroendocrine appearance. Age, site, and radiographic characteristics all play a role, and a diagnosis should never be made in isolation.

Mesenchymal Malignancies.

Mesenchymal tumors include those arising from connective tissues or bone or that recapitulate stages of mesenchymal differentiation. Lipomas are the most common benign mesenchymal tumor, followed by schwannoma/acoustic neuroma. Malignant mesenchymal tumors (sarcomas) are exceeding rare but are responsible for high morbidity and mortality when they occur, due to the complex anatomy of the region and difficulty in obtaining complete resection. Osteosarcomas typically arise in the jaw, whereas both chondrosarcoma and chordoma affect the skull base. Angiosarcoma is predisposed to arise in sun-damaged skin of the scalp, whereas rhabdomyosarcoma has a predilection for the sinuses. Although discovery of characteristic molecular alterations in many entities has improved diagnosis of mesenchymal tumors, undifferentiated or unclassifiable tumors with no known distinguishing morphologic, immunophenotypic, or molecular alterations remain a particular problem and often are unresponsive to adjuvant therapy.

Radiation-induced sarcomas are a rare secondary complication of radiation therapy for primary epithelial malignancies. Secondary sarcomas occur with variable latency period after radiation, from ~5 years to decades following therapy, and occur within the radiation field. Radiation-induced sarcomas tend to be aggressive and commonly take the form of osteosarcoma (if arising from bone), angiosarcoma (in the skin), or undifferentiated sarcoma, although other variants have been reported. Clinical correlation is required to establish the diagnosis.

Hematolymphoid Malignancy.

Lymphomas account for ~5% of all malignancies of the head and neck and are often subclassified as Hodgkin and non-Hodgkin lymphomas. The 2008 World Health Classification of Tumours recognizes over 50 subtypes of non-Hodgkin lymphoma,[204] nearly any one of which may present in the head and neck. The most frequent types of non-Hodgkin, B-cell, and T-cell lymphomas seen in this region are B-lymphoblastic leukemia/lymphoma, chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), extranodal mucosa-associated lymphoid tissue (MALT) B-cell lymphoma, follicular lymphoma, mantle cell lymphoma, diffuse large B-cell lymphoma, Burkitt lymphoma, and nasal extranodal NK/T cell lymphoma.[205] The head and neck is rich in lymphoid tissue, and lymphoma should be kept in mind in the differential diagnosis of cervical lymphadenopathy or asymmetrical tonsillar hypertrophy within Waldeyer ring in the adult population. Lymphomas may also arise secondary to long-standing chronic autoimmune inflammatory disease such as Hashimoto thyroiditis or Sjögren syndrome.[205] EBV infection can be associated with lymphomas of the head and neck, with the most aggressive form arising in extranodal NK/T cell lymphoma, nasal type (formerly referred to as lethal midline granuloma, among other terms).[206,207]

Correct diagnosis of lymphoma is highly dependent on adequate sampling and tissue preservation. When lymphoma is suspected, tissue must always be sent fresh, with the differential diagnosis clearly indicated on the requisition, to ensure that tissue is triaged for flow cytometry or molecular studies, as appropriate.

Differentiation (Grade)

Histologic grade is used to describe how well differentiated a malignant tumor is, that is, how well it recapitulates normal tissue. Although grade has been applied to all types of malignancies, it is not always applicable, particularly in mesenchymal tumors that may have intrinsic biologic potential independent of grade, for example, angiosarcoma, or that may not resemble any known normal tissue type. Epithelial malignancies are highly amenable to grading, as they are readily comparable to normal epithelium. A well-differentiated, "low-grade" keratinizing squamous cell carcinoma shows obvious keratinization and intracellular bridges and may grow in a more cohesive pattern, whereas poorly differentiated "high-grade" tumors progressively lose these features and tend to grow in a less cohesive,

infiltrative pattern.

At the extreme end of the spectrum, undifferentiated, anaplastic tumors lose all resemblance to the putative lineage of differentiation. Undifferentiated carcinomas mimic mesenchymal tumors, in that the malignant cells become discohesive, develop a spindled morphology, and commonly express mesenchymal markers such as vimentin, rather than cytokeratins specific of epithelial origin. Historically, the term “dedifferentiated” has been used for these tumors in the belief that the cell of origin had undergone progressive phenotypic losses. More recently, the term “epithelial to mesenchymal transition (EMT)” became popular to explain the phenomenon and account for cell motility.[208] Both terms are, to some extent, misnomers. Mounting evidence suggests that the cell of origin for carcinoma is a pluripotent stem cell.[209,210] In well-differentiated carcinomas, this neoplastic cell produces a clone capable of nearly complete epithelial differentiation but characterized by abnormalities in proliferation, survival, and migration.[209,211] Over time, progressive molecular alterations in mitotically active cells produce a clone, which is unable to fully differentiate but may have survival, migratory, or proliferative advantages over better differentiated subclones within the tumor.

Poorly differentiated tumors present diagnostic difficulties and often require ancillary studies such as immunohistochemistry, electron microscopy, or molecular analysis to elucidate evidence of a line of differentiation. These techniques are discussed in greater detail in “Ancillary Studies (Pathologic Toolbox) and Applications” section, below. An attempt to make a definitive diagnosis is key, as undifferentiated “spindle cell” squamous cell carcinoma has a distinct biologic behavior different than that of most spindle cell sarcomas and will respond differently to adjuvant therapy. In some cases, evidence of epithelial origin may be completely lost, resulting in false-negative diagnostic studies. In such cases, a high index of suspicion based on the clinical features and site of origin may still result in the correct diagnosis being made.

Poorly differentiated (high-grade) tumors are thought to behave more aggressively than do well-differentiated tumors.[212] Therefore, grading can assist with prognostication. Each different lineage of tumors has general grading criteria, and some individual tumor types have specific grading criteria. Grading criteria that rely on objective factors, such as the number of

mitotic figures, presence of necrosis, extent of nuclear atypia, or specific growth patterns as with mucoepidermoid carcinoma or adenoid cystic carcinoma,[213–217] tend to perform better in prognostication than do poorly reproducible subjective systems such as are used for squamous cell carcinoma.[218,219] Nevertheless, a considerable degree of subjectivity in assessment remains. Another important consideration is that high-risk prognostic features such as lymphatic or perineural invasion may supercede the relevance of grade in predicting tumor behavior, particularly in low-grade carcinomas. In oral squamous cell carcinoma, higher grade is generally associated with higher-stage disease[220] and may predict poor survival, although differing methodologies of grading make comparisons between studies difficult.[219,221,222]

Staging (TNM)

Staging systems are used to describe the anatomic extent of a malignancy. Staging criteria are based either on the specific subtype of malignancy or on tumor site. Although clinical and pathologic staging systems both report the same components, they may produce different results, due to the ability of histopathologic review to detect subtle, clinically occult involvement by tumor. Staging reflects three aspects of tumor spread: T—local extent of the primary tumor, N—presence and extent of involvement of regional lymph nodes by tumor, and M—presence or absence of distant metastases.[223] These parameters have largely been shown to predict outcomes in squamous cell carcinoma, and TNM staging is widely used for routine cancer management.

Tumor Site

The majority of TNM staging criteria are based on primary tumor site rather than on histologic subtype. Thus, cancer of the oral cavity is staged differently than cancer of the larynx, with criteria refined to better stratify for risk as emerging studies contribute to a better understanding of disease. Site groupings are important to take into account both the biology of tumors common at these sites as well as typical patterns of nodal or distant metastasis. Site is also critical in early diagnosis. Tumors that are visible to patients (cutaneous malignancies) or that present with symptoms in early stage of disease (e.g., tumors arising on the true vocal fold) are much more likely to be detected at an early stage when curative therapy is possible.

Tumors arising in occult locations such as sinus, tonsils, or hypopharynx, on the other hand, may not come to clinical attention until an advanced stage tumor causes obstruction or palpable nodal metastases. Site is also important as the etiology and natural behavior of squamous cell carcinoma arising in the oropharynx is distinct from those arising in the oral cavity, nasopharynx, or glottis. Site, therefore, has been reported as an independent prognostic factor in and of itself[224,225] and must be taken into account when assessing patient outcomes.

Tumor Size

Extent of primary disease is based on tumor size and involvement of adjacent structures. In most sites of the head and neck, a low-stage (pT1) tumor is one that is no more than 2 cm in maximal dimension, whereas a high-stage (pT3) tumor is large (>4 cm). Small tumors may be upstaged if they show evidence of aggressive behavior, such as invasion through cortical bone in oral carcinomas (pT4a), or extension to perithyroidal soft tissues in carcinoma of the thyroid (pT3).[223] Tumor size generally correlates with resectability; larger tumors are more likely to have positive margins at resection[80,226] and are thus at higher risk for local recurrence and death.[120,227] Size is not the only predictor of aggressive behavior; as further discussed below, additional criteria factor into determining biologic behavior, and some small tumors behave in a highly malignant fashion whereas other large, but superficial tumors may be quite indolent.

Lymph Nodes

Presence of tumor metastasis in cervical lymph nodes has been shown to be the single most important adverse prognostic factor in squamous cell carcinoma of the head and neck.[228–230] In patients with lymph node metastases, 5-year overall survival drops to 59%, compared to 82% for patients with node-negative disease.[231]

Whereas clinical staging relies on radiographic (CT, MRI, ultrasound, and positron emission tomography [PET]) evidence of nodal involvement (enlarged, metabolically active nodes) or the presence of a palpable mass in the neck, pathologic node staging has the ability to detect subcentimeter micrometastases and isolated tumor cells within lymph nodes. Number, size,

and laterality of nodal involvement all contribute to stage,[223] with larger metastases and contralateral or bilateral metastasis portending worse outcomes.[232]

Conventional nodal staging may not be appropriate for oropharyngeal HPV-associated carcinomas, as metastases are frequently bilateral due to the location in the midline base of tongue, and may be large due to cystic change. As such, the present AJCC 7th edition staging system[223] has been shown to have poor correlation with survival in HPV-associated carcinoma.[233] Some investigators have proposed a new staging system for HPV-associated carcinoma to reflect the better prognosis for patients presenting with nodal metastasis compared to conventional squamous cell carcinoma.[234] However, such proposals may be premature until it is determined if therapy for HPV-associated carcinomas can be safely de-escalated relative to conventional squamous cell carcinoma.

Recent studies to further refine nodal staging criteria have investigated the prognostic value of number of positive lymph nodes in head and neck cancer. Because the number of positive nodes may increase with the completeness of node dissection and identification, the lymph node ratio (total positive number of nodes divided by total nodes found) is used to normalize reporting. High lymph node ratio has now been reported to be independently predictive of poor outcomes in patients with oral cancer and nodal metastasis and may perform better in risk stratification than does N classification.[235–239] Lymph node ratio is also prognostic in cancer of the larynx,[240] postchemoradiotherapy squamous cell carcinoma of the hypopharynx,[241] and carcinoma of the oropharynx.[242]

Although not considered a factor in lymph node staging, cervical level of nodal involvement is also important. Long-standing and aggressive tumors will progressively spread from upper levels to lower levels along normal lymphatic drainage channels, leading to higher disease burden, and worse outcomes.[232,243–245] Quantitatively, patients with multiple levels involved have been reported to have twice the risk of distant metastasis compared to patients with only one level (36% vs. 18%).[225] In addition, level of involvement may be important for determining radiation fields and dosage when planning adjuvant therapy.[246]

Ideally, each anatomic lymph node level is identified by the surgeon at

the time of dissection and sent separately for pathologic evaluation,[247] as selective dissections do not provide anatomic structures required for accurate orientation and level assessment. Intact radical neck dissections do not require orientation for pathologic determination of levels during specimen processing. Lymph node size and number is documented grossly by the prosecting pathologist. If grossly identified, the size of the largest metastatic focus should be measured and gross extracapsular extension or the presence of lymph node matting documented. Although matting may convey a worse prognosis, for documentation purposes, matted lymph nodes are counted as a single metastatic focus. All identified lymph nodes are submitted for histologic evaluation. If few nodes are identified, the remaining adipose tissue from the neck is submitted to search for microscopic lymph nodes. Thorough neck dissection of all five cervical levels should yield 30 to 50 lymph nodes, on average.[247]

Tumor deposits in soft tissue may represent completely replaced lymph nodes,[248] or possibly vascular invasion, and present a similar risk for relapse as a lymph node with extracapsular spread (ECS).[249]

Sentinel Lymph Node Biopsy.

Sentinel lymph node biopsy is commonly used to accurately evaluate the necessity of regional lymph node dissection in malignancies such as melanoma and breast carcinoma.[250,251] In the head and neck, the role of sentinel node biopsy as an alternative to neck dissection in clinically N0 squamous cell carcinomas continues to be an evolving field.

Sentinel node biopsy relies on the concept that lymphatic drainage follows an orderly progression, with tumor first spreading to the most proximal catchment basin before subsequently involving more distal levels.[252] The lymph nodes in this proximal field are designated the sentinel lymph nodes and may be identified by injecting the area around the tumor with radioactive ^{99m}Tc–labeled colloid tracers and/or dye prior to surgery and selectively harvesting all nodes subsequently found to contain tracer after a specified time has elapsed.[253] Ideally, these nodes are the most likely to reflect the true disease status, and if all such identified sentinel nodes are negative for carcinoma, then further neck dissection is unnecessary, as the tumor will not have spread further.[254,255] Sentinel node biopsy, therefore, improves staging over radiographic/clinical N stage, while preventing

unnecessary surgical morbidity due to extensive neck dissection—morbidity that has been shown to significantly affect quality of life.[255–259]

Most institutions routinely perform elective neck dissection for clinical T1/T2 N0 oral and oropharyngeal carcinomas. This procedure allows for nodal staging and clears radiographically occult disease. However, only 25% to 30% of patients are reported to have occult neck disease after complete pathologic evaluation,[260–262] resulting in "unnecessary" neck dissection in the remaining 70% to 75%. Several prospective multi-institutional trials have confirmed the predicted distribution patterns of nodal metastasis in oral cancer and reported sentinel node biopsy to have a negative predictive value (NPV) of ~96% for nodal metastasis.[263,264] Civantos and coauthors reported a 26.4% rate of positive sentinel nodes, whereas Alkureishi et al. found positive sentinel lymph nodes in 34% of patients, on par with the expected rate of occult disease in clinical N0 patients. These two studies confirmed the results of a number of smaller single-institution series, which found the NPV of sentinel node biopsy to be between 90% and 98%, with false-negative rates of <6%.[265–273]

Methodologies used for evaluation of sentinel node vary and may have an impact on the sensitivity of biopsy. Examination of one H&E level only, as was initially performed at submitting institutions in one recent study, resulted in an NPV of 94% for nodal metastasis.[263] With subsequent sectioning at 2 to 3 mm, and evaluation using immunohistochemical studies for four different cytokeratins, five cases were reclassified. Two cases positive for micrometastases at referring centers were negative in tissue available for central review, and in three initially negative cases, micrometastases were identified on immunohistochemical stains.[263] Several protocols advocate the evaluation of sentinel nodes using initial 2- to 3-mm gross sectioning followed by 150-μm step sections with serial sections cut at each level for H&E and immunohistochemical evaluation.[274,275] This protocol results in increased sensitivity for micrometastases.[264,276] However, because such extensive procedures are not used in routine lymph node dissections to detect micrometastases or isolated tumor cells, the true prognostic significance of their detection in sentinel nodes remains unclear.

Sentinel node biopsy may be less sensitive for occult nodal metastases in tumors arising in the floor of mouth, although data are limited.[263,264] False-

negative results in sentinel node biopsy may be due to procedural factors relating to injection and detection of radionuclide/dye tracer, lymphatic obstruction by tumor, particularly with bulky disease,[274,277] or analytical factors relating to node sectioning and size of metastasis. Sentinel node biopsy is not recommended for T3/T4 primary tumors.[274]

The use of frozen section has been evaluated for sentinel node biopsy, with reported NPVs of ~92% to 94% after taking into account patients with negative sentinel nodes who later developed neck recurrence.[112,278,279] Sentinel node biopsy has not been extensively validated for carcinomas of other sites, for example, larynx, or for HPV-associated carcinomas of the oropharynx.

Extracapsular (Extranodal) Spread.

ECS of lymph node metastasis occurs in between 41% and 85% of conventional squamous cell carcinoma of the oral cavity and larynx.[280–282] The presence of ECS in any node is associated with increased frequency of distant metastasis and more rapid locoregional recurrence and portends poor survival in conventional squamous cell carcinomas of the larynx[280,283,284] and oral cavity.[228,281,285–289] Because ECS predicts locoregional recurrence, it is considered to be an indication for aggressive postoperative radiation or chemoradiation therapy.[228,287,290,291]

Macroscopic ECS is detectable clinically as enlarged, fixed nodes or as lymph node matting. As ECS is seen in up to 75% of lymph nodes larger than 3 cm,[284,286,292,293] it is unclear if this finding has independent prognostic significance in the context of a stage pN3 neck. Microscopic ECS is present in 17% to 48% of subcentimeter nodes (Fig. 3.13),[284,286,294] and, in this context, it is associated with increased regional relapse.[295] Controversy exists as to the significance of extent of extranodal spread, either loosely defined as "macroscopic" versus "microscopic"[296,297] or measured more precisely as the perpendicular distance in mm from lymph node capsule, with or without desmoplastic stromal reaction.[288,295]

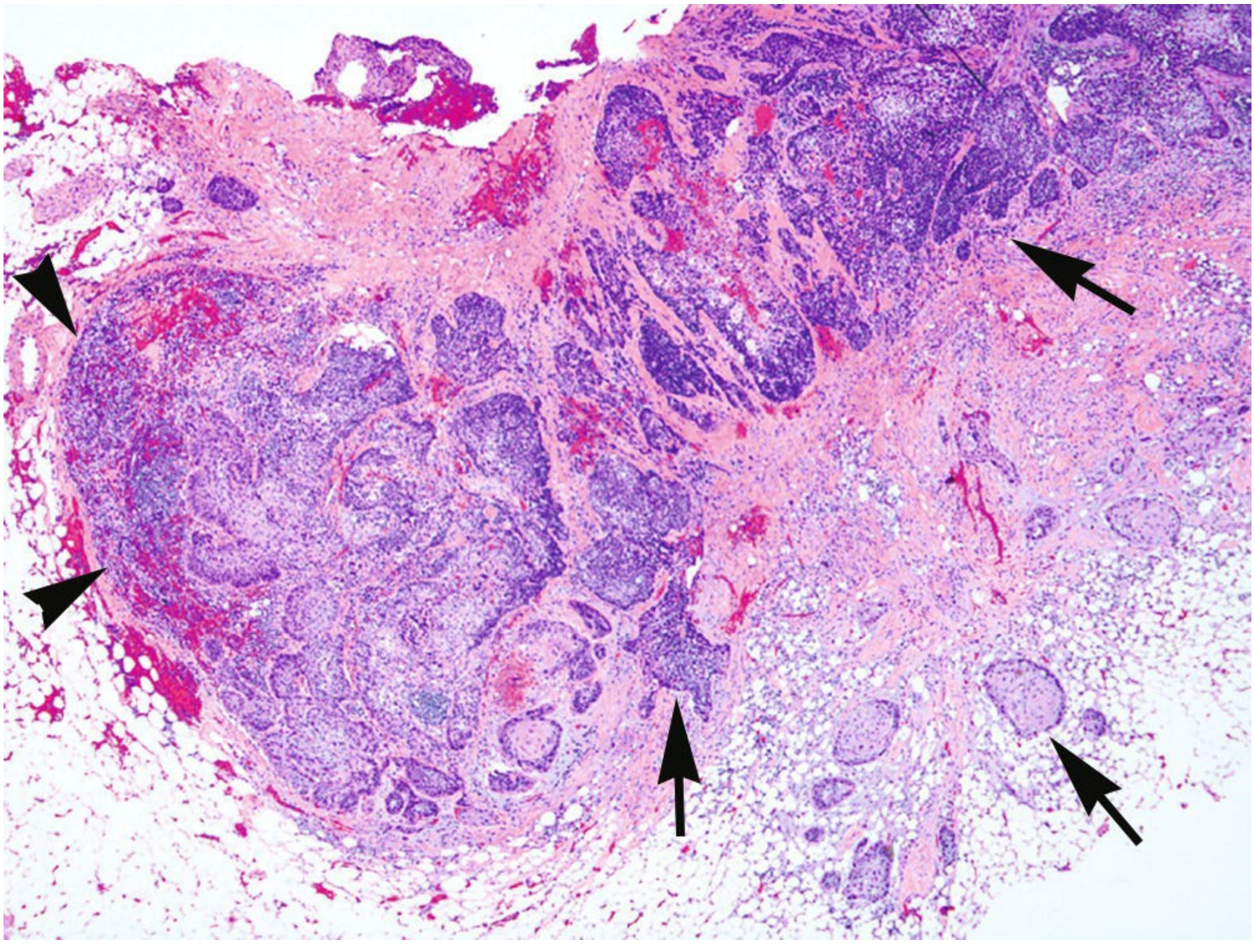

Figure 3.13 Extracapsular speed (ECS). At low magnification, residual lymph node parenchyma (*arrowheads*) is present with near complete effacement by metastatic squamous cell carcinoma, the latter extending into perinodal soft tissues (*arrows*).

The prognostic impact of ECS in HPV-associated oropharygeal squamous cell carcinoma is less certain than that for conventional keratinizing squamous cell carcinoma. One study, using a novel grading system for ECS, reported that only complete lymph node eradication (“soft tissue metastasis”) had prognostic value in univariate analysis of p16-positive oropharyngeal carcinomas, but this lacked independence in multivariate analysis.[298] In a follow-up study by the same group, 82% of 152 p16-positive oropharyngeal carcinomas were reported to have ECS (of which the researchers considered only 52% to represent “true” ECS). No prognostic significance was found for ECS, and moreover, in contrast to keratinizing squamous cell carcinoma, aggressive adjuvant therapy conveyed no additional benefit.[299] More

recently, a study comparing p16-positive carcinomas of the oropharynx with p16-negative carcinomas of the same subsite found no prognostic significance of ECS on disease-specific survival in either type.[300]

Cystic Lymph Node Metastasis.

Cystic metastases from squamous cell carcinoma were historically thought to represent carcinoma arising in a branchial cleft cyst—so-called branchiogenic carcinomas.[301] Subsequent investigations revealed an oropharyngeal primary tumor in nearly all cases.[23,302,303] Approximately 40% to 60% of lingual or palatine tonsillar squamous cell carcinomas present with at least one cystic metastatic lymph node and up to 36% with cystic metastases only.[304,305] Both primary and metastatic tumors are usually p16 and HPV positive.[305] Although PTC may also develop cystic metastases, other mucosal primary sites of the head and neck are only rarely, if ever, associated with cystic metastases.[305] Cystic metastasis should be clearly distinguished from centrally necrotic solid metastases, which are not necessarily associated with HPV infection.[305]

Distant Metastases.

Squamous cell carcinoma of the head and neck only rarely presents with distant metastases, with reported incidence rates ranging from 2% to 24%.[306–308] Rate of distant metastases is associated with extent of locoregional spread, and increased risk is seen in locally advanced disease (T3/T4), patients who present with lymph node metastases, hypopharyngeal primary site, and locoregional recurrence.[306] Multiple metastatic nodes, ECS, and inferior level neck nodal metastases have variously been found to be significant predictors of distant metastasis.[228,285,306,309] Distant metastases convey a poor prognosis, with 5-year survival rates of only 36% for oral, pharyngeal, or laryngeal squamous cell carcinoma metastatic at presentation.[231] Even in contemporary series, median survival rates for patients with distant metastases are only 8 to 9 months.[308,310] Patients with HPV-associated carcinomas have a slightly better prognosis with median survival rates of up to 19 months after development of distant metastases.[310]

The most common sites of distant metastases for head and neck squamous cell carcinoma are lung (50% to 70% of cases), bone (20% to

30%), and liver (5% to 10%).[307] Care should be taken to exclude a second primary tumor in the case of lung metastases, and morphologic and molecular correlation between the two tumors may be helpful, particularly in the case of HPV-related oropharyngeal tumors. In some cases, it is not possible to distinguish primary lung squamous carcinoma from a metastasis.

Additional Parameters

Tumor Thickness

Tumor thickness is a prognostic variable in T1 and T2 oral squamous cell carcinomas. Thickness is measured perpendicularly from the tumor surface (preferably using an ocular micrometer) to the deepest point of invasion and recorded in millimeter.[311–313] This is distinct from the depth of invasion that measures tumor depth relative to normal epithelium and may be recorded from the basement membrane of adjacent, noninvasive epithelium, or defined in terms of presence or absence of skeletal muscle invasion.[120,314] In the oral cavity, tumor thickness of 4 to 5 mm or more is associated with up to 60% risk of nodal metastases,[311,315–317] whereas microinvasive tumors with thickness of no more than 1.5 to 2 mm develop nodal metastases in <2% of cases.[311,312] Prognostic value of tumor thickness is independent of stage and, at least in T1/T2 oral squamous cell carcinoma, is more predictive of outcome than T stage.[311,312,318] Other studies of tongue, floor of mouth, palate, and lip have, in general, reported similar results, although methodologies for measuring tumor thickness varied between studies, as did cutoffs for significant thickness in predicting occult metastases.[313,315–330]

Of note, although the concept of tumor thickness as a prognostic factor was first used for cutaneous melanomas[331,332] and subsequently tested in carcinomas, it does not apply to risk assessment of mucosal melanomas.[333]

Patterns of Invasion

All invasion is not the same. Slow-growing, cohesive tumors, such as verrucous carcinoma, advance into underlying soft tissue with a broad, pushing tumor front while maintaining relatively normal patterns of squamous maturation toward the mucosal surface. Well-differentiated squamous cell carcinomas may invade as variably-sized, rounded nests,

which maintain relative maturation and polarity and remain closely apposed to the main bulk of tumor. These patterns are thought to represent less aggressive patterns of disease. Small nests, single cell infiltration of stromal tissues, and dispersed patterns of invasion with widely separated satellite foci characterize more aggressive disease (Fig. 3.14). Tumors with the most aggressive growth pattern (dispersed growth) are associated with increased local recurrence[334] and worse overall survival.[335]

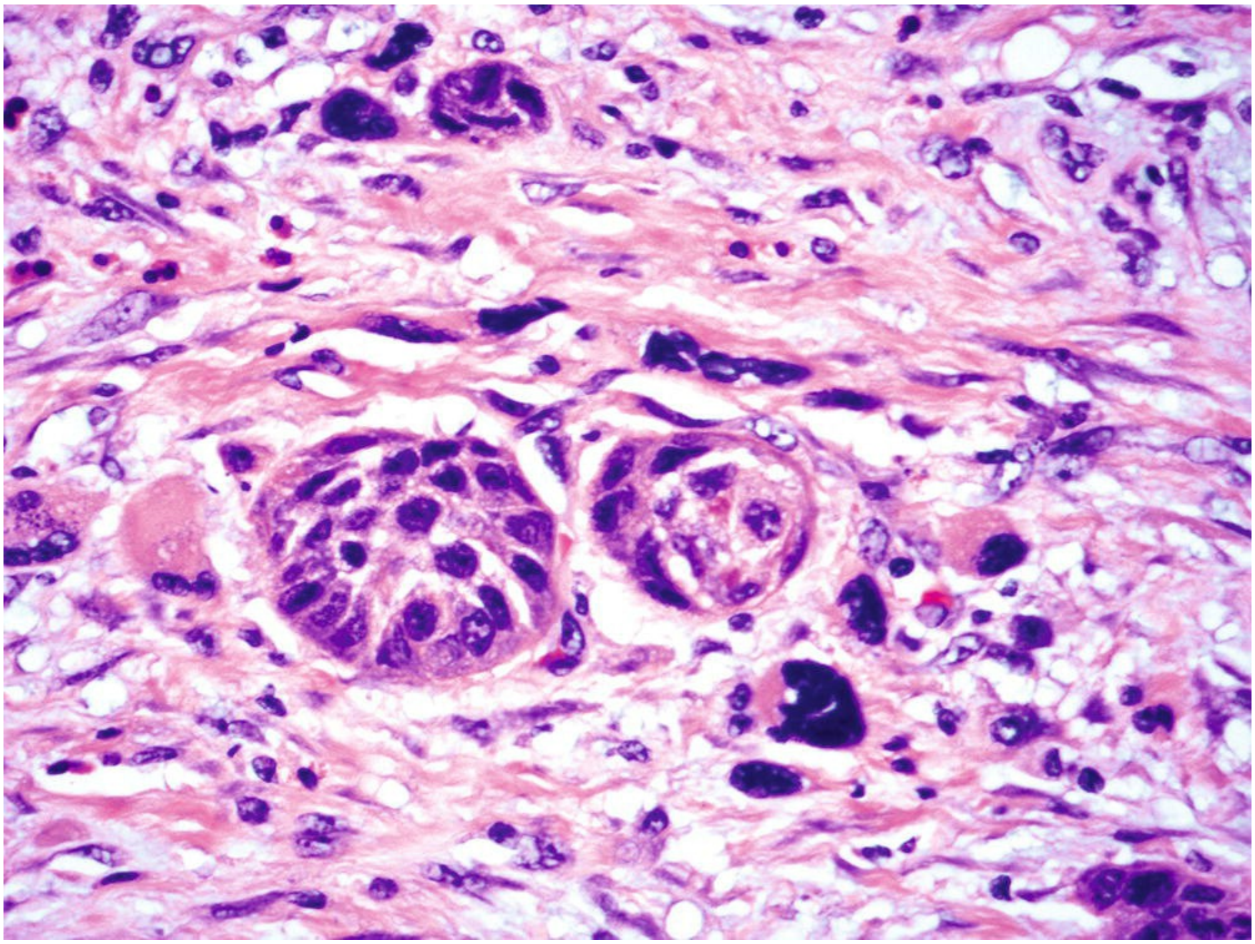

Figure 3.14 Infiltrative squamous cell carcinoma in which the carcinoma invades as cohesive cell nests as well as individual (dyscohesive) malignant cells.

Inflammatory Response

Inflammatory response to tumor is thought to be a sign of active immune defense against malignant cells. Early studies of floor of the mouth T1–T2 tumors demonstrated that tumors with the least amount of inflammatory

response were most likely to develop nodal metastases.[311,336] Subsequent studies have further refined understanding of this phenomenon. Currently, activated cytotoxic tumor-infiltrating T lymphocytes (TILs) are thought to be the important drivers of autoimmune response to malignancy. Studies have shown that increased density of CD3+ and CD8+ TILs predicts improved overall survival in patients treated with curative intent.[337,338] HPV-associated oropharyngeal carcinomas are also reportedly associated with increased T cells, particularly CD3+, FoxP3+, PD-1+, or CD8+ T-cells,[339–341] a finding that has been suggested to contribute to their favorable prognosis.[342] It is hypothesized that response to viral antigens is the stimulus for this aggressive antitumor immune response.[343]

Other studies have found that the presence of increased peritumoral neutrophils[344] or high neutrophil-to-lymphocyte ratio within peripheral blood are poor prognostic features for head and neck squamous cell carcinoma.[345,346] Eosinophilic infiltrates, although commonly seen in invasive oral squamous cell carcinomas,[347,348] have not been clearly shown to have prognostic implications.[349–352]

Aggressive tumors are thought to exert potent immunosuppressive effects on the tumor microenvironment.[353] It is hoped that reversal of this immunosupression will result in more effective antitumor response during the course of tumor therapy.

Lymph–Vascular Invasion

Invasion of lymph–vascular spaces is a widely cited risk factor for poor outcomes (Fig. 3.15).[334,354–356] However, large contemporary series have reported conflicting findings. In one recent analysis of buccal carcinoma, no patients with LVI survived to 5 years, whereas 64% of those without did.[120] Nevertheless, in multivariate analysis, LVI was not an independent prognosticator; only T classification, margin status, and treatment modality predicted overall survival.[120] Vincent and coauthors reported similar findings in late-stage (T3/T4) oral carcinomas,[227] and Lee et al.[308] found that LVI did not independently predict distant metastasis in a large Korean series.

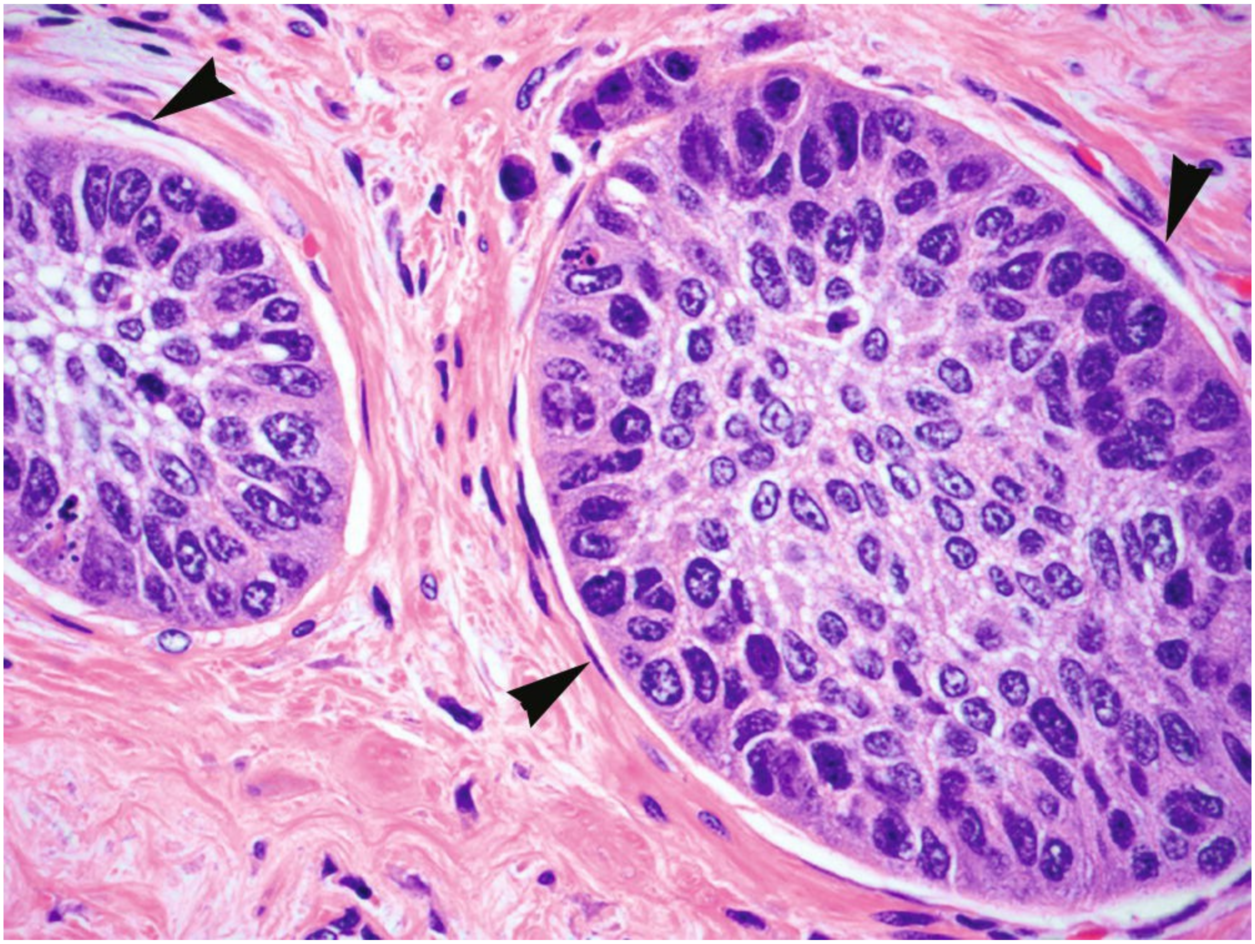

Figure 3.15 Lymph–vascular invasion. Foci of squamous cell carcinoma completely filling and adherent to the wall of the involved lymph–vascular spaces; the latter shows the presence of residual endothelial cells (*arrowheads*) allowing for their identification even in the absence of immunohistochemical staining for endothelial-related markers (e.g., CD31, others).

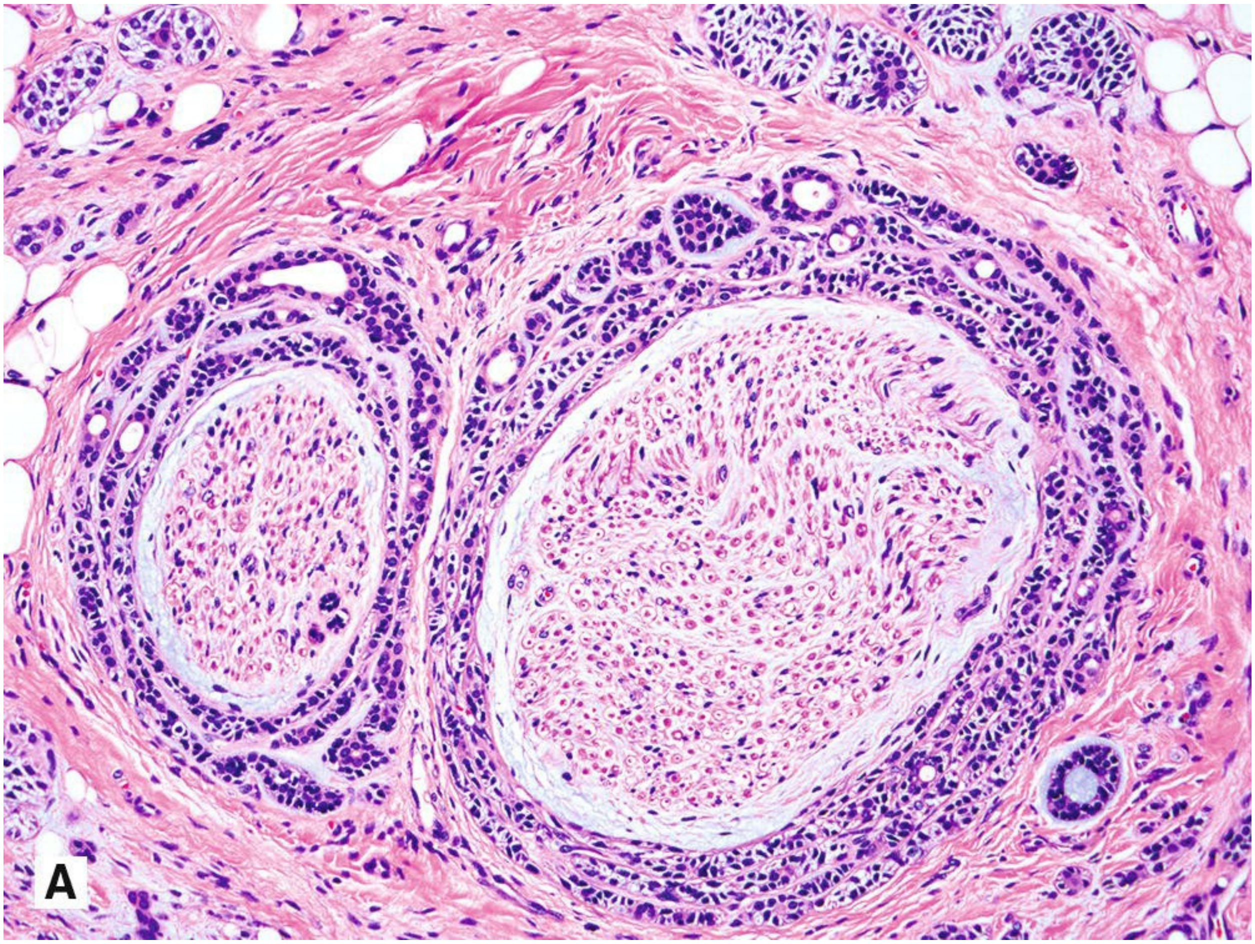
Some investigators have made the distinction between lymphatic and vascular invasion, again, with contradictory results. In some series, lymphatic involvement was not an independent prognosticator, but microvascular invasion predicted locoregional recurrence and death.[357,358] In contrast, Liao et al.[359] found that both lymphatic invasion and microvascular invasion were adverse prognostic features in stage III/IV oral tumors. Brandwein-Gensler et al.[335] reported that the presence of LVI was a negative sign, independent of both tumor grade and nodal metastasis, whereas Michikawa et al.[358] (2012) found lymphatic invasion to be a risk factor for nodal metastasis.

One possible explanation of the contradictory findings is that they are due to difficulties in distinguishing lymphatic from microvascular invasion on H&E-stained slides, as well as varying methodologies, tumor stages, disease sites, outcome end points, and population sizes used in different series to achieve their conclusions. Some authors relied on immunohistochemical studies to distinguish lymphatics from vascular channels, whereas in other series, the method used is unclear, rendering the data somewhat open to interpretation. Moreover, the presence of tumor emboli in lymphatic spaces does not necessarily indicate the presence of a viable tumor clone capable of seeding lymph nodes or distant sites and surviving in such foreign microenvironments. Further rigorous studies are required to clearly delineate the prognostic value of both lymphatic and vascular invasion in contemporary management of head and neck squamous cell carcinoma.

Invasion of large vessels such as the jugular vein is usually only seen in bulky late-stage disease.[360]

Perineural Invasion

Squamous cell carcinomas of the head and neck exhibit a high frequency of neurotropism, as do salivary gland carcinomas, in particular adenoid cystic carcinoma (Fig. 3.16).[361] Perineural invasion in the oral cavity involves reciprocal signaling between nerves and tumor cells,[362–367] stimulating increased migration ability in malignant cells. Thus, perineural invasion in squamous cell carcinoma results in both poor locoregional control[368,369] and high risk of nodal metastasis.[368] Subsequently, perineural invasion is a poor prognostic factor for survival.[335,368,370]



A

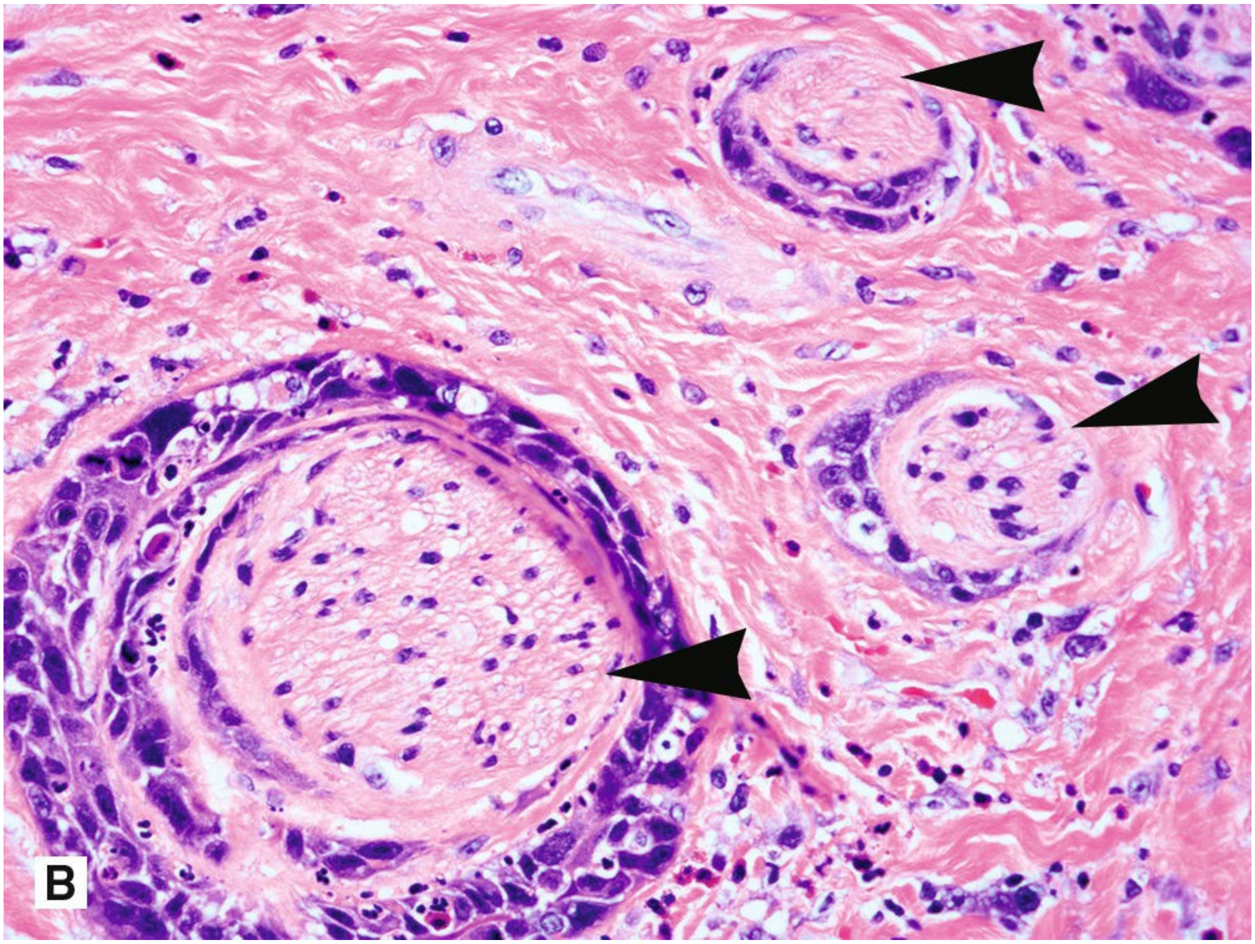


Figure 3.16 Perineural invasion in which tumor wraps around nerves is a common feature of adenoid cystic carcinoma **(A)** but can be seen in other malignant tumors including squamous cell carcinoma **(B)** (*arrowheads* detailing the nerves).

Histologically, the identification of perineural invasion requires tumor cells to be present within the nerve sheath, or demonstrate circumferential growth around at least 33% of the nerve. Entrapped nerve within tumor that does not demonstrate such evidence of neurotropism is not considered to represent perineural invasion.[371,372] It is unclear if the prognostic effects of perineural invasion depend on nerve diameter.[335,373] Extratumoral perineural invasion may portend worse outcomes.[374]

Perineural invasion is an indication for adjuvant chemoradiation therapy.[375,376] Improved outcomes after therapy may result not only from destruction of tumor cells but also from disruption of the nerve–tumor signaling microenvironment.[365]

Bone and Cartilage Invasion

Invasion of bone or cartilage by tumor is a sign of aggressive behavior and is largely associated with large primary tumors.[377–379] Whereas focal cortical erosion is common, particularly adjacent to teeth in gingival squamous cell carcinoma, only true medullary invasion is associated with local recurrence and poor survival rates, even in small tumors (Fig. 3.17).[380,381] Similarly, cartilage invasion by squamous cell carcinoma of the larynx or ear canal is historically associated with more aggressive tumors and higher rates of locoregional recurrence.[382–384]

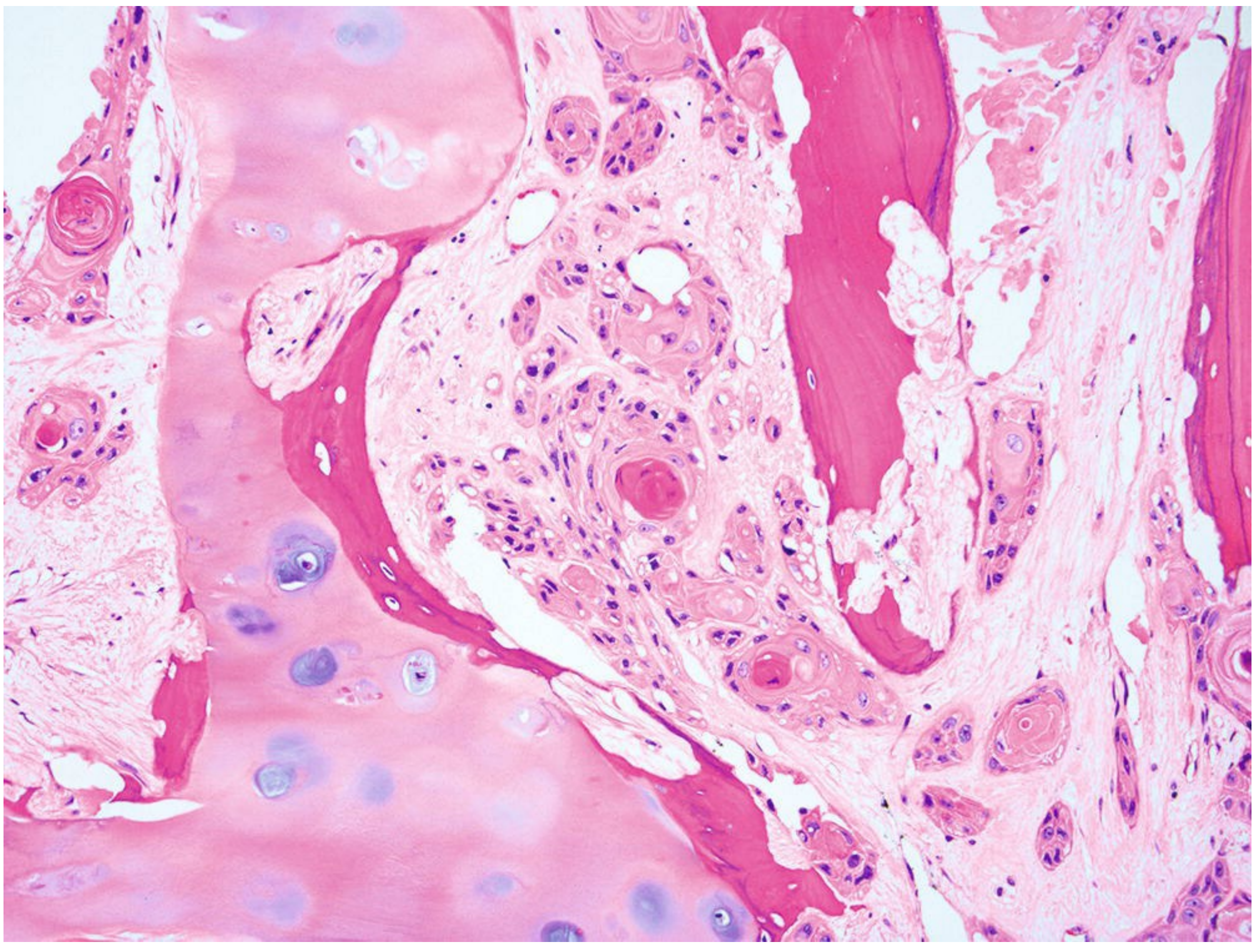

Figure 3.17 Squamous cell carcinoma invasive into the ossified cartilage of the larynx.

Margin Status

The presence of invasive carcinoma at or near surgical margins is a risk

factor for local recurrence[80,120,385–387] and worse survival.[385,388] Depending on the type of resection, resection margins include mucosal margins, soft tissues (including vascular and neural structures), and bone. Definition of what determines a positive margin can be a controversial issue, with differences of opinion on the significance of extent of involvement (R1-microscopic vs. R2-macroscopic), and what constitutes a “close” margin versus clear margins. In general practice, “close” is defined as ≤5 mm,[226] a number that does not take into account the difficult anatomy and limited resectable area of head and neck subsites.[389] In a meta-analysis of 15 publications, Alicandri-Ciufelli and coauthors[389] reported variability in the definition of close margin by anatomic subsite and procedure. Although, in general, close margins (ranging from 1 to 7 mm) were associated with local relapse to variable degrees of significance, differences in methodology and treatment modality studied limit comparability of the data.[389] The interpretation of margin status is further clouded by the presence of dysplastic epithelium or noninvasive carcinoma at the resection margin. Squamous dysplasia, in particular, is problematic as an indicator of margin status due to both poor reproducibility of diagnosis and the possibility that dysplasia represents multifocal disease, rather than a problem of local control.

In general, margins within 5 mm of lesional tissue, including dysplasia and invasive or in situ carcinoma, should be commented on,[226] and both surgeons and pathologists should be aware that in specific cases, such as squamous cell carcinoma of the larynx or oropharynx, margins as close as 2 mm may be sufficient. In other sites, including oral cavity or hypopharynx, wider margins of up to 10 mm are required to ensure clearance. Margin status should never be used in isolation to determine patient risk but is only one factor of many, including tumor stage, pattern of invasion, and use of adjuvant therapy.

Correct interpretation of “final” margin status is a collaborative effort between the surgeon and the pathologist. In all cases where margins are sent separately from the tumor, it should be clearly indicated where the tissue originated from relative to the tumor specimen, which face of the margin represents actual margin, and which surface abuts previously resected tissue. Margins are inked with dyes, which are formulated to withstand tissue-processing conditions without washing off, running, or fading. Margins are best inked and sampled as “perpendicular” or “radial” margins,

demonstrating the tumor to the inked tissue edge (Fig. 3.18). “Shave” or “*en face*” margins are inadequate for measuring distance between tumor and margin and cannot distinguish between close and wide margins. Cautery artifact at the margin distorts tissue and may render shave margins uninterpretable, whereas in radial sections, comparison between cauterized tissue and unaffected tissue further away can assist with interpretation. Proper orientation to a specimen prior to sectioning and pathologic sampling is key, and best done in person between the surgeon and the pathologist.[79] Margins may be (1) removed directly from the main resection specimen by the pathologist, (2) removed from the resection specimen and sent separately by the surgeon, or (3) taken from the patient from the in situ area of defect left after removal of the tumor.[76] Each method has advantages and disadvantages.

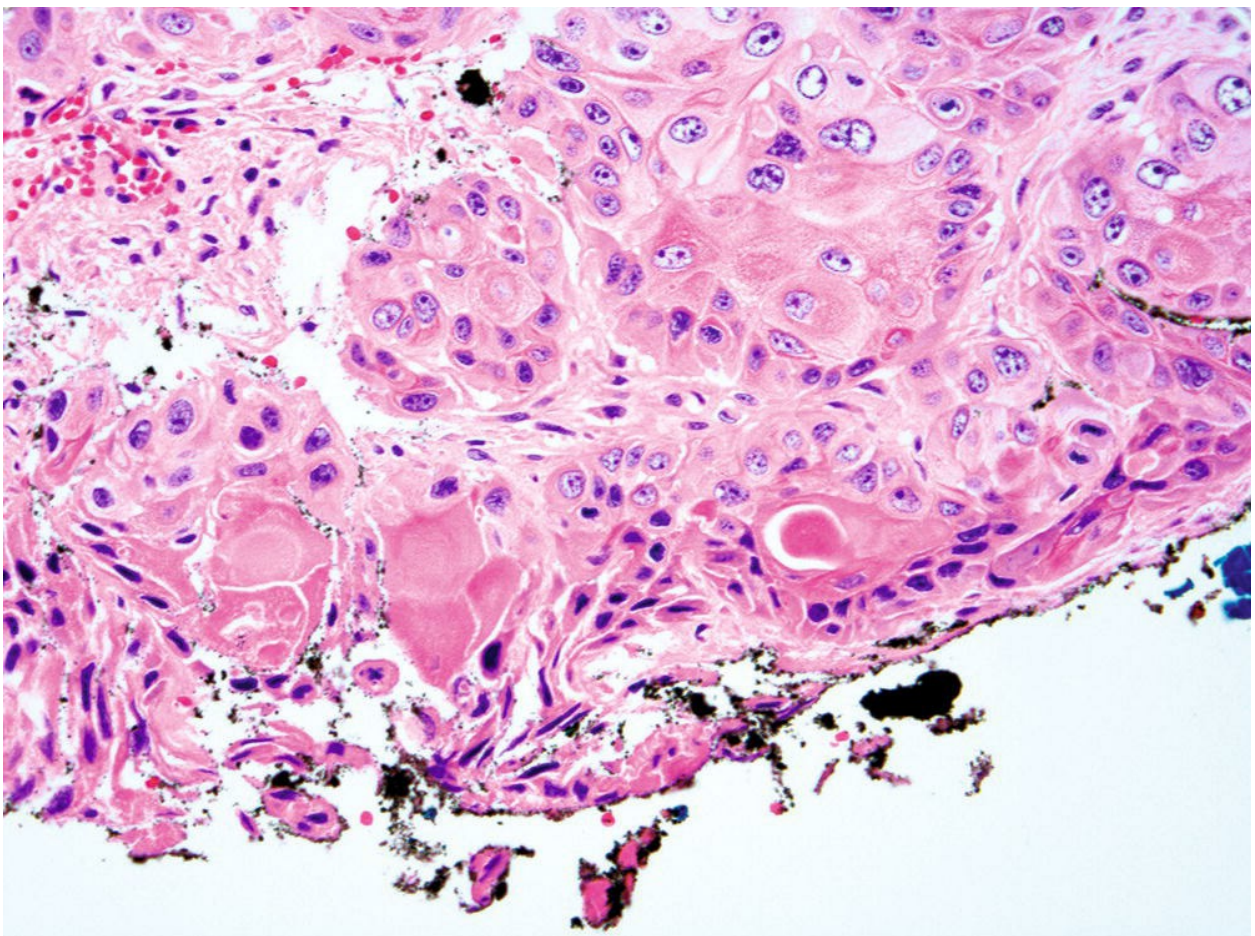

Figure 3.18 Well-differentiated squamous cell carcinoma with the tumor extending to the inked edge of the tissue specimen indicative of a positive resection margin.

In the first scenario, receipt of an intact specimen allows the pathologist to properly measure, orient, and ink the margins. In complex cases, the surgeon may wish to personally orient the pathologist to the specimen and discuss areas of particular concern. Tumor size and gross distance to all margins should be carefully measured and perpendicular sections of tumor at the closest extension to the margins selected for frozen section. This method ensures that positive margins can be precisely identified in relation to the tumor. But freezing perpendicular sections means that less of the margin can be evaluated and microscopic foci elsewhere may be missed. Specimen-removed margins sent by the surgeon are the equivalent of shave margins, and, although providing greater surface coverage, it is often unclear how they relate to the actual tumor. Removing tissue from the surgical defect as a margin produces even more difficulties in proper alignment due to tissue shrinkage and distortion.[390] Such margins are required to be taken if an initial margin is positive and should be labeled as specifically as possible (e.g., additional lateral gingival margin #1, not “additional lateral”) to provide clarity when interpreting subsequent pathology reports.

Tissue Shrinkage.

Further contributing to the margin controversy is the role of tissue shrinkage after resection and the subsequent adverse effects on measurements. In general, in situ tissue measurements and postresection measurements of oral tissues show 20% to 30% reduction.[391,392] Shrinkage begins as soon as the specimen is removed from the surrounding tissue and the natural tension is released. Formalin fixation and paraffin embedding further contribute to tissue shrinkage, albeit to a lesser extent than does contraction from innate tissue elasticity.[393] Pinning of specimens immediately after surgical excision can help to minimize tissue shrinkage—this must be done in the operating room, as by the time tissue reaches the pathology laboratory, the worst of the damage has already occurred.[391] Pinning of specimens, such as mucosal or tonsillar resections, is also an effective way to prevent curling of the margins during fixation and allows a more accurate gross measurement of tumor to margins.

Molecular Biology and Margin Assessment.

Molecular margin assessment relies on the concept of field cancerization (discussed below). If molecular alterations indicative of DNA damage are

present within morphologically “normal” epithelial cells, these are thought to be signs of a premalignant state and are associated with high risk of local disease relapse,[79] likely through the development of a second primary tumor. Molecular margin evaluation has not been shown to be relevant in HPV-associated carcinoma, and the technique remains primarily of preclinical investigative relevance.

Dysplasia

Mucosal intraepithelial dysplasia can be classified as keratinizing or nonkeratinizing, with keratinizing dysplasias being the more common of the two in the head and neck. Grading of head neck dysplasias is modeled on grading of intraepithelial neoplasias of the uterine cervix. However, this scheme does not translate well to grading of head and neck keratinizing dysplasias or take into account the propensity for carcinoma of the larynx to develop even in the absence of full-thickness dysplasia.[394] As a result, diagnostic reproducibility of head and neck squamous dysplasia is poor, particularly in three grade scales (mild, moderate, and severe).[395] Moreover, there is no significant difference for risk of invasive carcinomas between dysplasias graded as moderate, severe, or carcinoma in situ,[395] particularly as dysplasias lacking full-thickness epithelial atypia in this site may still develop invasive carcinoma (Fig. 3.19).

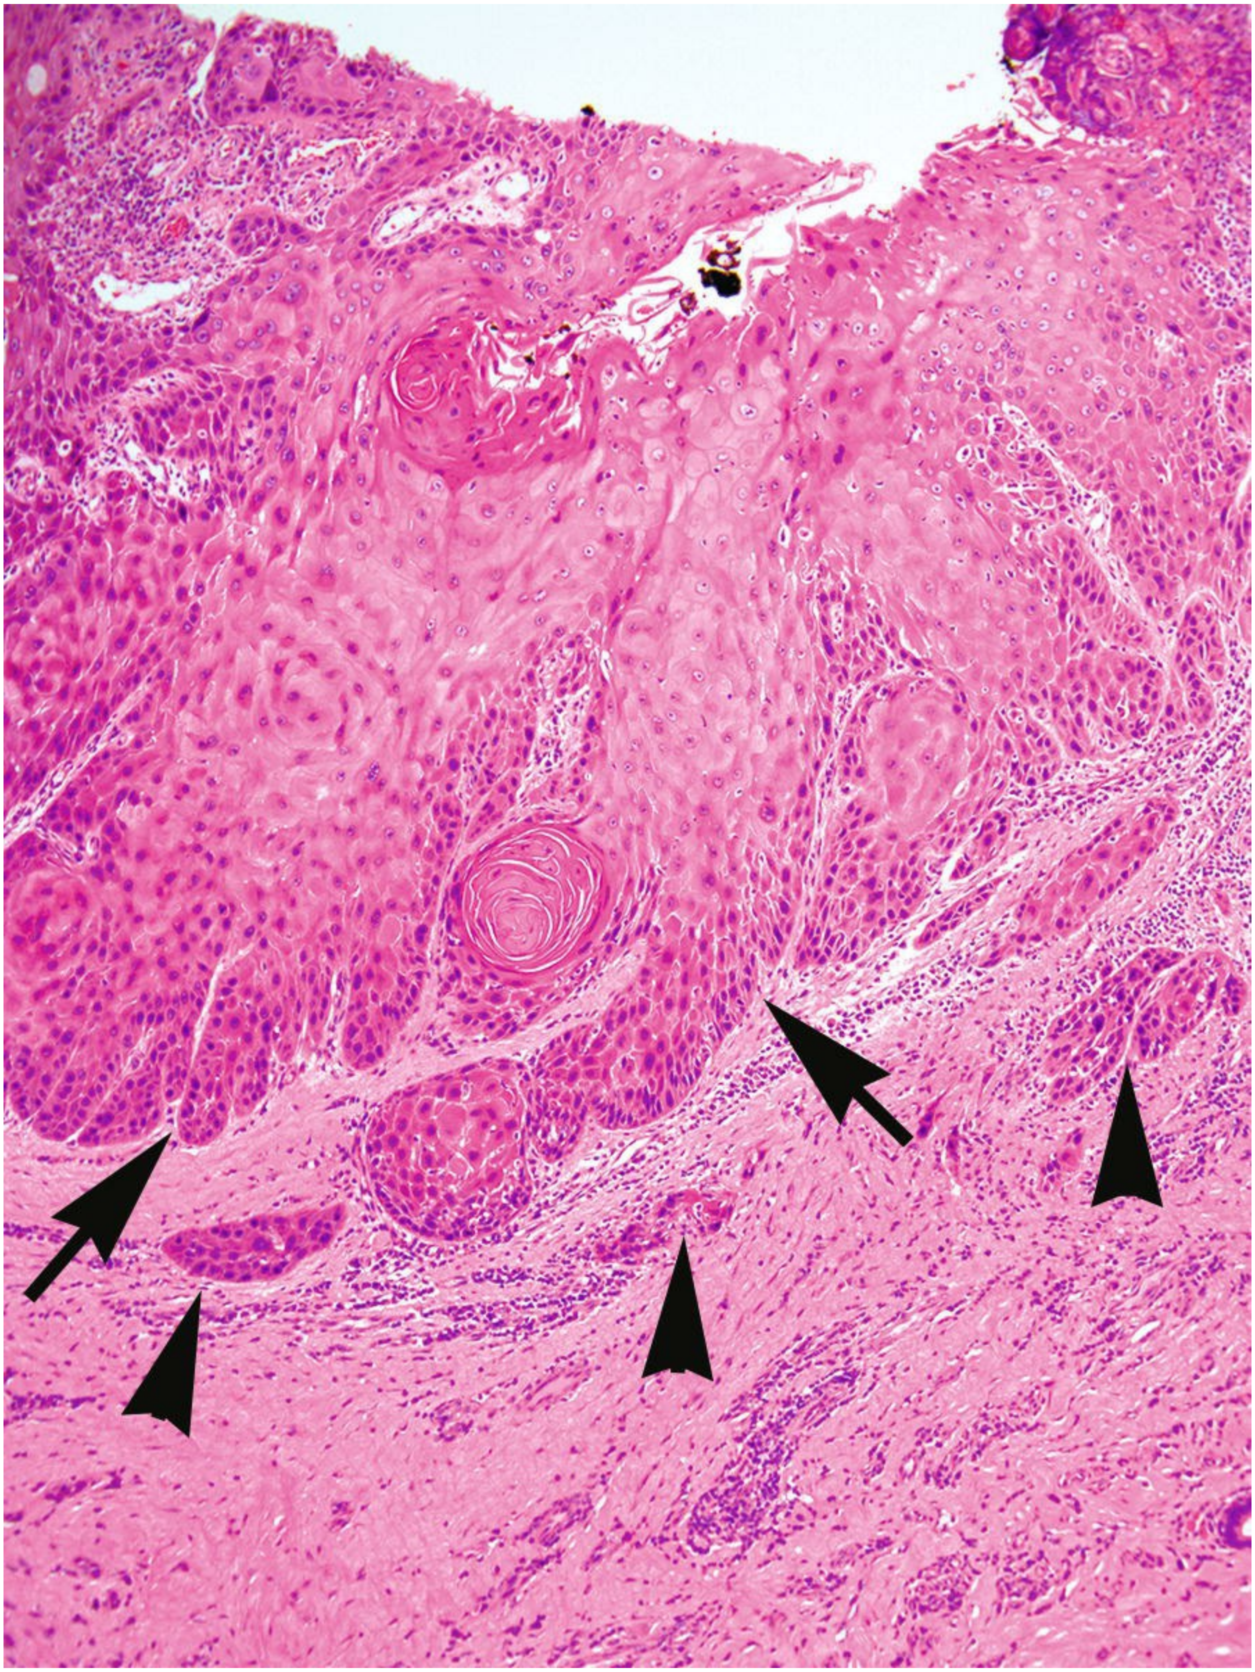

Figure 3.19 Keratinizing dysplasia, high-grade, with invasive carcinoma.

The dysplastic changes are limited to the lower (basal) zone epithelium (*arrows*) without full-thickness intraepithelial dysplasia but gives rise to nests of invasive carcinoma (*arrowheads*).

Because even moderate dysplasia carries a significant risk for development of invasive carcinoma, surgical intervention is warranted for both diagnostic and therapeutic reasons. When present at resection margins of surgical specimens, squamous dysplasias are best considered to represent positive margins, with inherent risk for local recurrence.

Microinvasive carcinoma, arising either in continuity with carcinoma in situ or directly from the base of histologically benign epithelium, represents a malignant lesion with outcomes similar to that of carcinoma in situ/high-grade dysplasia in the glottis.[396,397] In the supraglottis, microinvasive carcinoma may metastasize in up to 20% of cases, likely due to a higher concentration of readily accessible lymphatic channels subjacent to the mucosa in this region.[398]

Multiple Malignancies

Patients with an index head and neck malignancy have an increased risk of developing a second primary malignancy, with standardized incidence ratio of 2.2.[399] Etiologies include iatrogenic tumors induced as a secondary consequence of chemotherapy and/or radiotherapy, genetic predisposition, aging, and environmental carcinogens (e.g., smoking, heavy alcohol use).[400] The majority of second primary tumors are situated in the upper aerodigestive tract or may commonly arise in the lungs and more distal digestive tract.[401–406] Because the presence of a second primary tumor affects treatment approach and patient prognosis, panendoscopy or PET–CT to assess for multifocal disease is required prior to initiating therapy.

Continued smoking after treatment for the first primary tumor results in an elevated risk of developing a second primary tumor,[403] with annual incidence rates of 4.2% reported for the development of a second primary tumor, nearly 1.5 times the risk of those who quit smoking, and twice the risk of never smokers.[407] These findings underscore the importance of lifestyle modification in the treatment of head and neck carcinoma. Overall survival rates are reduced nearly 25% at 5 years after the development of second

primary malignancy,[408,409] with tumors of the lung or esophagus historically portending significantly foreshortened survival.[403]

Field Cancerization.

Multiple primary tissues may present concurrently (synchronous) or separated by a period of time (metachronous). Tumors that arise within 6 months of identification of the index primary tumor are generally considered to be synchronous, whereas those arising later than 6 months are defined as metachronous. Simultaneous primary squamous cell carcinomas of the keratinizing type have been described in 10% to 20% of cases,[401,405] whereas metachronous tumors arise in 20% to 30%.[400] In both instances, second primaries are mostly commonly thought to be associated with widespread cellular damage to the upper aerodigestive tract, a concept known as field cancerization.[410]

The theory of field cancerization proposes that DNA damage and premalignant molecular alterations do not only occur in a single cell that eventually gives rise to carcinoma as an isolated clonal event. Instead, it is thought that toxins such as alcohol or tobacco smoke, or repetitive injury from chronic inflammation and oxidative stress damage scattered cells throughout the affected mucosa.[410] These tracts of damaged cells may then give rise to multiple different neoplastic clones. Histopathologic assessment can discern damage in the form of epithelial dysplasia. However, not all altered cells may be apparent at the level of conventional H&E sections.[411] Immunohistochemical studies and molecular based techniques to detect common regulatory abnormalities associated with DNA-damaged cells (TP53 mutation, loss of heterozygosity, promoter methylation, or eIF4E overexpression) may predict local recurrence in such cases.[412–416]

Role of Immunocompromise in Multiple Malignancies.

Carcinoma is increasingly being recognized as a disease reflective of the failure of immune surveillance to eradicate altered cells. As discussed previously, patients who have squamous cell carcinoma with a healthy immune response in the form of tumor infiltrating lymphocytes have improved outcomes compared to those without. As a corollary to this, immunocompromised patients are at higher risk for development of carcinoma. Viral-associated carcinomas exemplify this risk. Merkel cell

carcinoma is often seen as a second malignancy in patients with an underlying lymphoma, particularly CLL/SLL.[417]–[419] Oropharyngeal HPV-associated squamous cell carcinoma, while being associated with very low rates of subsequent second malignancy,[399] may develop secondarily to immunocompromise—usually due to solid organ transplant[420]–[422] and potentially secondarily to chemoradiotherapy. Nonviral associated carcinomas of the oral cavity have also been reported to arise secondary to chemotherapy for ovarian cancer in patients with no other known risk factors.[423]

Ancillary Studies (Pathologic Toolbox) and Applications

Ancillary studies were developed to help elucidate diagnosis in cases where tumor histogenesis was not apparent on routine H&E-stained sections under light microscopy. Because proper therapy and clinical management require knowledge of specific tumor type, histochemical and immunohistochemical studies, along with electron microscopy techniques, were developed that could impart additional information as to the makeup of tissue and cellular components. Over the years, the understanding of the molecular basis for diseases of the head and neck has increased dramatically. Better understanding of the genomic, genetic, epigenetic, and proteomic alterations contributing to disease have come hand in hand with innovations in available technologies for evaluating underlying cellular alterations. Molecular and immunohistochemical findings are now able to guide diagnosis and can suggest targeted therapies for the treatment of malignancy based on identification of specific signaling pathway alterations. This section briefly reviews the diagnostic toolbox available to the modern pathologist, with examples of how these techniques contribute to clinical care.

Histochemical Stains

Histochemical stains are one of the oldest tools used by pathologists to analyze the components of tissue present in paraffin section. Hematoxylin and eosin, the routine stains for initial tissue evaluation, are histochemical

stains with affinity for negatively and positively charged tissue components, respectively. Other stains have varying degrees of specificity for both endogenous and exogenous compounds. Some stains detect particular chemical compounds (e.g., mucicarmine for epithelial mucins, iron stain, or melanin stain), whereas others are used for identification of microorganisms (Gram, Grocott-Gomori methanamine silver, Periodic acid Schiff [PAS], Ziehl-Neelsen, etc.) due to their affinity for complex carbohydrates or peptides seen in bacterial or fungal capsules. Others may be used to elucidate components of extracellular matrix, including reticulin, elastic stain, or Alcian blue (connective tissue mucins).[74] Prior to the era of immunohistochemistry, knowledge of tissue chemistry and appropriate application of histochemical stains were of vital importance in narrowing differential diagnoses and determining cellular makeup. Today, histochemical studies remain important in evaluation of inflammatory and infectious conditions, as well as playing a supportive role in diagnosis of a few neoplasms.

Immunohistochemistry

Immunohistochemistry relies on the detection of specific peptide antigens to discriminate between cell types, or to identify the presence of infectious agents. Although immunohistochemical staining techniques were developed in the 1970s, it was not until the late 1980s that the use of immunohistochemistry as a routine diagnostic technique in pathology became an important tool.[424]

Indirect immunohistochemical studies are based on antibody recognition of specific protein epitopes by polyclonal or monoclonal antibodies (derived from the serum of animals injected with the epitope in question or from the supernatant of in vitro hybridoma cultures, respectively). A secondary antibody conjugated to an enzyme is then used to recognize the FC region of the specific primary antibody, and the slide is incubated with the enzyme substrate, leading to a color reaction for visual detection of the presence of the epitope in question.[425]

Traditionally, immunohistochemistry has been used as an ancillary diagnostic study to distinguish the cell lineage (e.g., distinction of poorly differentiated squamous cell carcinoma from adenocarcinoma), site of origin (e.g., primary salivary gland adenocarcinoma, from metastatic

adenocarcinoma), or tumor subtype (e.g., intestinal type vs. nonintestinal type sinonasal adenocarcinoma).

More recently, immunophenotyping has been used to elucidate activation patterns of cell signaling pathways in carcinogenesis, by demonstrating altered expression of critical regulatory component, such as PTEN loss in oral[426] or thyroid carcinoma.[427,428] Although pathway expression studies reveal molecular alterations that are not entirely specific to one type of carcinoma, these analyses are increasingly important for theranostic purposes. For instance, membranous overexpression of the receptor tyrosine kinase Her-2 in salivary ductal adenocarcinoma is an indication that a patient may respond favorably to targeted therapy with trastuzumab.[429,430]

Immunohistochemical studies also have a role in the detection of infectious agents. Antibodies against specific pathogen-specific capsular antigens can help to elucidate the presence of viral infections, such as cytomegalovirus (CMV) or polyoma virus, or may detect hard-to-visualize bacteria, including spirochetes. Surrogate markers may also be used to assist the diagnosis of neoplasia and infection, and reflect changes in expression of endogenous proteins as a consequence of infection or oncogenic processes. Perhaps the most well known surrogate marker in diagnosis of head and neck cancer is $p16^{INK4a}$, the overexpression of which indicates HPV infection in oropharyngeal carcinoma. Care must be taken in the interpretation of such indirect biomarkers. P16 is a regulatory component in RB-mediated G1 cell cycle checkpoint signaling.[431] Both RB and p16 are negative regulators that function to inhibit cell cycle progression. When RB is down-regulated by exogenous viral proteins, p16 is reflexively up-regulated in an attempt to maintain homeostasis. However, p16 may be up-regulated in other contexts unrelated to viral infection, including both inflammatory conditions and other neoplastic contexts.

Technical issues in the performance of immunohistochemical studies may result in false-negative or false-positive results. False negatives commonly derive from the use of expired, degraded antibody, chromogen substrate, or other reagents; failure to perform adequate or appropriate antigen retrieval; tissue degradation; or inappropriate antibody incubation conditions, among other issues. False-positive studies most frequently result from failure to block endogenous tissue enzymatic activity and nonspecific interactions of antibody with other protein epitopes (often due to overly high concentrations

of antibody or inadequately stringent hybridization or wash conditions). In small laboratories, immunohistochemical studies are largely be performed by hand, resulting in greater variability of results from one run to the next and longer turnaround times. Large facilities with high volume of cases usually rely on automated staining machines for the majority of antibodies, resulting in greater standardization and more rapid processing.[432]

Thus, due to both technical and biologic reasons, there are inherent limitations in the interpretation of immunohistochemical studies. Furthermore, diagnostic utility of immunohistochemical studies is highly dependent on the experience of both the person performing the technical aspects of the study as well as the person interpreting the results. Interpretative errors can result from failure to recognize when a stain is technically faulty, lack of understanding of the appropriate subcellular localization of the antigen of interest, or, more commonly, from interpretive bias.[433] Interpretive bias results from assumptions made when selecting and interpreting antibody panels and from incomplete understanding of the specificity/sensitivity of the selected study for the diagnosis in question. One of the most frequent pitfalls in interpretation of immunohistochemical study is the evaluation of a single immunohistochemical study in isolation. No one antigen is ever 100% specific or sensitive for a diagnosis, and results must always be interpreted both within the context of tumor morphology and as part of an inclusionary and exclusionary diagnostic antibody panel. For instance, p63, a member of the TP53 family of transcription factors, is commonly expressed in stratified epithelium and basal cells of certain glandular structures.[434] In the head and neck, p63 is frequently used to diagnose poorly differentiated squamous cell carcinomas from salivary gland carcinoma or spindle cell squamous cell carcinoma from sarcoma. However, p63 is also expressed in salivary gland neoplasms with basal or myoepithelial differentiation, including mucoepidermoid carcinoma[435] and clear cell carcinoma[146] and may be rarely expressed in some spindle cell sarcomas.[436] Thus, expression of p63 alone is insufficient to render a specific diagnosis of squamous cell carcinoma.

One technique for minimizing subjective interpretive bias is the use of computer-assisted quantitative analysis. This method of immunohistochemical analysis is primarily used for tumors where quantification of a particular marker (e.g., KI-67 [Mib1], HER2, or TP53) has

prognostic or theranostic importance. Computer-assisted quantitative analysis has equal or improved reproducibility and accuracy compared to visual semiquantitative analysis for a variety of biomarkers.[437–439] In practice, however, the use of computer-assisted immunohistochemical analysis has not caught on widely, due to both preanalytic technical issues in staining reproducibility from case to case and analytic factors such the labor required to appropriately train the program.[440]

Electron Microscopy

Transmission electron microscopy (EM) is mainly utilized in pathology to evaluate cellular ultrastructure. Very thin tissue sections (<100 nm) embedded in a plastic polymer matrix are stained with heavy metals. A fine electron beam is then passed through the section, with the heavy metals impeding the beam due to their high density. This differential electron transmission is then detected on a fluorescent screen, which is magnified by a microscope for viewing.[441] EM revolutionized microscopy when it was first introduced in the 1950s and was responsible for much of the current understanding of the structure of cells and their component organelles, as well as for the detection and characterization of infectious disease, particularly viruses. However, since the advent of diagnostic immunohistochemistry and molecular testing, it has fallen out of favor in routine diagnostic practice, except in a few specialized situations. In the head and neck, EM is most frequently used in the evaluation of ciliary dyskinesia, a disease resulting from structural defects in proteins constituting motile cilia. Motile cilia are found in cells lining the respiratory tract, middle ear, fallopian tube, and sperm flagella. In the respiratory tract, cells with motile cilia are responsible for clearing mucus, and defective motility result in mucus accumulation and increased risk of respiratory tract infection.[442]

EM also continues to serve an important role in diagnosis of poorly differentiated tumors. Whereas immunohistochemical studies must be selected by the pathologist, and may be limited by minimal antigen expression, EM requires no a priori input and is therefore unbiased by preconceived inclusionary and exclusionary criteria. EM can distinguish, based on the presence of very few cells, squamous lineage (possessing desmosomes and bundles of cytoplasmic keratin filaments) from adenocarcinoma (short luminal microvilli), or melanoma (melanosomes), or

poorly differentiated neuroendocrine tumor (dense core granules).[441]

EM may be performed on either tissue specimens or on cytologic aspirates. Optimally, fresh tissue, no more than 1 mm in diameter, or cellular aspirate material is directly fixed in glutaraldehyde. EM can be performed on tissue removed from FFPE tissue blocks; however, ultrastructural preservation in such situations is often suboptimal.

Flow Cytometry

The use of flow cytometry in modern diagnostic surgical pathology is largely limited to the evaluation of hematolymphoid proliferations. Intact cells from fluid tumor aspirate, solid tumor aspirates, or fresh tissue biopsies are disaggregated and labeled with multiple fluorescent-tagged antibodies to specific immune antigens. Individual cells are then passed through a laser light source, allowing the detection of antigen coexpression on each cell. While detection and image analysis technologies once limited the number of antigens detectable in one reaction to four, modern technologies are enabling increasingly multiplexed reaction and detection assays.[443] Although flow cytometry can be quite sensitive, it is vital to provide appropriate clinical history so that appropriate antibody panels may be selected. In a patient with, for example, a history of a myeloid leukemia and a new mass in the neck, a panel with myeloid markers would be required to exclude myeloid sarcoma, whereas in most cases with only a history of “mass in the neck,” only a standard lymphoid panel for B-cell neoplasia is required. Flow cytometry is insensitive to detection of rare events, such as the small clonal population seen in Hodgkin lymphoma, and may result in false negatives for large cell lymphomas, due to cell fragility and propensity to lyse during specimen preparation and analysis.[444–446]

Flow cytometry may also be used on disaggregated nuclei from fresh or FFPE tissues to analyze DNA ploidy and fraction of cells undergoing DNA replication (S-phase).[447] Although several studies suggested that aneuploidy may be diagnostically[448,449] or prognostically[450] relevant in malignancy, aneuploidy may also be seen in benign neoplasms and represents a finding of uncertain significance in that context.[451] With advances in molecular diagnostics more precisely able to detect specific alterations at the DNA level, flow cytometric analysis of ploidy as a diagnostic technique has fallen

out of favor and remains largely a historical footnote.

Molecular Diagnostics

Molecular pathology is one of the most rapidly expanding disciplines within diagnostic pathology. Technically, molecular pathology is the study of disease via examination of subcellular factors, including proteins, DNA, RNA, and small molecules. Broadly interpreted, molecular pathology incorporates all facets of pathology, from the simplest histochemical stain to identifying the most complex posttranslational protein modifications by mass spectrometry. In common usage, however, molecular pathology as a discipline began with attempts to understand the genome structure and nucleotide alterations characteristic of disease (genomics and genetics). Since then, it has expanded to include gene expression profiling and proteomics, as well as investigations of regulatory mechanisms, such as miRNA, epigenetics, and posttranslational modifications, to name a few. Although many of the newer techniques pioneered in molecular pathology remain confined to the research setting, their contribution to understanding of disease pathogenesis may be rapidly translated to the clinical setting in the coming years.

Karyotype

The gold standard of classical cytogenetic analysis of chromosome number (ploidy) and structure is the metaphase karyotype. Tumor cells are taken from fresh pathology specimens and cultured in vitro. Dividing cells are then harvested and lysed to yield condensed metaphase chromosomes, the structure of which is visualized using partial enzymatic digestion and histochemical staining (typically with Giemsa stain). Such staining results in reproducible banding patterns unique to each chromosome pair. At best, conventional karyotypic banding may detect genomic alterations on a 1.5-megabase scale and typically has an average resolution of 7 to 10 megabases.[452] Due to this low resolution, small “cryptic” genomic alterations are undetectable by conventional karyotyping. Moreover, the source of genetic material in complex rearrangements and extraneous marker chromosomes may be impossible to identify. Further limiting the utility of karyotype is the difficulty in culturing tumor cells, which may not grow well under in vitro conditions or which may be overgrown by normal stromal

cells.

Cytogenetic studies have shown that genomic alterations are common in keratinizing squamous cell carcinoma of the head and neck, in particular losses of 3q, 5q, 7p, 8p, and 9p.[453,454] Although insufficiently specific for diagnostic purposes, such alterations were historically used to map chromosomal loci of tumor suppressor genes. Karyotypic studies are valuable in diagnosis of hematolymphoid malignancies and soft tissue sarcomas, both of which frequently possess characteristic chromosomal rearrangements,[455,456] and have the potential to be useful in other tumor types with characteristic translocations, including salivary gland carcinomas.

In Situ Hybridization

In situ hybridization (ISH) is a technique for visualizing specific DNA or RNA sequences present within cells of interest. Compared to conventional karyotype analysis, ISH has the dual advantages of increased speed and flexibility as to tissue preparation. Where karyotyping may require weeks for tumor cells to grow, ISH may be performed in a matter of days. With appropriate procedural modifications, ISH may be performed on frozen tissue sections, standard FFPE, or cytology aspirates and smears. Metaphase chromosomes are not required. Another advantage of ISH is that when intact tissue sections are used, it is possible to more accurately localize lesional tissue for evaluation.

ISH is performed using chromogen-labeled nucleotide probes complementary to specific sequences of interest. Probes [from 250 to 1,500 base pairs in length for RNA chromogenic ISH (CISH) to 50 to 500 kilobases for fluorescence ISH] cannot be used to detect single base pair mutations. Tissue sections or disaggregated tissue nuclei are treated to permeabilize cellular and nuclear membranes to the probe and then heated to denature nucleic acids. The probe is then added and allowed to anneal to the tissue DNA. After washing to remove excess probe and nonspecific interactions, the chromogen can be visualized by cytochemical stain (conventional ISH) or by fluorescence microscopy (fluorescence ISH). Unlike karyotypic analysis, ISH requires some a priori knowledge as to the abnormality that one is expecting to find. Probes are generated to specific sequences, and it is up to the treating team to convey necessary clinical information that along with histopathologic features will enable pathologists to select the most

appropriate test.

Chromogenic In Situ Hybridization.

CISH has long been used in the head and neck for the detection of pathogenic (viral) DNA. Nucleotide probes against specific DNA or RNA sequences are conjugated with an enzyme and incubated directly on permeabilized, denatured tissue sections and allowed to bind to complementary sequence within the tissue. After washing away excess and nonspecifically bound probe, the slide is incubated with colorimetric enzyme substrate to generate colored signal in order to visualize hybridized probe.[457] Because normal cells only have two alleles that may bind the probe, and it requires many enzymatic reactions to generate visible color, CISH is generally too insensitive for detection of small DNA mutations or deletions. Viral infection generates many copies of the viral genome or mRNA within an infected cell and is therefore readily detectable.[457] ISH for kappa and lambda light chain mRNA is also sometimes used in place of immunohistochemistry to type plasma cells neoplasms but lacks sensitivity.[458]

In the head and neck, the use of ISH to detect Epstein-Barr–encoded RNA (EBER) has proved invaluable in diagnosis of nonkeratinizing NPCs and lymphomas. HPV ISH for detection of high-risk versus low-risk HPV infections is widely used but is less sensitive or specific than PCR-based detection methods (discussed below).[121]

Fluorescence In Situ Hybridization.

Until recently, fluorescence in situ hybridization (FISH) was not considered a routine part of the diagnostic arsenal for tumors of the head and neck. Whereas the utility of conventional ISH is limited by the low resolution of the cytochemical chromogen, FISH is characterized by a relatively high resolution and, like conventional karyotypic analysis, is mainly used to identify the presence of alterations of genomic copy number or structure. The most commonly used FISH probe sets are locus/centromeric probes and break-apart probes. A third probe set, fusion probes, are less frequently seen in clinical practice.

Locus/centromeric probes function to enumerate copy number alterations of specific gene loci. The probe set involves two probes, one to the gene locus of interest and a second to the centromere of the chromosome the gene

is normally situated on. Each probe is tagged with a different color fluorescent chromophore to distinguish them from one another. The number of signals of the gene locus are counted and tabulated against the number of centromeric signals. In a normal cell, the ratio between target and centromere is 1–2:1 depending on if the cell is undergoing DNA replication. Thus, the centromeric probe acts as a control to normalize for aneuploidy (aberrant chromosome copy number) and tissue sectioning artifact. In the head and neck, locus/centromeric probes are most commonly used to evaluate for the presence of high-level *HER2* amplification in salivary ductal carcinoma, with low copy number increase and high-level amplification generally considered as target:centromere signal ratio ≥2 and ≥9 to 10, respectively.[459,460]

Break-apart probes consist of a set of probes designed to flank a specific gene or chromosomal locus of interest. As with locus/centromeric probes, each probe is tagged with a different fluorescent chromophore, typically green and orange. In a normal chromosome, the signals are juxtaposed such that they appear as a single yellow dot (due to spectral overlap) or as closely apposed green and orange dots. If a chromosomal translocation occurs such that the breakpoint lies in the region flanked by the probes, the signals become visualized as spatially distinct dots.

In recent years, a number of characteristic gene translocations have been identified in tumors of the salivary gland (Table 3.6), the existence of which has begun to transform diagnostic criteria. For instance, (hyalinizing) clear cell carcinoma of the salivary gland, first described in 1994,[461] was, until a few years ago, considered to be a diagnosis of exclusion, representing a “wastebasket” term for a heterogenous group of tumors. Recently salivary gland clear cell carcinomas were found to have a specific *EWSR1-ATF1* translocation in over 90% of cases,[146] whereas other salivary tumors lacked this gene rearrangement.[148] Thus, for the first time, clear cell carcinoma was proven to be a distinct entity. Similarly, identification of a characteristic *ETV6-NTRK3* translocation finally allowed mammary analogue secretory carcinoma, long misdiagnosed as a zymogen granule–poor form of acinic cell carcinoma, to be recognized as a distinct entity.[462,463] The therapeutic and prognostic implications of these subtypes are still being investigated. Nevertheless, FISH has now become an integral part of the workup for salivary gland neoplasia.

Thyroid malignancies also harbor recurrent translocations, albeit at lower

frequency than do *RAS* or *BRAF* point mutations, with *RET/PTC* rearrangements present in ~20% of papillary carcinoma and *PAX8-PPARγ* fusions in 35% of follicular carcinomas and a limited number of follicular adenomas, NIFTPs, and FVPTCs (Table 3.7).[176] Unfortunately, the relative infrequency of these fusions and the diverse array of *RET* family members involved, as well as limited data as to their prognostic significance, largely precludes utility of diagnostic FISH tests for these rearrangements.

With both enumerative and break-apart FISH probes, analysis of FISH performed on 4-μm paraffin section requires signal evaluation in between 100 and 200 tumor nuclei for accurate interpretation, although in some circumstances, such as very small biopsies, 50 may be used. High numbers of nuclei are evaluated to compensate for technical factors such as sectioning artifact or contamination of counts by nonneoplastic stromal or inflammatory cells. True quantitative analysis is not possible.

The use of disaggregated tumor nuclei for FISH, although technically more challenging, does allow for signal number quantitation, although contamination by nontumor cells poses a higher risk than on paraffin section. The use of disaggregated nuclei for FISH is primarily a consideration when precise distinctions must be made as to the cutoff for gene locus amplification. FISH is also susceptible to false-negative results and technical failures due to nucleotide degradation during processing and may not yield results in cases that have undergone over- or underfixation or that have been subjected to decalcification.

Spectral Karyotyping.

Spectral karyotyping (SKY) is a form of FISH that may be used to more precisely identify chromosome of origin in complex karyotypes. An array of chromosome-specific nucleotide probes, each tagged with different fluorescent chromogens, are hybridized to a metaphase preparation, thereby "painting" components of each chromosome in a different color.[464] This technique may identify small insertions and can be used to resolve complex rearrangements, but its use in clinical practice is limited by technical difficulties in performing and interpreting the study.

Polymerase Chain Reaction

Polymerase chain reaction (PCR)–based techniques offer a higher resolution

look at nucleotide sequence abnormalities than does either karyotyping or ISH. PCR is a highly flexible technique that may be performed on genomic DNA or RNA transcripts [reverse transcriptase–PCR (RT–PCR)] and has been incorporated into a variety of assays to detect the presence of infectious pathogens, genetic point mutations, deletions, chromosomal rearrangements (including cryptic insertions, inversions, and translocation), and even epigenetic silencing via promoter methylation. PCR-based reactions are also the foundation for second- and third-generation sequencing technologies.

Real-time (quantitative) PCR (Q-PCR and QRT-PCR) is an improvement on traditional, semiquantitative PCR. QPCR uses a system of paired fluorescent chromophore and quencher molecules for detection of PCR products after each cycle of amplification. Upon successful amplification, fluorescent chromophores associated with either primers or sequence-specific probes for the amplicon of interest are dissociated from the quencher, and quantitation of transcript number is performed via analysis of fluorescence intensity.[465] QPCR has the advantage over conventional PCR of more accurate quantitation, high sensitivity, and the ability to multiplex reactions, using differently colored chromophores. These advantages have made QPCR the preferred platform for both research and clinical diagnostics.[466]

RT–PCR is sometimes used to detect chromosomal translocations in mRNA transcripts. However, its use in this context is limited by the requirement that both of the translocation partners and their respective breakpoints be known. This technique is not broadly implemented in the clinical diagnosis of head and neck carcinoma, in part because recurrent fusions are still being elucidated in epithelial neoplasia, and fusion partners and their frequencies are as yet poorly understood, and in part due to technical limitations of working with severely fragmented transcripts. In most cases, RT–PCR performed on FFPE tissues is ideally designed for a transcript of 150 base pairs or less and a maximum of 300 base pairs.

PCR offers improved sensitivity to ISH for the presence of exogenous DNA or genetic mutations, due to the target sequence amplification process inherent to PCR. Thus, PCR is an ideal technique for small biopsies or when only scant DNA or RNA can be retrieved. Care must be taken to avoid cross- and carry-over contamination from other specimens being processed. Preanalytic factors also play a role in the success of PCR. Tissue degradation begins at the moment of surgery with ischemic changes. Both DNAses and

RNAses are active in tissue, and unfixed specimens at room temperature do have measurable declines in the amount and quality of retrievable nucleotides. Specimen processing in formalin results in further degradation and fragmentation, with RNA being the most susceptible. Decalcification, which often relies on strong acids, may further degrade nucleotide quality.

PCR-based techniques are sometimes used as ancillary studies in the diagnosis of thyroid nodules with indeterminate cytology on FNA biopsy (Bethesda class 3–5). *BRAF* mutations (n.T1799A, p.V600E) are relatively specific to papillary carcinoma and are not present in benign lesions, whereas *NRAS* or *HRAS* mutations (most commonly codon 61) are more common in follicular pattern lesions (including follicular variant of papillary carcinoma, NIFTP, and follicular carcinoma, as well as, less frequently, follicular adenoma.)[173] The regions of interest harboring possible mutation are readily amplified by PCR, and wild-type and mutant alleles are then detected by melting curve analyses and/or Sanger sequencing. *BRAF* mutational testing has variable sensitivity for PTC, with detection rates as low as 39% and accuracy from 69% when applied to all tumors classified as Bethesda 3–5.[467,468] When testing is limited to Bethesda 3 lesions only, the sensitivity drops to 14%.[467] Limiting testing to indeterminate lesions (Bethesda 3 and 5) improves sensitivity to 80% when combined with cytologic findings.[469] The specificity of *BRAF* mutation for malignancy is >99%.[468–470]

Combined testing for a panel of mutations, including PCR for *BRAF*, and *RAS* mutations and FISH for *RET/PTC* and *PAX8/PPARγ* rearrangements, offers improved sensitivity for malignancy, at the cost of specificity, with ~87% of cases with mutations subsequently being shown to be histologically malignant. In contrast, approximately 6% to 28% of mutation-negative nodules were ultimately malignant, depending on whether lesions had been previously classed as Bethesda 3, 4, or 5.[471]

In some institutions, PCR has supplanted ISH as a more reliable test for detection and genotyping of HPV viral infection in oropharyngeal squamous cell carcinoma. To screen for the presence of high-risk HPV, consensus primers are chosen that will amplify a high number of different HPV genotypes. Target sequences are conserved regions of the HPV genome such as the gene for the L1 capsid protein.[472,473] In cases that test positive for high-risk HPV, the specific genotype can then be identified using either

direct sequencing or secondary genotype-specific PCR (often performed with QPCR and primers to the L1 or E6/E7 regions of the HPV genome, as a multiplexed reaction), among a variety of other techniques.[474]–[476] These tests have high sensitivity for detection of HPV.[121]

Array-Based Technologies

Newer technologies in nucleotide analysis are based on the principle of massively parallel processing of short fragments of DNA/RNA followed by computational analysis with reference to a source database to identify quantitative or sequence variations.

Array-based techniques such as array comparative genomic hybridization (array CGH) and gene expression analysis (GEA) rely on a chip upon which thousands of short oligonucleotide probes are immobilized. Probes are then hybridized to fluorescently labeled nucleic acids in the analyte sample; intensity analysis of probe signal allows for quantitation of copy number of DNA or RNA (cDNA). Expression arrays are also used to assess noncoding RNAs such as microRNA (miRNA) expression profiles. CGH is performed to detect copy number variations (genomic gains or losses). Array CGH offers considerable advantages over its precursor, metaphase CGH, in that the use of a standardized array allows significantly finer detail as to the sites of copy number variations, providing resolution at the 100 to 200 kbp level (compared to 5 to 10 megabases for conventional CGH), while also offering increased sensitivity of detection.[477]

Gene expression array assays have gained popularity in clinical diagnostics for assisting risk stratification of thyroid cytology specimens with indeterminate risk of malignancy. Understanding the limitations of such techniques is critical for proper application in the clinical context. As described above, mutational analysis in indeterminate thyroid FNAs have a low sensitivity for malignancy. A gene expression classifier developed by comparing expression profiles of benign entities against those of malignant tumors was, in pilot studies, reported to have 84% specificity and sensitivity >90%.[478] In a subsequent validation series, sensitivity for malignancy was found to be 92% but specificity only 52% in indeterminate lesions.[479] In practical terms, a negative result for an indeterminate nodule has a NPV of 94%[479] and can be used to exclude malignancy, but a positive result is not

informative.

Many microarray-based gene or miRNA expression profiling studies have been reported in the head and neck literature for squamous cell carcinomas, proposing to variously improve prediction of outcomes, or for screening purposes, but these assays are not yet ready for clinical use.[480] Gene and miRNA expression profiling of saliva has also been proposed as a diagnostic and theranostic tool for inflammatory conditions such as Sjögren syndrome.[481]

Next Generation Sequencing.

There are a wide variety of second and third technologies in development or practice for sequencing of high-volume data sets (genomic, exomic, transcriptomic DNA). Most second-generation sequencing is characterized by massive throughput at relatively low cost. These technologies have led to the revolution in so-called personalized medicine in which it is now possible to analyze the entire exome of protein-coding sequences in normal or neoplastic tissue for only a few thousand dollars.[482,483] Most second-generation technologies rely on prior specimen amplification. These amplified templates are immobilized on a substrate and synchronously analyzed using a PCR-based strategy known as sequencing by synthesis. Sequencing reads are obtained using fluorescently labeled nucleotides, with serial imaging after each nucleotide addition (“wash and scan cycles”). Sequence read lengths are shorter than conventional Sanger sequencing, and computational analysis is required to align thousands of overlapping reads into complete sequences.[484] Next generation sequencing (NGS) is currently gaining in favor is some institutions for screening tumors for broad panels of actionable or diagnostic genetic or genomic alterations. Such alterations most commonly consist of point mutations or gene fusions that can readily be detected using customized probe sets for the specific regions of interest. In head and neck cancer, NGS panels are most commonly utilized for diagnosis of thyroid tumors in cytologic preparations. It should be noted that widespread adoption of NGS in pathologic diagnosis of the head and neck may be limited by prohibitive cost of validation and heavy regulatory requirements in some states.

The aim of many third-generation sequencing technologies is to provide reads at the single molecule level without a need for either an initial

amplification step or synchronized sequencing reactions. However, currently, third-generation technologies suffer from lower raw read accuracy compared with first- or second-generation sequencing, with error rates of at least 5%.[484] Technologic hurdles facing both second- and third-generation technologies include developing adequate informatic infrastructure for computation and interpretation of large, complex data sets and ensuring fidelity and relevance of results in the clinical diagnostic context.

Proteomics

Modern proteomics studies use mass spectroscopy to identify peptide fragments, which then are analyzed to reconstruct proteins present in a tissue or fluid sample. Depending on the type of mass spectroscopy performed, the expression can be quantitated or peptides assessed for posttranslational modifications such as phosphorylation or acylation. In this way, a snapshot of the actual cellular components at a given point in time can be identified. The use of proteomics as a diagnostic modality is somewhat limited in anatomic pathology, in part due to the severe alterations and damage to cellular proteins from formalin fixation and processing. However, in the research setting, proteomic analyses are beginning to gain prominence in the identification of potential druggable targets.[485]

Solid phase microarray platforms such as reverse phase protein array (RPPA) are another way to detect presence of proteins in cellular extracts. Lysates are printed, in replicate, as multiple individual spots on the microarray and then incubated with antibody against the antigen of interest. Unlike mass spectroscopy, however, the targets of interest must be determined beforehand in order to select and validate antibodies.[486] At the current time, proteomic studies are of growing interest to researchers in the field of personalized medicine but are not yet ready for application to clinical practice.

Epigenetics

Epigenetics is the study of modifications affecting the chromosome without altering DNA sequence.[487] Such modifications include silencing of gene promoters by hypermethylation, as well as modifications to chromatin conformation by posttranslational modifications to histones.[488] Studies are

conducted using a variety of molecular techniques including methylation-specific PCR, proteomics, and immunohistochemistry, among others. Epigenetic modifications are not actively studied for diagnostic purposes at the present time; however, studies are ongoing into epigenetic profiles of head and neck carcinomas,[489–493] with the hope that better understanding the effects of these alterations on gene expression will lead to improved risk assessment and therapies for these malignancies.

Conclusions

Tremendous advances have been made in the past few decades in establishing tumor diagnosis and prognosis based on histopathologic and molecular features. The ever-accelerating pace of modern medicine leads to challenges in keeping up with the latest advances in disease biology. Nevertheless, treatment planning is reliant upon tissue diagnosis, and the entire multidisciplinary team must work together to understand the implications of new findings and evolve their approach to meet new challenges. At the same time, an appreciation of the basics, including handling of the gross specimen and, in particular, evaluation of margins, cannot be overlooked, even in the molecular age.

4 Epidemiology, Demographics/Disparity

Stacey A. Fedewa Amy Y. Chen

Cancer may involve many sites in the head and neck including the oral cavity, pharynx, larynx, salivary glands, thyroid, and sinonasal cavity. These cancers have a variety of biologic behaviors, and whereas some of these subsites share common risk factors, others do not. Smoking is a major risk factor for cancers of the oral cavity and larynx but is not considered a risk factor for cancer of the thyroid. Human papillomavirus (HPV) is a risk factor for squamous cell carcinoma of the oropharynx but not for other more common cancers of the head and neck such as larynx and thyroid. The risk factors for cancers of the head and neck vary by site (location); therefore, the incidence of cancers of the head and neck, as shown in Tables 4.1 and 4.2, varies markedly across sites, time, and gender. The risk factors, incidence, prognosis, and survival will be presented separately for each site. The discussion in this chapter is mostly confined to the United States. Information on global trends in cancer of the head and neck appears elsewhere in this book (see Chapter 25).

Table 4.1 Male Age-Adjusted Incidence by Cancer Site, 1973–2009

	1973–1989	1990–1999	2000–2009	APC 2000–2009
Oral cavity and pharynx	20.19	17.55	15.80	–0.1

CANCER OF THE ORAL CAVITY AND PHARYNX

Approximately 29,620 men and 11,760 women in the United States are diagnosed each year with cancer of the oral cavity and pharynx.[1] Cancer of the oral cavity and pharynx (OCPC) includes several subsites: lip, tongue, salivary glands, floor of the mouth, gum and other mouth, nasopharynx, tonsil, oropharynx, hypopharynx and other oral cavity, and pharynx. Other oral cavity and pharynx cancers include Waldeyer ring, overlapping lesions of lip, oral cavity, and oropharynx as well as not otherwise specified (NOS) cancers. As shown in Figure 4.1, the most common type of OCPC is cancer of the tongue (28%), followed by tonsil (15%) and gum and other mouth (14%). Squamous cell carcinoma is the most common cancer (82%) of OCPCs. Other less common histopathologies include adenocarcinomas, mucoepidermoid carcinomas, as well as ductal and lobular cancers.[2]

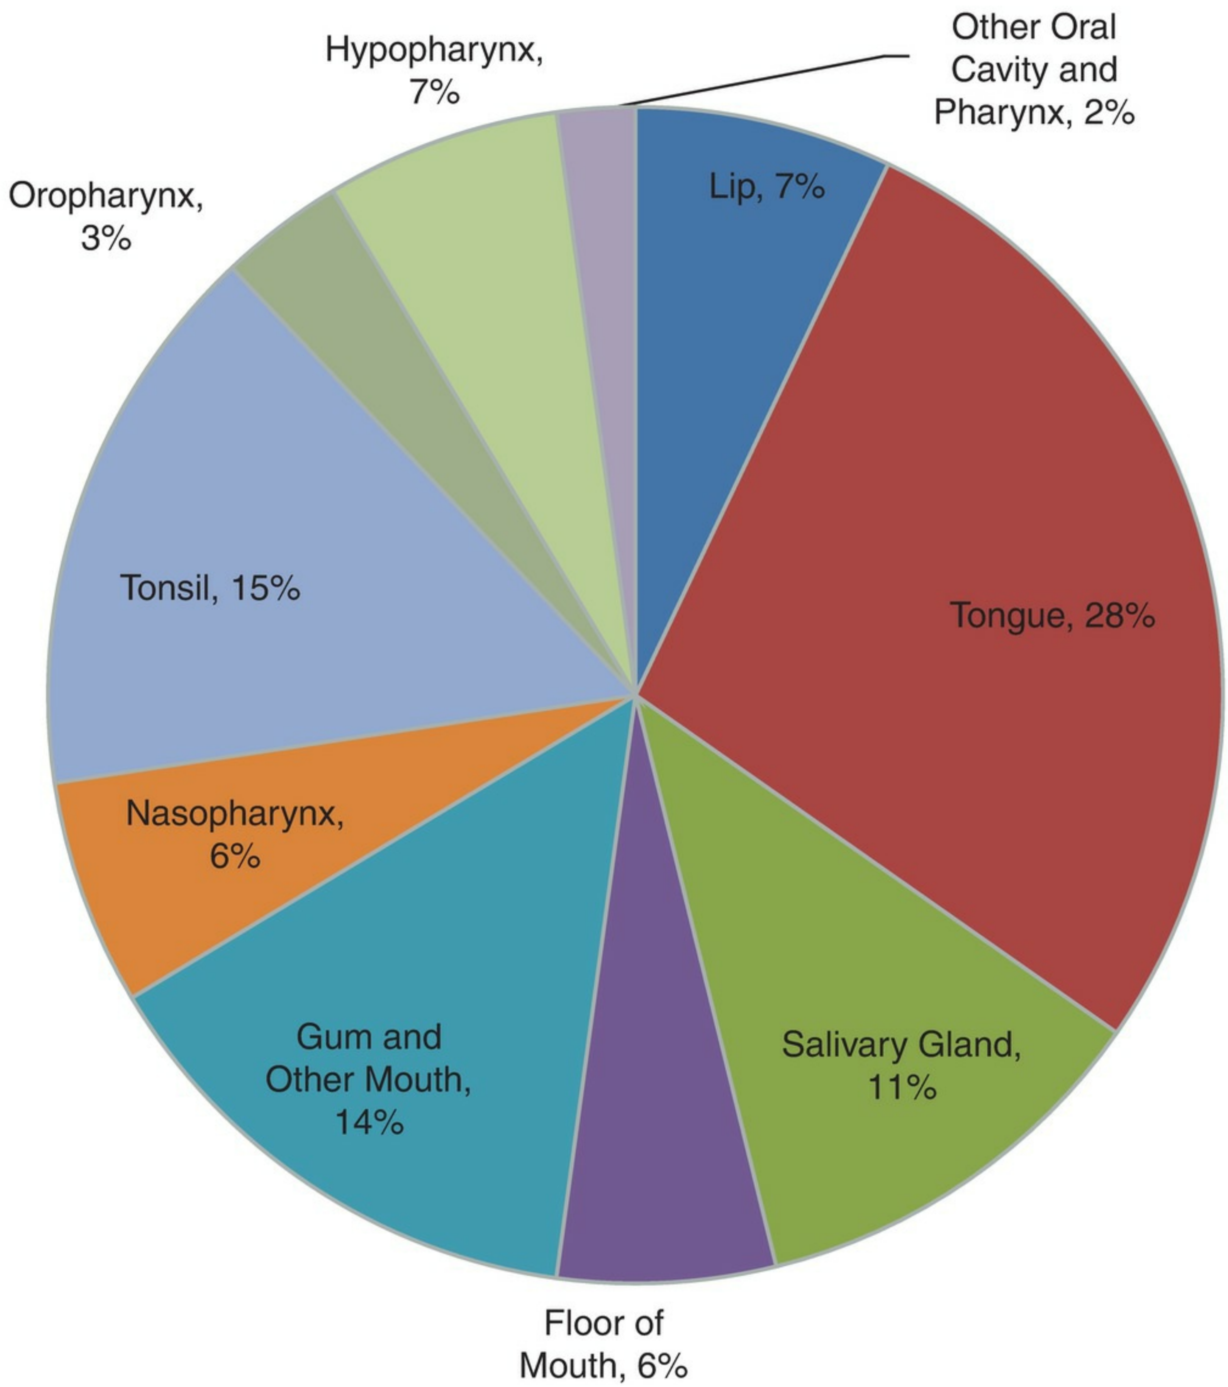

Figure 4.1. Distribution of cancer of the oral cavity and pharynx by subsite in SEER 18 2000–2009. (Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission.

http://www.seer.cancer.gov)

Risk Factors

The International Agency for Research on Cancer (IARC) has classified smoking tobacco as a cause of cancer of the oral cavity.[3] Studies have consistently shown an increased risk of cancer of the oral cavity and pharynx among smokers.[4–9] Case–control studies have reported up to 11 to 12 times risk of OCPC among current smokers compared to never smokers,[4,5] and the risk of OCPC increases with amount and duration of smoking.[6–9] In addition, the synergistic effect of alcohol on smoking has been established in several studies.[6,7,10] For example, among never drinkers, the odds of oral cavity and pharyngeal cancer are 1.7 to 1.9 higher for cigarette smokers, and for heavy drinkers, these odds are 9.60 to 11.37 higher.[6] There is some heterogeneity in the effect of cigarette smoking by OCPC subsite as tobacco exposure is found to be more strongly associated with cancers of the soft palate than other sites.[11] Additionally, the use of black versus blond tobacco may have an even greater risk of oral cavity and pharyngeal cancer.[12] Among former smokers, the risk of cancer of the oral cavity is less than that of smokers, and one study reported that after 10 years of quitting, former smokers had the same risk of OCPC as never smokers.[9,13]

Several forms of smokeless tobacco are associated with cancer of the oral cavity and pharynx. Smokeless tobacco in the form of snuff, which is found most commonly in the United States, is independently associated with cancer of the oral cavity and pharynx in US studies.[14] However, studies of smokeless tobacco in Sweden and Norway, where moist snuff or snus is more common, have not reported increased odds of oral or pharyngeal cancer.[15,16] Another form of chewing product called betel quid used in Asia that may or may not contain tobacco, is also associated with OCPC. IARC concluded that betel quid with tobacco causes cancer of the oral cavity and pharynx, whereas betel quid without tobacco causes cancer of the oral cavity only.[17,18]

Not only does alcohol interact with tobacco to increase the risk of cancer of the oral cavity and pharynx, but also there is an independent contribution of alcohol on OCPC.[16,19,20] Among nonsmokers, the risk of cancer of the oral cavity and pharynx is elevated among alcohol drinkers compared to

nondrinkers.[21,22] A dose–response relationship between alcohol consumption and cancer of the oral cavity and pharynx has also been observed as heavy drinkers have a particularly high risk of cancer of the oral cavity and pharynx.[10,16,19,21] A meta-analysis found a 4.6- and 6.6-fold increase in odds of cancers of the oral cavity and pharynx among heavy drinkers compared to never drinkers, respectively.[23] Some studies have suggested variations in the effect of alcohol by subsite; however, the pattern is inconsistent across studies.[10,12,24]

Although historically, cancers of the oral cavity and oropharynx have been attributed to tobacco and alcohol, in recent years, an increasing number of cases of squamous cell carcinoma, particularly those in the oropharynx, have been associated with HPV infection. Several case–control studies have demonstrated an association between HPV and the risk of squamous cell carcinoma of the head and neck, independent of tobacco and alcohol use.[25–28] A multicenter case–control study containing 1,670 cases and 1,732 controls from nine countries reported a positive association between HPV deoxyribonucleic acid (DNA) positivity in oral biopsies and oropharyngeal cancer (OR 4.9, 95% CI 2.6 to 9.1), after having been adjusted for demographic information as well as smoking and alcohol intake.[26] In the same study, the association was even stronger when the presence of high-risk HPV 16 was considered.[26] A subsequent case–control study in the United States also reported a strong association between cancer of the oropharynx and HPV oral infection (adjusted OR 14.6, 95% CI 6.3 to 36.6) as well as HPV 16 E6 and E7 positivity (OR 58.4, 95% CI 24.2 to 138.3).[27]

HPV 16 accounts for the majority of HPV-related cancers, followed by HPV-18, and even more rare are HPVs 33, 6, and 11.[26,29,30] Case series report a wide range of HPV prevalence from 4% to 80% among oral cavity squamous cell carcinoma (OCSCC) and 14% to 57% among oropharyngeal squamous cell carcinoma (OPSCC), which is likely due to variations in populations, risk factors, and HPV detection methods.[29] A pooled analysis of over 2,500 OCSCC cases across several continents including Asia, Europe, Australia, North America, and South America reported a 23.5% (95% CI 21.9 to 25.1) prevalence, whereas the prevalence of HPV positive among 969 OPSCC cases in this pooled analysis was higher (35.6%, 95% CI 32.6 to 38.7).[30] Though the aforementioned pooled study reported an overall higher

HPV positivity among North American cases of OPSCC (47%) and OSCC (16%) than the worldwide combined estimate, other multinational studies have shown no differences in HPV prevalence among OPSCC and OSCC across continents.[26]

The potential synergistic effect of tobacco, alcohol, and HPV positivity is less well understood. Several investigators have studied this issue using a variety of methods including hospital- and population-based case–control studies with incidence of cancers of the head and neck, whereas some studies included only cancers of the oropharynx. A population-based study of oral cavity and oropharyngeal cancer reported a higher prevalence of smoking in HPV-seropositive cancers (31.3%) compared to HPV-seronegative cancers (20.1%).[27] The finding of additive interaction for tobacco and HPV exposure has been observed in other studies as well.[26] However, a hospital-based case–control study found a similar proportion of smokers in HPV-positive (63%) and HPV-negative (67%) cases.[31] Similarly, other studies have found no interaction between HPV and smoking.[25,32]

Some occupational studies have found increased odds of cancer of the oral cavity and pharynx among workers exposed to aromatic amines, polycyclic aromatic hydrocarbons, solvents, and nitrosamines[33,34]; however, these associations are not consistent across studies and some studies were unable to control for tobacco use. Consumption of mate, a popular infused drink in parts of Latin America, may be related to increased cancer of the oral cavity though it is not known if the increased risk is due to its hot temperature, a potential carcinogenic effect of mate, or a combination of the two.[35,36] Fruits and vegetables are protective against OCPC; a pooled analysis indicated that high vegetable consumption was associated with a 50% reduction in OCPC.[37] In contrast, individuals with diets high in meat and dairy, controlling for alcohol and tobacco consumption, are at an increased risk of cancer of the oral cavity.[38] Other factors related to oral cavity cancer include a family history as cases with a first-degree relative with cancer of the oral cavity are at an increased risk for the disease after taking into account their consumption of alcohol and tobacco.[39] Inheritable disorders, including Fanconi anemia, are also linked to cancer of the oral cavity.[40] Additional genetic mutations that may be related to oral cavity mutation include germline mutations in p16.[41]

Descriptive Statistics

Incidence Patterns

Cancer of the oral cavity and pharynx is more common in males than females as shown in Tables 4.1 and 4.2.[42] The higher incidence among males compared to females is likely due to higher smoking rates and alcohol consumption among males. Incidence increases with age; incidence rates among those <40 years of age are <7 per 100,000 and increase to 11.7 among those aged 45 to 49. Incidence rates continue to increase to 19.9 per 100,000 for ages 50 to 54 and double by the age of 70 to 74 where the incidence rate is 40.1 per 100,000.[42] Globally, the age-standardized incidence rates for cancer of the oral cavity in developed and developing countries are estimated at 6.9 per 100,000 men and 4.6 per 100,000 men, respectively.[43] Cancer of the oral cavity and pharynx is nearly equivalent among women in developed (2.4 per 100,000 women) and developing (2.6 per 100,000 women) countries.[43] Among men in the United States, Whites have the highest age-adjusted incidence of cancer of the oral cavity and pharynx (16.7 cases per 100,000 men) followed by Blacks (14.9 per 100,000 men), Asian/Pacific Islanders (11 per 100,000 men), American Indian/Alaska Natives (11.1 cases per 100,000 men), and Hispanic men (9.3 per 100,000) (Fig. 4.2).[2] For females, the incidence of OCPC is also highest among whites; however, the differences by race are less marked than patterns observed for males (Fig. 4.3).[2] The overall higher incidence of cancer of the oral cavity and pharynx among whites compared to blacks reflects higher smoking rates among whites compared to blacks.[44] Furthermore, the prevalence of adult blacks who report any alcohol consumption and heavy alcohol consumption is less than that of whites.[45] Incidence patterns by race vary by subsite where the incidence of cancer of the palate, tonsil, and pharynx was higher among blacks than whites for males and females. Cancer of the lip is more common in whites than blacks; this difference may in part be due to higher susceptibility to solar keratosis among whites.[46]

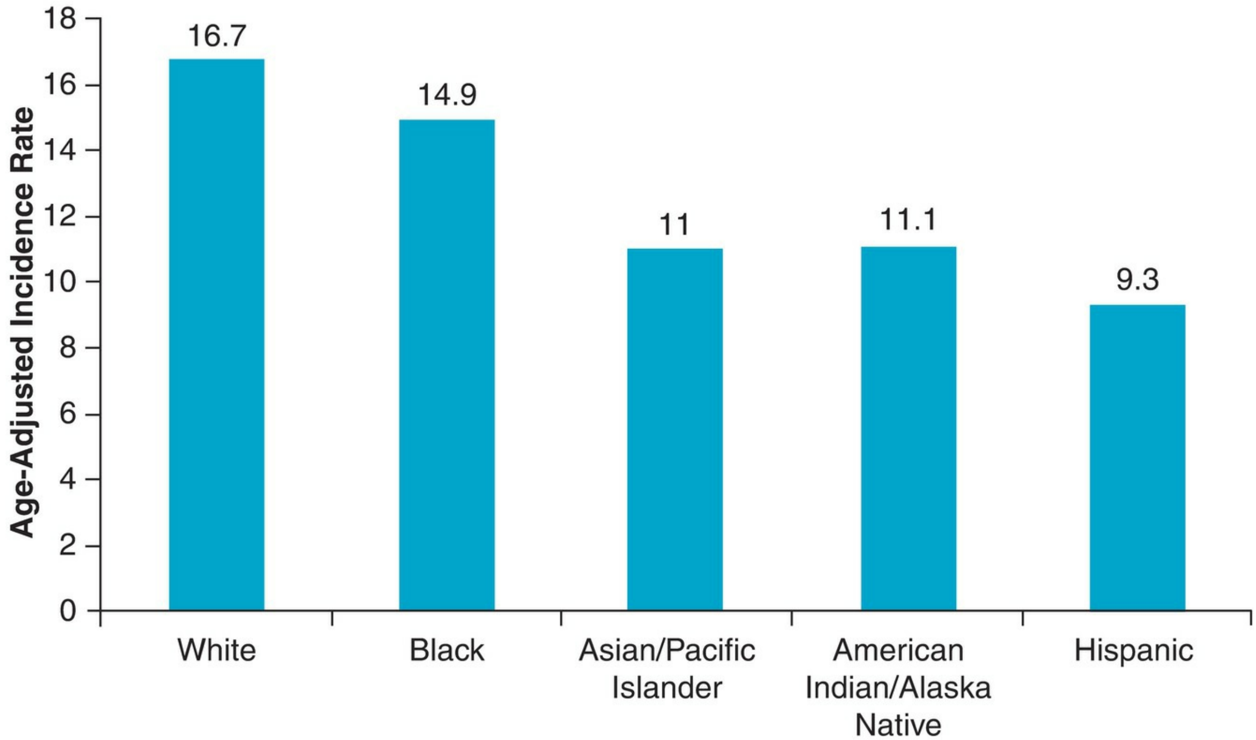

Figure 4.2. Age-adjusted incidence of cancer of the oral cavity and pharynx by race/ethnicity among males, SEER 18 2006–2010. (Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov)

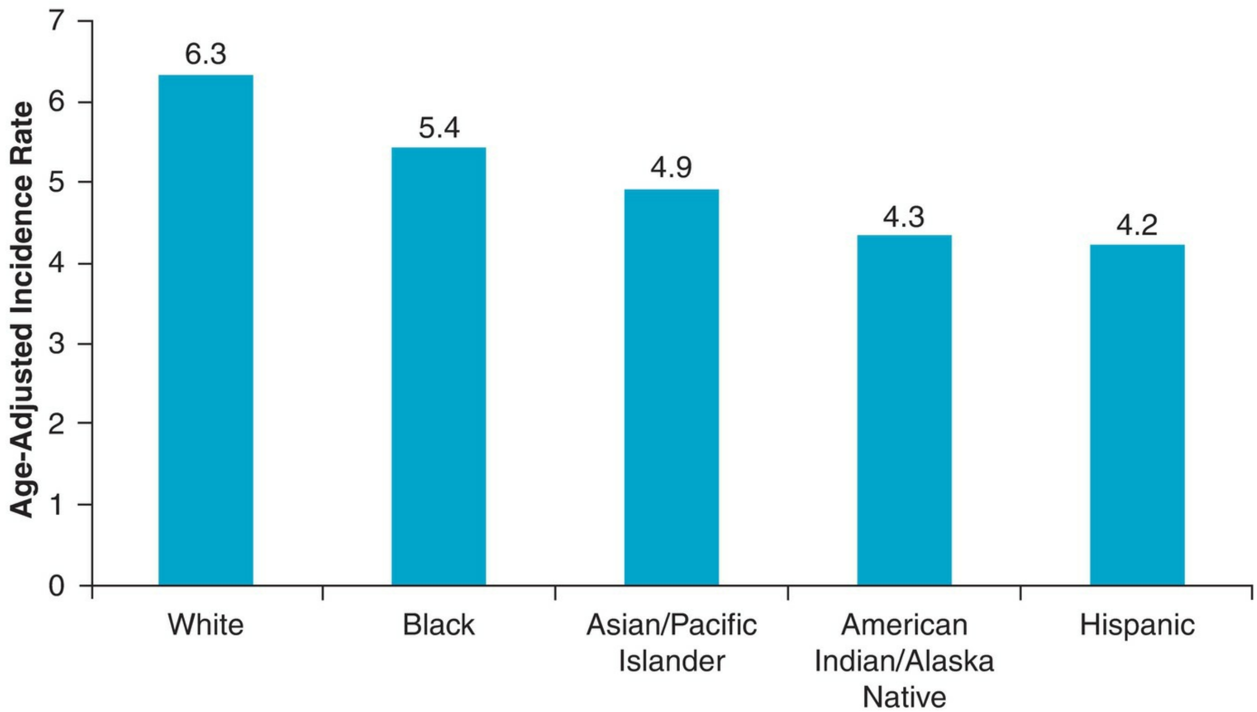

Figure 4.3. Age-adjusted incidence of cancer of the oral cavity and pharynx by race/ethnicity among females, SEER 18 2006–2010. (Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov)

Most recent studies of trends in cancer of the oral cavity and pharynx have been examined in the context of HPV-associated and non–HPV-associated cancers. HPV-associated cancers include lingual tonsil, palatine tonsil, and Waldeyer ring, whereas non–HPV-associated cancers include tongue, gum, floor of the mouth, and palate.[47] HPV-related squamous cell carcinoma (SCC) of the oral cavity and oropharynx have been increasing, whereas non–HPV-associated SCC of the oral cavity and oropharynx have been decreasing as depicted in Figure 4.4.[47–49] Between 1988 and 2004, HPV-related OPSCC increased 225% whereas HPV-unrelated OPSCC declined 50% during the same time period.[49] Starting in 2004, the incidence of HPV-related OPSCC and OCSCC approached non–HPV-related OPSCC and OCSCC.[47] Declines in HPV-unrelated OPSCC are attributed to the

reduced prevalence of cigarette smoking in the United States as well as decreases in per capita use of hard alcohol.[47] Smoking prevalence for adults in the United States has decreased from 42.4% in 1965 to 18.9% in 2011.[44] HPV-related OPSCC and OCSCC have increased across all age groups; however, there are particularly marked increases in more recent birth cohorts, suggesting differences in sexual practices over time. Though data on HPV prevalence in cancers of the oral cavity over time are limited, a study in Colorado reported that the prevalence of HPV in cancer of the oropharynx rose from 33% in the 1980s to 82% in the mid-2000s.[50]

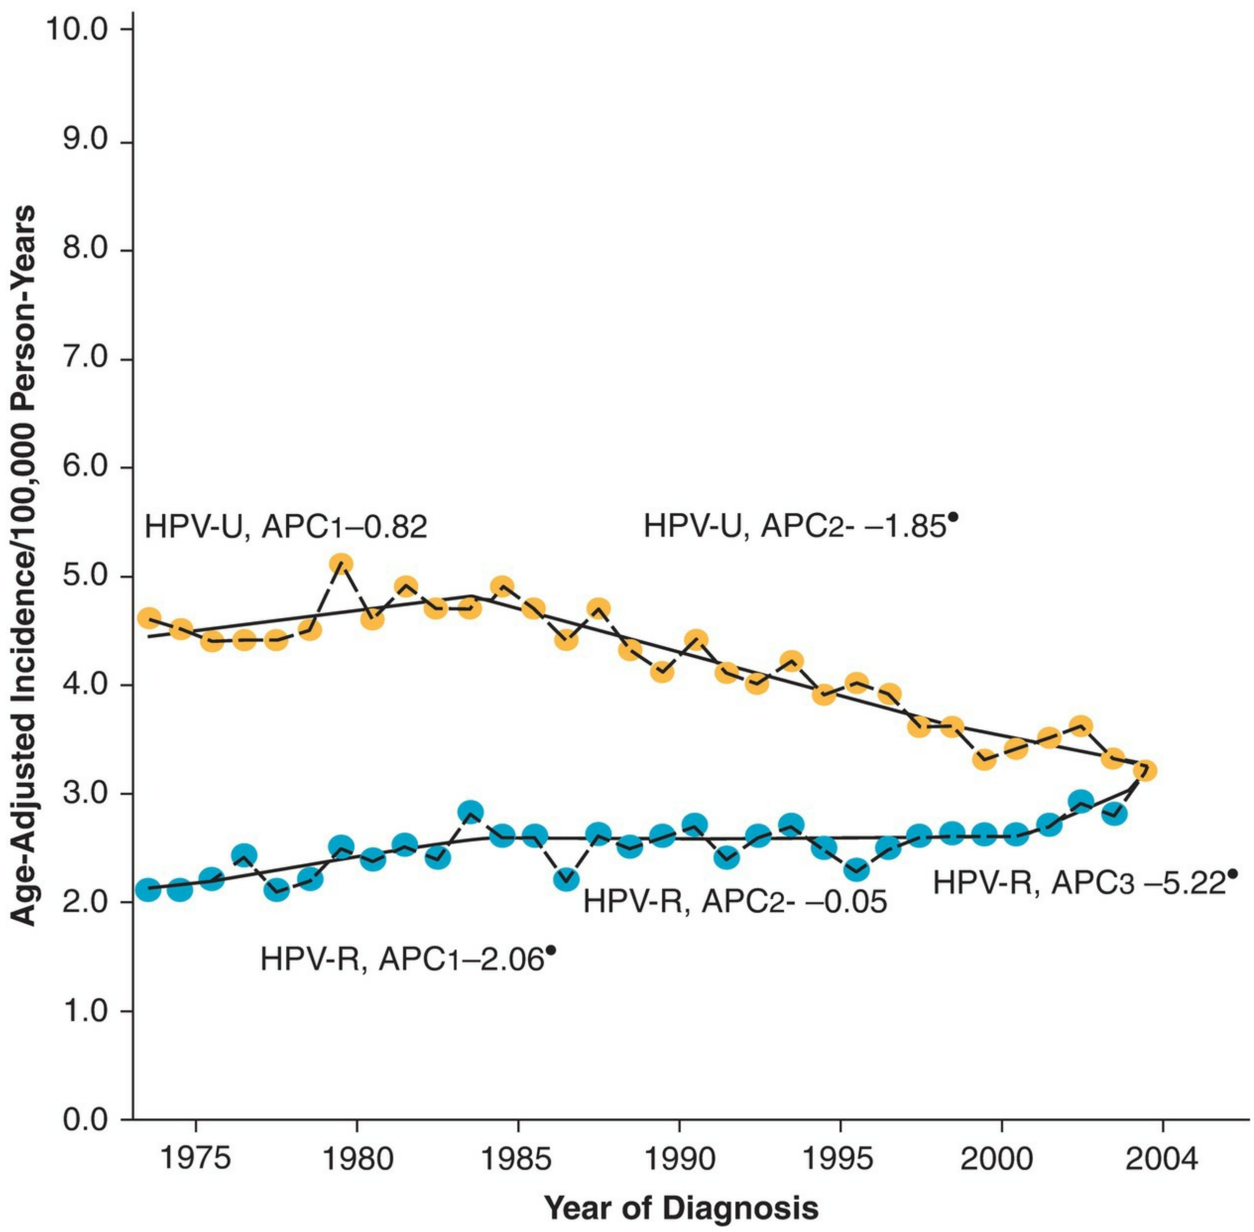

Figure 4.4. Incidence of HPV-related and HPV-unrelated squamous cell carcinomas of the oral cavity, 1975–2004. (Chaturvedi AK, Engels EA, Anderson WF, et al. Incidence trends for human papillomavirus-related and -unrelated oral squamous cell carcinomas in the United States. *J Clin Oncol.* 2008;26:612–619.)

In general, HPV-related OPSCC and OCSCC incidence has increased among white men; however, the incidence among black males has declined.[51] This opposing temporal trend for black and white males has led to dwindling overall differences in black–white incidence rates as shown in Figure 4.5 where incidence trends for squamous cell carcinoma of the oral cavity and pharynx (excluding lip, salivary glands, and nasopharynx) are displayed. For example, the incidence of HPV-related OSCC for black men was double that compared to white men between 1973 and 1991, and between 1992 and 2007, the increased incidence among black men was only 43% higher.[51] A recent study also found that HPV-related OSCC incidence rates particularly increased for men residing in low socioeconomic neighborhoods.[52] For women, HPV-related OPSCC and OCSCC have recently declined for both black and white women, though the incidence among black women remains 25% higher relative to white women. Asian/Pacific Islanders and Hispanics have significantly lower HPV-related OCSCC and OPSCC compared to whites for both males and females.[51] These temporal differences in incidence by race may reflect differences in sexual practices by race/ethnicity.[51]

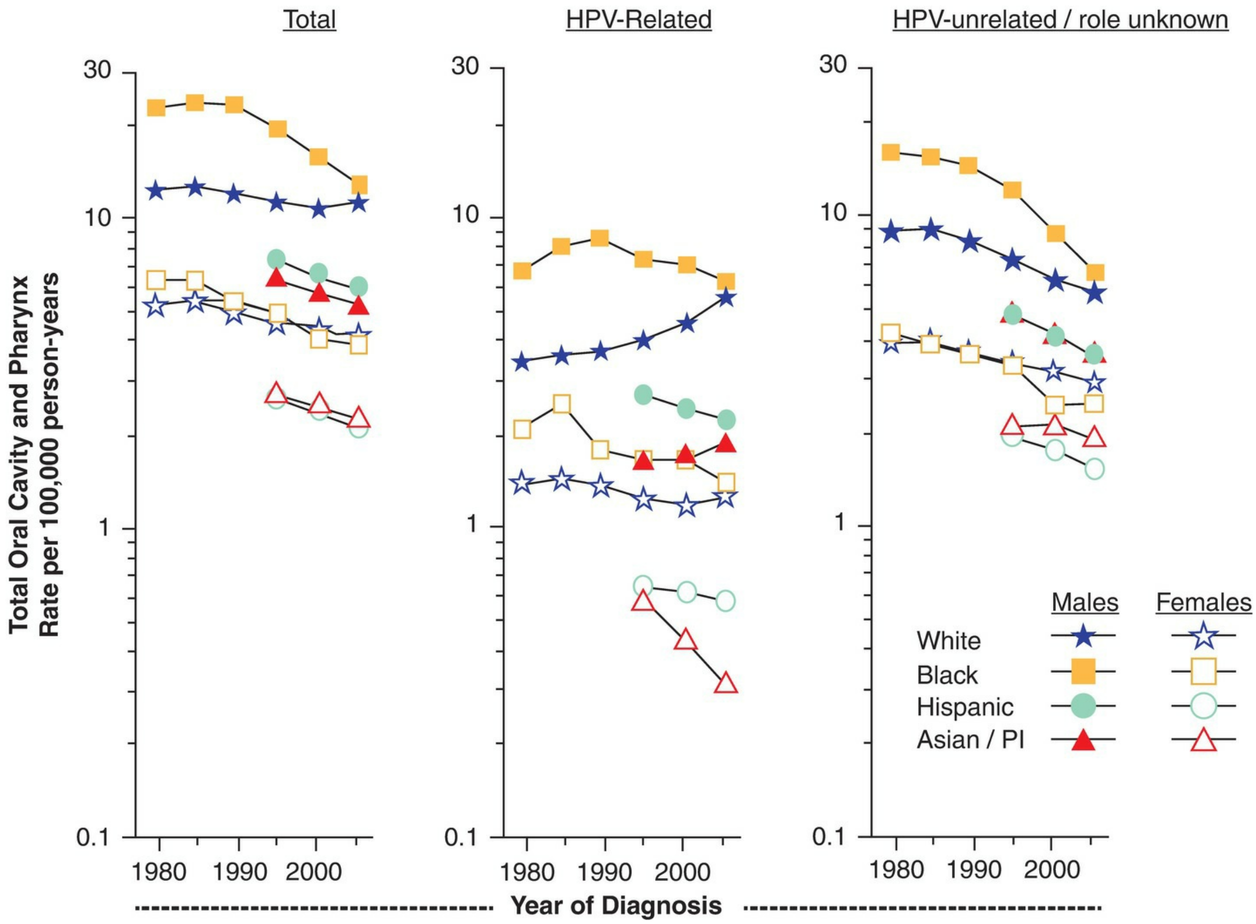

Figure 4.5. Age-adjusted HPV-related and HPV-unrelated squamous cell carcinoma of the oral cavity by diagnosis year, race, and gender, 1977–2007. (Brown LM, Check DP, Devesa SS. Oropharyngeal cancer incidence trends: diminishing racial disparities. *Cancer Causes Control.* 2011;22:753–763.)

Prognosis

Approximately one-third of cases of cancer of the oral cavity and pharynx are diagnosed with localized disease, 47% are diagnosed with regional disease, 17% are diagnosed with distant-stage disease, and 6% are unstaged. The prognosis for cancer of the oral cavity and pharynx is not favorable; the overall survival rate for cancer of the oral cavity and pharynx is 62% and ranges from 36.3% among distant stage to 82.7% for localized stage. Stage-specific survival rates have improved throughout time; between 1977 and 1991, the 5-year relative survival rate among localized cancers was 61.4% and increased to 72.9% between 1992 and 2006. During the same time intervals, the gains observed for regional- and distant-stage disease were even

more noticeable as survival increased from 36.8% to 52.5% among regional disease and 15% to 27.6% for distant-stage disease.[51] There has been some improvement in the 5-year survival of cancer of the oral cavity and pharynx across all race and gender categories since the mid-1970s as well (Fig. 4.6).[2] The 5-year relative survival rates among black males have increased the most with a 36% increase in survival from the mid-1970s to mid-2000s. During the same time period, white males experienced a 20% increase whereas white females and black females' 5-year relative survival increased by 17% and 11%, respectively.

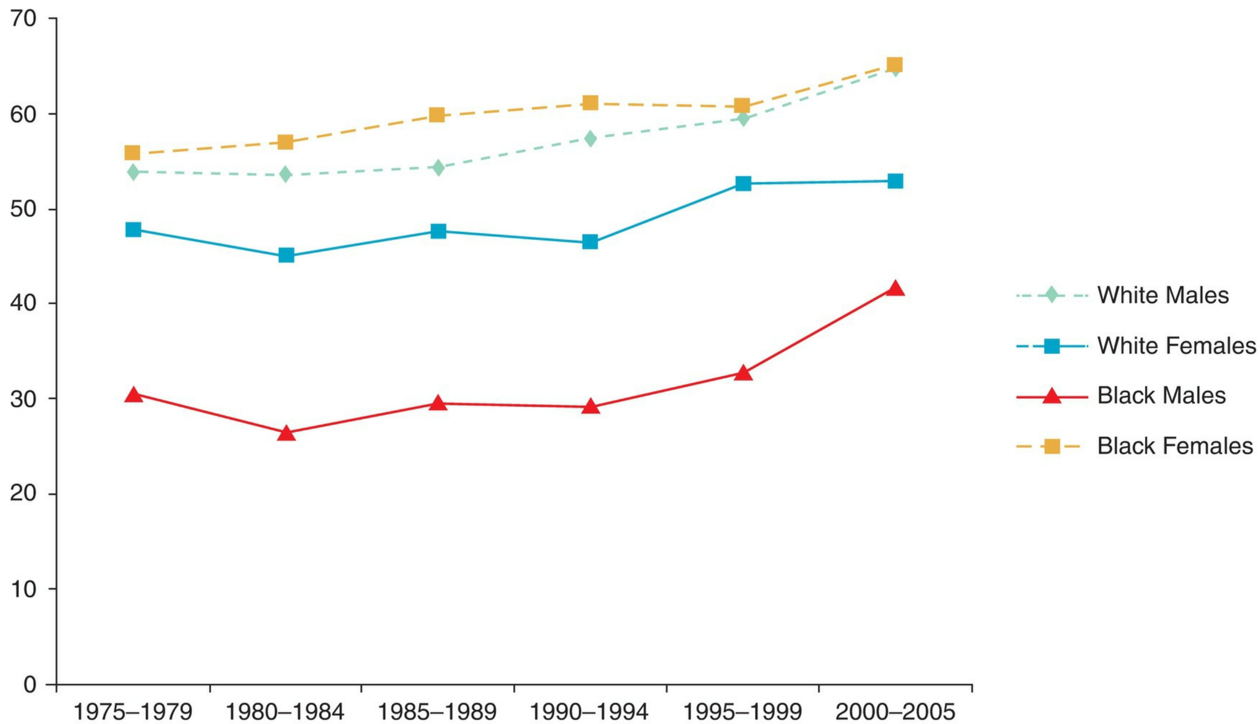

Figure 4.6. A 5-year relative survival for cancers of the oral cavity and pharynx by race and gender, SEER 18 1975–2005. (Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov)

Despite gains in survival over time, there remains a considerable survival disparity by race. Recent 5-year relative survival rates are 63.6% for white

males and 38.6% for black males, whereas the 5-year relative survival for white and black women is 64.6% and 53.0%, respectively. Some of these survival disparities are attributed to later stage at diagnosis.[53,54] Figure 4.7 demonstrates that blacks are disproportionately diagnosed at advanced stage, which may be attributed to delays in diagnosis and access to care. One study examining cancer of the oropharynx did not observe increased advanced-stage disease among blacks when insurance was adjusted for, which supports the hypothesis that access to care is one component of advanced-stage disease among blacks.[55] However, blacks have poorer survival even among those with localized cancer, indicating that other factors, including lower socioeconomic status (SES) and suboptimal treatment, also contribute to poorer survival among blacks than whites.[53] Black patients with cancer of the oral cavity and pharynx were less likely to receive cancer-directed surgery and more likely to receive radiation without chemotherapy.[56] Even after adjusting for treatment, insurance, and other sociodemographic factors, blacks had a 45% increased risk of all-cause death in a recent study of over 20,000 cases of cancer of the oropharynx.[57] Some of the increased hazard of death among blacks could be due to other competing causes of death as this study examined overall survival; however, after adjusting for comorbidity, blacks still had a higher hazard of death in this study.

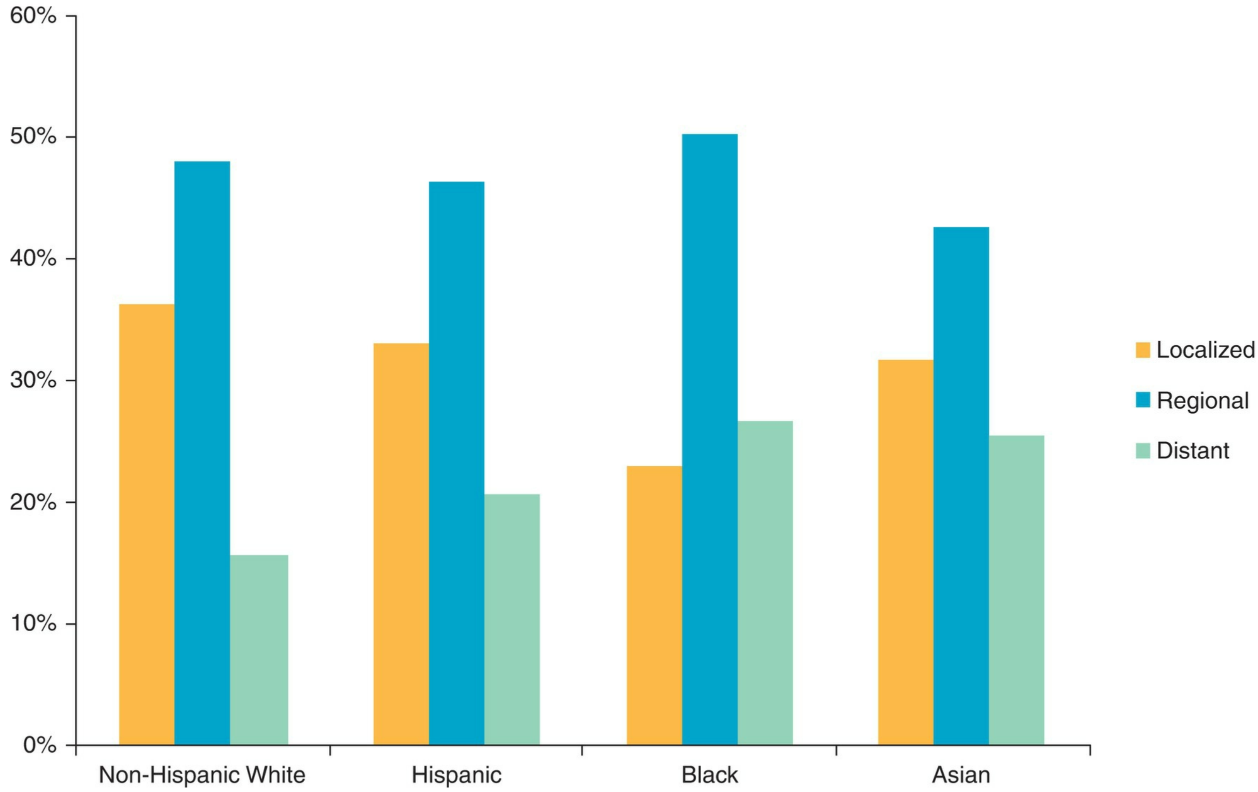

Figure 4.7. Stage distribution among cancers of the oral cavity and pharynx by race/ethnicity, SEER 18 2000–2010. (Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov)

Interestingly, the proportion of Asian Americans diagnosed at late stage (26%) is similar to that of Blacks (27%). Despite this similarity, the 5-year relative survival among Asian Americans is higher than that of any other race/ethnicity overall (Table 4.3). Among cases with distant stage, Asian Americans' survival is considerably higher than that of other race/ethnicities where survival among Asian Americans is ~50% compared to <40% among non-Hispanic Whites. Adjusting for stage in addition to other sociodemographic and clinical factors, the survival benefit among Asian Americans with cancer of the oropharynx, nasopharynx, and hypopharynx compared to Whites was not statistically significant.[58] However, similar factors including receipt of treatment, SES, and age were important predictors

of survival among Asians, which is what is observed for other race/ethnicities.[58]

Table 4.3 Five-Year Relative Survival for Pharynx Cancers of the Oral Cavity by Race/Ethnicity, Stage, and Gender, SEER 18 2003–2009

	Males				Females			
	Total	Localized	Regional	Distant	Total	Localized	Regional	Distant
Non-Hispanic White	63.7%	81.5%	63.4%	37.9%	64.8%	83.4%	56.1%	35.6%
Hispanic	57.0%	81.9%	56.9%	34.0%	69.1%	90.0%	58.6%	44.5%
Black	38.7%	72.6%	38.0%	23.2%	51.3%	82.3%	40.5%	29.1%
Asian	64.8%	86.4%	62.8%	50.6%	71.5%	85.3%	70.4%	50.8%

Surveillance, Epidemiology, and End Results (SEER) Program. Studies have shown that HPV-positive patients with squamous cell carcinomas of the head and neck have better survival than do patients who are HPV negative.[59] In addition, significant reductions (59% to 83%) in cause-specific hazards of death for HPV-positive head and neck squamous cell carcinoma (HNSCC) have been reported, after adjusting for important confounders including age, clinical characteristics, and tobacco and alcohol consumption.[31,60] A meta-analysis reported a 15% reduction in overall hazard of death as well as marked disease-free survival among HPV-positive versus HPV-negative patients with cancer of the head and neck.[59] Although some of the aforementioned factors, including younger age at diagnosis, may explain some of the survival advantage among HPV-related OSCC tumors, it does not explain it entirely as several studies have adjusted for age and other prognostic factors. Improved survival among patients with squamous cell carcinoma of the oropharynx is likely multifactorial and is in part due to increased sensitivity of the cancers to radiation and response to chemoradiation.[61]

CANCER OF THE SALIVARY GLANDS

Cancer of the salivary glands is often included with cancers of the oral cavity and pharynx for etiologic and descriptive epidemiologic studies. Cancer of the salivary glands includes major salivary glands, including parotid, sublingual, and submandibular, as well as minor salivary glands found in the mucosa of the upper aerodigestive tract.

Cancer of the Major Salivary Glands

Cancer of the major salivary glands is uncommon, representing only 11% of the 41,380 cancers of the oral cavity and pharynx diagnosed each year; however, unlike other cancers of the oral cavity and pharynx that are almost all squamous cell cancer, the histology of cancer of the salivary glands is heterogeneous.[62] The incidence of cancer of the major salivary glands varies by histologic type; the most common histologic type is mucoepidermoid carcinoma (2.85 per 100,000), followed by squamous cell carcinoma (1.83 per 100,000), acinic cell carcinoma (1.38 per 100,000), adenoid cystic carcinoma (1.30 per 100,000), and adenocarcinoma NOS (1.22 per 100,000).[62] The remaining histologic types, which include salivary duct carcinoma, basal cell carcinoma, oncocytic carcinoma, clear cell adenocarcinoma NOS, cystadenocarcinoma, mucinous adenocarcinoma, polymorphous low-grade adenocarcinoma, sebaceous carcinoma, malignant mixed tumors, and other rare carcinomas, have incidence rates that are <1 per 100,000.[62] The most common site of cancer of the major salivary glands is the parotid gland (80%) followed by the submandibular (15%) and sublingual glands (4%).

Though major salivary glands have been included in some case–control studies as part of investigations of etiologic factors related to cancer of the oral cavity and pharynx, few studies have examined the etiologic factors specific to major salivary glands. In a case–control study with 150 cases of cancer of the major salivary glands and 191 controls, current smoking was associated with salivary gland risk among males. However, this study did not observe an association between smoking among women.[63] Additionally, two other case–control studies did not observe an association between smoking for men or women.[64,65] The association between alcohol consumption and salivary gland cancer occurrence is also unclear as some studies have reported a positive association among males,[63] whereas another reports a significant association for females only[64] and another study reported null

findings for both males and females.[65] Studies have more consistently reported an association between radiation exposure and cancer of the major salivary glands.[63,64,66] Some studies have reported an association between occupational exposures and cancer of the major salivary glands,[63,66] whereas others have not.[65]

The age-adjusted incidence rate of cancer of the major salivary glands is ~1.62 per 100,000 among males and 1.01 per 100,000 among females as shown in Table 4.4.[2] The incidence of cancer of the major salivary glands varies by age, sex, and histology. Among mucoepidermoid salivary gland cancers as well as all WHO-classified cancers combined, women have a slightly higher incidence compared to men until the fifth decade of life, and after that, the incidence of cancer of the major salivary glands is higher among males.[62] This age–gender interaction has not been explained though it is hypothesized that a hormonal component may be related to these findings.[62] A study of reproductive and hormonal factors related to major salivary glands did find a positive association between early menarche and null parity and cancer of the salivary glands, which is congruent with the hypothesis that hormones may be involved with salivary gland tumorgenesis.[67] However, the incidence of squamous cell carcinoma and non–WHO-classified tumors for men is markedly higher than that for females across all ages, which may indicate more distinct risk factors by histologic type.[62]

Table 4.4 Age-Adjusted Incidence of Cancer of the Major Salivary Glands by Sex, Site and Race/Ethnicity, and Age per 100,000 Person-Years, SEER 18 1990–2009

	Males	Females

Black	1.27	0.94
Other	1.09	0.86

Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov

As shown in Table 4.4, the incidence of cancer of the major salivary glands among white males is slightly higher (1.69 per 100,000) compared to black (1.27 per 100,000) and men of other races (1.09 per 100,000). For females, there is little difference in age-adjusted incidence rates where the incidences for white, black, and other females are 1.01, 0.94, and 0.86 per 100,000, respectively. A study examining incidence patterns by histology and

race noted significantly lower incidence rates among blacks compared to whites for squamous cell carcinoma, and acinic cell carcinoma, but not for other histologic types.[62] The same study reported lower incidence rates of squamous cell, acinic cell, adenocarcinoma NOS, and non–WHO-classified tumors for Asian/Pacific Islanders compared to Whites.[62]

Approximately half of all cases of cancer of the major salivary glands are diagnosed with localized cancer (49.6%), 27.5% are diagnosed with regional metastases, and the remaining 12.9% are diagnosed with late-stage cancer.[2] The stage distribution varies by gender as the proportion of women diagnosed with localized disease (55%) is greater than that of men (39%) and men have a higher proportion of regional (39%) and distant stage (14%) compared to women (29% regional, 9% distant).[2] Black men (46%) and men of other races (50%) are more likely to be diagnosed with early-stage cancer compared to whites (41%), though the proportion of distant-stage cancer is generally the same across racial groups (14% to 16%).[2] Among females, the stage distribution is essentially the same across racial groups. The stage distribution does vary with histologic type. For major salivary glands, mucoepidermoid, adenocarcinomas, and adenoid cystic carcinomas tend to be diagnosed at earlier stages as 59.7%, 54.2%, and 49.6%, respectively, are diagnosed with localized cancer, whereas only 23.4% of squamous cell and 18.7% of non-WHO are diagnosed with localized cancer.[2]

The estimated 5-year relative specific survival rate for males is 67.2%. Females have a better prognosis with 5-year relative survival of 80.5%,[68] which is likely due to women's more favorable stage distribution. Survival decreases steeply with age. The 5-year survival rate for cases diagnosed before the age of 50 is ~90%, whereas the 5-year relative survival rate declines to 75% among cases diagnosed between the ages of 50 and 64.[68] Further declines in survival are observed for cases aged 65 to 74 (68%) and cases 75 years and older (55%). Unlike other cancers of the oral cavity and pharynx, survival is similar across racial groups.

However, histologic type does impact survival. Among cancers of the parotid gland, 5-year survival for acinic cell carcinoma and mucoepidermoid carcinoma had the highest rates, which were both ~80%. Furthermore, high-grade mucoepidermoid cancer had significantly worse survival than did low or intermediate grade (40% vs. 80%). In fact, tumor grade within each

histology was an independent prognostic factor. The 5-year survival rates among adenocarcinomas (66%), malignant mixed tumor (73.3%), adenoid cystic carcinoma (70.1%), and squamous cell carcinomas were lower (46.1%).[69] Other factors related to survival include the presence of positive nodes, extraglandular extension, and cancer grade; a multivariate analysis demonstrated that these pathologic features and age were the most important predictors of survival.[69]

Cancer of the Minor Salivary Glands

Cancer of the minor salivary glands is rare, which is reflected in the paucity of data on these cancers. Cancer of the minor salivary glands may arise from the 500 to 1,000 salivary glands located throughout the mucosa of the upper aerodigestive tract.[70] The most common sites for cancer of the minor salivary glands to occur is the hard palate, upper lip, base of the tongue, and buccal mucosa.[70] The most common histology is mucoepidermoid carcinoma (49.8%), followed by adenoid cystic carcinoma (26.3%), adenocarcinoma (21.7%), and acinic cell carcinoma (2.2%) according to data from 639 minor salivary gland carcinomas in the SEER database.[71] The causes of cancer of minor salivary gland origin are largely unknown, and the risk factors for cancer of the minor salivary glands are often not delineated from those cancers of the major salivary glands.

Some studies have reported a higher proportion of females compared to males,[70] and according to population-based SEER data on 639 cases, 45% of cases were male and 55% were female.[71] According to this study based on SEER data, the majority of cancers of minor salivary gland origin do present with nodal involvement and 43%, 19.4%, 2.8%, and 35.2% are diagnosed with T1, T2, T3, and T4 stage, respectively.[71] Several single-institution studies have reported survival rates ranging from 66% to 80% 5 years after diagnosis and 57% to 70% 10 years after diagnosis.[70,72–76] According to SEER data, the median survival time is ~13.15 years, which is generally consistent across histologic types.[71]

CANCER OF THE LARYNX

Cancer of the larynx is the 21st most frequently occurring cancer among

males and females in the United States.[77] In 2012, an estimated 12,260 patients will be diagnosed with cancer of the larynx and 3,360 will die from the disease in the United States.[77] Approximately one-half of cancers of the larynx arise in the glottis (52%), and one-third arise in the supraglottis (34%), and over 95% of cancers of the larynx originate from squamous cells.[2] The median age at diagnosis is 65 years of age and the median age at death is 68 years.[42]

Risk Factors

Tobacco and alcohol are the primary risk factors for cancer of the larynx. The population attributable risk for tobacco is greater (52%) than that for alcohol (3%).[78] In 1986, the IARC confirmed tobacco as a cause for cancer of the larynx.[79] The risk associated with smoking varies widely; some reports have noted odds ratios around 4, whereas others have reported odds ratios over 20.[7,80] A pooled analysis of case–control studies found odds of cancer of the larynx that were 6.8 times higher in tobacco users compared to nontobacco users among nondrinkers.[78] Tobacco appears to have a stronger effect on cancer of the supraglottis compared to cancer of the glottis.[80,81] There is also a dose–response relationship between tobacco and cancer of the larynx; as the number of cigarettes smoked per day and the number of pack years smoked increases, so do the odds of laryngeal cancer.[7,78,82] Former smokers have lower odds of laryngeal cancer compared to current smokers.[80] Cessation of smoking is thought to lower the risk of cancer of the larynx in case–control studies[80,81]; however, a pooled analysis showed no statistically significant reduction of cancer of the larynx after cessation of smoking.[83] In addition to cigarette smokers, cigar and pipe smokers are at an increased risk of laryngeal cancer.[7] Conversely, studies of Indian men showed no association between chewing tobacco and laryngeal cancer[84] and studies of Swedish men noted a null association between snuff use and cancer of the larynx.[15]

In 2007, IARC concluded that alcohol was a risk factor for laryngeal cancer.[85] The evidence for low consumption of alcohol intake and cancer of the larynx is less clear and weaker than the observed associations between moderate and heavy alcohol intake and cancer of the larynx.[86,87] In this meta-analysis, light drinking (≤1 drink per day) was not associated with cancer of the larynx, but moderate (>1 and <4 drinks per day) and heavy drinking (≥4

drinks per day) were associated with a 1.5 and 2.5 increased odds of cancer of the larynx, respectively.[87] Most studies examining cancer of the larynx and alcohol have been of case–control design. One cohort study found no association between alcohol and cancer of the larynx[88] whereas another observed an increasing risk of cancer of the larynx among women consuming >7 drinks per week.[86] Additionally, a pooled analysis observed an association between cancer of the larynx and heavy consumption of alcohol.[78] The variation in the magnitude and significance of the effect of alcohol on cancer of the larynx could be due to a variety of factors including unmeasured confounding and exposure misclassification because the use of alcohol is frequently underreported, particularly among those who are heavy drinkers.

Tobacco and alcohol are synergistically related to cancer of the larynx, meaning the risk of cancer of the larynx among those who smoke and drink is greater than the independent effects of each.[7,80,81,89] A pooled case–control study reported nonsmokers who consumed 29 to 35 drinks per week had OR of 1.6, which increased to 5.0 for light smokers, 7.1 for intermediate smokers, and 10.4 for heavy smokers.[7] In contrast to other reports observing an interaction,[7,80,89] a pooled analysis of case–control studies found increasing odds ratios associated with both smoking and drinking, but the statistical test for interaction was not significant.[78] The interaction between these two exposures is not fully understood, and untangling the effects of alcohol from tobacco is difficult as many heavy drinkers are also smokers.[80] Furthermore, there is still some debate over the role of a biologic interaction versus a statistical interaction.[80]

The relationship between gastroesophageal reflux disease (GERD) and cancer of the esophagus has been established, which has led researchers to examine the association between GERD and cancer of the larynx, which is in close proximity to the esophagus. Among nonsmokers and nondrinkers, the odds of cancer of the larynx were 1.78 among those reporting heartburn compared to individuals with no reported heartburn.[90] A meta-analysis of four studies found a pooled odds ratio of over 2 for GERD and laryngeal cancer[91]; however, results were heterogeneous and a subsequent case–control study reported no association.[92]

The role of HPV on laryngeal squamous cell carcinoma is not as clear as for cancer of the oropharynx. The prevalence of HPV in cancer of the larynx

from tissue across 55 studies ranged from 0% to 79% with an average of 28%.[93] Case–control studies examining this issue have reported varied results and varied methods of HPV detection. A systematic review of six studies reported a pooled odds ratio of cancer of the larynx among HPV-positive cases to be 2.5 (95% CI 1.4 to 4.4)[94] indicating an association between squamous cell carcinoma of the larynx and HPV; however, an aforementioned case series study reported a low proportion of HPV-positive cases of cancer of the larynx. Therefore, the results are mixed and not strongly indicative of an association between HPV and cancer of the larynx.

There are several other risk factors for cancer of the larynx. Dietary risk factors have been associated with cancer of the larynx. Consumption of animal products[95] has been shown to be associated with cancer of the larynx, whereas consumption of fruits and vegetables is inversely associated with cancer of the larynx.[82,96] There are several occupational exposures that have been proposed as risk factors for cancer of the larynx with varying degrees of certainty, and the number of cases of cancer of the larynx related to occupational exposures is estimated to be <3%.[97] Several occupational exposures including asbestos, wood dust, cement, and coal dust have also been suggested as potential risk factors for cancer of the larynx.[98–100] However, a systematic review of asbestos found no association between cancer of the larynx and asbestos,[101] and another study only found a weak association.[102]

Descriptive Epidemiology

Incidence

The incidence of cancer of the larynx is higher in males compared to females. Incidence also increases with age where the incidence rate among individuals <50 years of age is <8 per 100,000. The incidence for those aged 45 to 54, 55 to 64, and 65 to 74 is 16.2, 30.2, and 28.6 per 100,000, respectively. At about the age of 75, the incidence of cancer of the larynx begins to decline more significantly where the incidence drops to 17.0 per 100,000 and declines to 4.8 per 100,000 among those aged 85 years and older.[42]

The incidence of cancer of the larynx is higher for men in developed (5.5 per 100,000 men) compared to developing countries (3.5 per 100,000 men).[43]

Within the United States, the age-adjusted incidence rate of cancer of the larynx is highest among black men (9.6 cases per 100,000 men), ~1.6 times higher than whites. The incidence rate for Hispanics is similar to that of Whites, and incidence rates for Asian/Pacific Islanders is slightly lower (see Table 4.1).[2] For females, the incidence of cancer of the larynx is similar between developing and developed countries with age-standardized incidence rates of 0.6 per 100,000 women. Within the United States, the incidence of cancer of the larynx is low among women (1.12 cases per 100,000 women) and rates are generally similar across race/ethnicities although there is a slightly elevated incidence of cancer of the larynx among black women (IR compared to whites 1.47, 95% CI 1.28 to 1.66) (see Table 4.2).[2] The higher incidence of cancer of the larynx among black males is not fully explained by smoking and alcohol consumption as blacks have slightly lower smoking rates and are less likely to drink heavily than are whites.[44,45] Blacks also have a higher incidence[42] of cancer of the lung and at least one study examining black–white differences in cancer of the lung risks suggests that blacks may smoke more intensely (i.e., smoke more cigarettes per day) than do whites, which may partially explain higher incidence rates of cancer of the larynx among blacks despite lower smoking prevalence.[103]

Cancer of the larynx also varies by geographic location. For males, cancer of the larynx is high in the southeastern states, sometimes referred to as the "tobacco belt." A similar geographic pattern is not evident for women.[104] The male incidence patterns reflect higher smoking prevalence among southeastern states, which range from 21% to 29% compared to <20% for states located outside this area.[105] Studies examining incidence of cancer of the larynx by education have not been conducted, as individual-level education status is not available in population-based registries. However, smoking prevalence is highest among non–high school graduates; about 47% of adult males with a high school education smoke compared to <10% for college graduates.[105] Similar patterns are observed for women.[105]

Statistically significant declines in the incidence of cancer of the larynx in the United States have been largely attributed to reductions in smoking rates, and in the most recent time period, cancer of the larynx has decreased by 2.6% and 2.3% per year for males and females, respectively (Fig. 4.8). The declines in the incidence of cancer of the larynx for men began before the decline for women, which is due to temporal trends in smoking rates.

Male smoking prevalence peaked in the 1950s and 1960s, and female smoking prevalence did not peak until the late 1960s.[106] Current smoking rates have been stabilized at around 21.6% and 16.5% for men and women, respectively.[44] Alcohol consumption patterns have also declined in the United States since 1980, which may partially explain declines in the incidence of cancer of the larynx.[107]

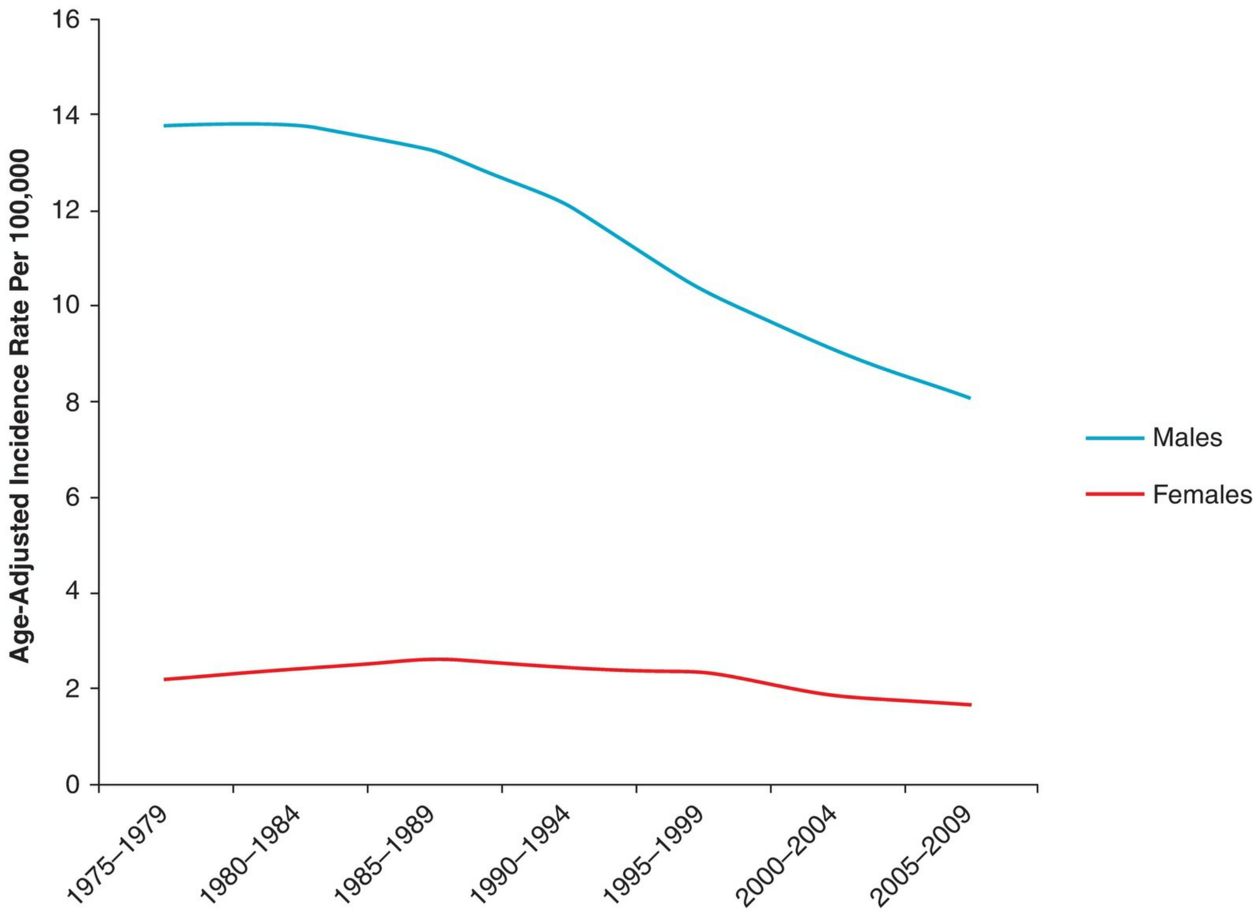

Figure 4.8. Age-adjusted incidence rates for cancer of the larynx by diagnosis year, and sex, SEER 18 1975–2009. (Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov)

Prognosis

Approximately 60% of cancers of the larynx are diagnosed with localized cancer, 21% are diagnosed with regional metastases, and 19% are diagnosed with distant metastases. Stage at diagnosis varies by race/ethnicity as 52% of black men are diagnosed with localized cancer compared to 64%, 63%, and 60% among non-Hispanic Whites, Asians, and Hispanics (Fig. 4.9). Over half (56%) of non-Hispanic White and Hispanic women are diagnosed with localized cancer compared to only 42% of black women (Fig. 4.10). Though the proportion of Asian women diagnosed with localized disease is slightly lower (48%) than that of non-Hispanic White and Hispanic women, they have the lowest proportion of distant-stage cancer (15%). Black–white differences in stage at diagnosis have been noted among National Cancer Data Base (NCDB) patients after adjusting for other factors.[108] Some of these differences may be related to access to care; yet, the aforementioned NCDB study reported a 38% increase in odds of advanced laryngeal cancer for blacks compared to whites after adjusting for insurance status as well as other sociodemographic factors.[108] This finding suggests that other factors may contribute to delays in seeking care including cultural or social barriers. It is worth noting that insurance seems to be a stronger predictor of advanced stage as Medicaid and uninsured patients were two times as likely to be diagnosed with advanced-stage cancer of the larynx compared to privately insured patients after adjusting for other factors.[108] Uninsured and Medicaid-insured patients are less likely to have a usual source of care and may delay seeking care for symptoms of cancer of the larynx that include hoarseness, dysphagia, and voice changes.[108]

Black men have a poorer 5-year relative survival (55.2%) compared to white men (62.4%) (Table 4.5). The survival disparities are likely multifactorial as a study adjusting for stage and other sociodemographic factors noted a statistically significant higher hazard of death among blacks compared to whites.[109] The 5-year relative survival for Hispanic men is slightly lower compared to non-Hispanic White males, whereas Hispanic females have slightly higher survival than do non-Hispanic White females (Table 4.5). However, these survival differences by Hispanic ethnicity are not observed in studies adjusting for clinical, demographic, and treatment-related factors.[109] Asians have a slightly better 5-year relative survival compared to non-Hispanic Whites among males and females.

Table 4.5 Five-Year Relative Survival for Cancer of the Larynx by Gender and Race/Ethnicity, SEER 18 2004–2009

[a]Statistic could not be calculated due to sparse data.

Mortality from cancer of the larynx has declined from 1.69 per 100,000 individuals to 1.08 per 100,000 in 2009 in the United States.[42] These declines are due to changes in incidence, as the survival rate for cancer of the larynx has not improved over time.[42,110,111] In fact, some studies have suggested decreases in survival for cancer of the larynx, particularly for advanced stages.[110–112] Cosetti et al.[110] suggest several explanations for the decline in survival, including spurious associations in earlier time periods and better survival of competing risks leading to more patients with cancer of the larynx dying from cancer as opposed to other causes. Stage drift (i.e., more localized cancers being considered as later stages) and detection of cancers earlier do not contribute to the observed declining survival over time as inclusion of less advanced cancers would actually improve survival statistics among late-stage disease.[110] One study found declining survival only among middle-aged patients and suggested a birth cohort effect as potential reason for declining survival among patients with cancer of the larynx.[110] Another reason suggested for declines in survival is related to changes in treatment protocols for cancer of the larynx.[110,111] In 1991, the Veterans Affairs Laryngeal Cancer Group demonstrated equivalent survival among advanced-stage patients treated with chemoradiation as compared to advanced-stage patients treated with laryngectomy, which was the primary form of therapy before the trial.[113] Since this trial, laryngectomies among advanced-stage patients have

declined from over 50% in the late 1980s to around 30% in 2007 with a concomitant increase in chemoradiation from <10% in the 1980s to around 50% by 2007.[109]

CANCER OF THE THYROID

There are several distinct histopathologic subgroups of cancer of the thyroid. Approximately 90% of cancers of the thyroid arise from the epithelial tissue and are well-differentiated papillary and follicular carcinomas (PFCs). PFC have a good prognosis with 5- and 10-year cause-specific survival rates of 98% to 96%, respectively.[2] Anaplastic cancers, which also arise from the epithelial tissue, only represent 1% to 2% of cases diagnosed but are highly fatal with a survival rate of <10% within 5 years of diagnosis.[2,114,115] Only 5% to 10% of cases are diagnosed with medullary thyroid carcinomas (MTCs) with a survival rate that is estimated to be 86% and 65% after 5 and 10 years after diagnosis, respectively (Table 4.6).[116,117]

Table 4.6 Five-Year Relative Survival for Carcinoma of the Thyroid by Race/Ethnicity and Histologic Type, SEER 18 2000–2005

	Anaplastic	Medullary	Follicular	Papillary
Non-Hispanic White	8.8%	86.0%	95.7%	99.2%
Hispanic	6.9%	81.6%	95.0%	98.1%
Black	9.3%	78.4%	92.2%	98.0%
Asian	9.9%	87.7%	94.0%	97.9%

Surveillance, Epidemiology, and End Results (SEER) Program. Risk Factors

It is estimated that 25% of medullary thyroid cancers are hereditary and are a result of three syndromes: multiple endocrine neoplasia (MEN) type 2A, MEN type 2B, and familial medullary thyroid carcinoma.[118] The remaining sporadic MTC are largely unexplained. A pooled analysis of case–control studies across Europe, North America, and Asia aimed at understanding risk factors for sporadic MTC reported positive associations between MTC and benign thyroid disorders, gall bladder disease, and hypertension, though these factors have not been widely studied.[119]

The causes and risk factors for anaplastic cancers are not well understood, though studies have associated elevated risk with prior history of goiters and several genetic alterations, including alterations of p53.[120] Genetic factors, specifically rearrangement of the oncogene RTEN and BRAF mutations, are associated with papillary thyroid cancer.[121] There are several other reported risk factors for papillary and follicular cancers including age, gender, and radiation. The relationship between cancer of the thyroid and radiation exposure was established following the study of survivors of the atomic bombs in Hiroshima and Nagasaki in the 1940s.[122,123] The strong association between radiation and cancer of the thyroid was further studied and confirmed with the study of individuals exposed to the 1986 Chernobyl Disaster.[124,125] Exposure to radiation during childhood has been shown to be particularly important as risk ratios for cancer of the thyroid among children exposed to high doses of radiation notably exceeds that of adults exposed to similarly high doses of radiation.[124] These findings highlight the sensitivity of naive thyroid tissue to radiation exposure. Prior treatment of childhood cancer is also associated with an increased risk of cancer of the thyroid.[126] However, the risk of low-dose radiation in childhood, which is much more prevalent in the general population, on cancer of the thyroid is unclear as it is difficult to ascertain low-dose exposure levels. Additionally, models extrapolating risks of high-dose exposures to low-dose exposures may not be accurate, though it may be reasonable to assume a linear dose–response for some forms of radiation.[127]

Unlike other cancers of the head and neck, tobacco exposure is not positively associated with cancer of the thyroid. In fact, there is a growing body of research suggesting an inverse association between papillary and

follicular thyroid cancer and tobacco exposure.[128–130] A pooled analysis of prospective studies reported current smokers had a statistically significant 30% decreased risk of cancer of the thyroid compared to never smokers,[129] and there was no significant association noted for former smokers. However, some studies have shown decreased risk in never smokers.[130] Additionally, dose–response relationships have been noted with declines in risk of cancer of the thyroid with increasing duration and amount of cigarette use.[130] The mechanism through which smoking decreases thyroid cancer risk is thought to be through decreased thyroid stimulation hormone among smokers.

The association between other thyroid disorders and cancer of the thyroid has mixed results and is difficult to examine given the increased probability of detecting indolent cancer of the thyroid in populations seeking medical treatment for these disorders that include goiters, hypothyroidism, and hyperthyroidism.[131] The relationship between cancer of the thyroid and Hashimoto thyroiditis,[132] an autoimmune disease responsible for hypothyroidism, is unclear. A systematic review of the literature did not support an association between cancer of the thyroid and Hashimoto thyroiditis among population-based studies with fine needle aspiration–biopsied cancers, but an association was noted for studies examining thyroidectomy specimens, which are subject to selection bias.[133] A pooled analysis reported a null association between hypothyroidism and thyroid cancer and only a tentative association between hyperthyroidism and thyroid cancer.[134] This pooled analysis,[134] however, reported a higher risk of cancer of the thyroid among those with a history of a goiter as well as those with a history of a benign disorder of the thyroid.

Other suggested risk factors for cancer of the thyroid include dietary factors. One study reported that iodine deficiency is related to follicular carcinoma risk whereas excess iodine intake is related to papillary carcinoma[135]; however, other studies reveal inconsistent findings.[136] Ecologic studies comparing the incidence of cancer of the thyroid before and after iodine supplementation also show mixed results. Increasing incidence of thyroid cancer was noted following the halt of iodine supplementation in Poland,[137] although a study in Argentina found an increased incidence of papillary thyroid cancer following the addition of iodine to salt and a study in Sweden found similar temporal trends of PFC of the thyroid in areas with

high and low iodine intake.[138] Similarly, a study in Denmark did not observe differences in incidence by histologic type in high and low iodine regions.[139] In addition to iodine consumption, consumption of cruciferous vegetables (including cabbage, cauliflower, bok choy, and broccoli) that contain goitrogens has been thought to be related to cancer of the thyroid based on animal models.[140] However, a pooled case–control analysis of cruciferous intake and cancer of the thyroid did not report a positive association but rather a slightly protective effect among consumption of noncruciferous vegetables and cancer of the thyroid.[141] Environmental factors, including polyhalogenated aromatic hydrocarbons (PHAHs), particularly polybrominated diphenyl ethers (PBDEs), may be associated with cancer of the thyroid.[142]

Reproductive factors may also be associated with cancer of the thyroid; however, two recent cohort studies examining factors associated with estrogen levels that have been used in breast and gynecologic cancers, including parity, age at menarche, and age at menopause, do not support a relationship between female sex hormones and cancer of the thyroid.[143,144] Another cohort study did observe a positive association between late menarche and cancer of the thyroid but only for women <45 years old.[115] Case–control studies have reported associations between early and late age at menarche and parity with cancer of the thyroid[145,146]; however, these results are not consistent and a pooled analysis of case–control studies showed only a weak association.[147]

Descriptive Statistics

Incidence

Cancer of the thyroid is the most frequently encountered cancer of the head and neck in women with an incidence rate (15.84 per 100,000) that has increased substantially over time. The incidence of cancer of the thyroid has also increased throughout time for men; a more detailed discussion of these temporal trends and reasons for such trends will be featured later in this chapter. The age distribution for PFC is uniquely low compared to other cancers as the average age at diagnosis is ~46 years for women and 50 years for men.[2] The average age of diagnosis for medullary carcinomas is in the

early 50s for both males and females, and anaplastic carcinomas are typically not diagnosed until the late 60s for men and early 70s for women.[2]

Papillary and follicular cancer of the thyroid (PFTC) occurs more commonly in women compared to men with an incidence rate 2 to 3.5 times that of men, whereas the incidence of medullary and follicular carcinoma is similar for men and women. The female to male PFTC ratio is observed across race/ethnicities, with some variation, and across different continents including North America, Asia, and Europe.[148] The female to male ratio of PFTC also varies by age as ratio ranges from 5 to 6 for ages 20 to 29 and drops to 1 to 1.5 for 70- to 79-year-olds.[149] The converging incidence of male and female cancer of the thyroid with age has led to speculation that female sex hormones may contribute to cancer of the thyroid as mentioned earlier. Descriptive studies across several countries have noted these differences in the incidence of cancer of the thyroid for pre- and postmenopausal women; however, as mentioned above, the association between reproductive factors and cancer of the thyroid is equivocal.[147]

The incidence of cancer of the thyroid among females is over two and half times higher in developed (9.1 per 100,000 women) compared to developing countries (3.4 per 100,000 women). Within the United States, the incidence of cancer of the thyroid among non-Hispanic White women (19.4 cases per 100,000 women), Asians (17.9 per 100,000 women), and Hispanic females (16.4 per 100,000 women) are similarly high, and the incidence of black females (10.5 per 100,000 women) and American Indian/Alaska Natives (11 per 100,000 women) is lower. The lower incidence of cancer of the thyroid for Black and American Indian/Alaska Native women compared to non-Hispanic White is observed for each type of cancer of the thyroid except for anaplastic carcinomas.[149] As mentioned above, cancer of the thyroid is not common among men though the age-standardized incidence among men in developed countries is (2.9 per 100,000 men) is more than twice that of those in developing countries (1.1 per 100,000 men).[43] Among men, differences in incidence by race are less marked and range from 5.8 cases per 100,000 men for non-Hispanic Whites compared to 3.2 cases per 100,000 for Black men (see Table 4.1).

The lower incidence of PFTC among blacks is not fully understood and could be due to biologic or diagnostic reasons. The proportion of blacks

without health insurance is higher than that of whites[150] and they may be less likely to be diagnosed with smaller indolent cancers. Cases of cancer of the thyroid among blacks are more likely to be diagnosed at late stage at diagnosis and with larger size cancers.[151,152] Race/ethnicity is closely linked to SES, and studies have also noted a decreased incidence of cancer of the thyroid among residents residing in low SES census tracts[153] and those residing in counties with higher proportions of uninsured and non–high school graduates.[154] However, in a study of Kaiser Permanente health maintenance organization members, with presumably equal access to care, blacks had a lower incidence of cancer of the thyroid compared to whites.[155]

Hispanics are also more likely to be uninsured compared to non-Hispanic Whites; however, Hispanics have a similarly high incidence rate of PFTC as Whites. Hispanics who were born in the United States have incidence rates similar to Whites; however, Hispanics migrating to the United States have lower incidence rates.[156] Authors of this recent migrant study did not believe that the higher incidence of thyroid cancer among US-born Hispanic women is related to improved detection or overdiagnosis as the incidence of cancer of the thyroid has increased in other countries in the world.[156] Horn-Ross et al.[156] suggest that these differences could be due to variations in nutrient intake, specifically iodine intake, as well as reproductive factors.

Asian Americans have a similar incidence of cancer of the thyroid as White women in the United States. Among Asian Americans, Southeast Asian women, including Vietnamese, Filipino, and Cambodian, have higher incidence rates than do non-Hispanic White, Korean, Japanese, and Chinese American women.[157–159] A case–control study examining cancer of the thyroid among Southeast Asians observed an association between benign thyroid disorders and phytoestrogens including goiters, among patients with cancer of the thyroid.[160] Compared to their US-born counterparts, foreign-born Filipino and Chinese women have a lower incidence of cancer of the thyroid and foreign-born Japanese women have a higher incidence than do US-born Japanese women.[157]

Temporal Patterns

Papillary and follicular thyroid carcinoma has unequivocally increased in the United States; however, the temporal trends for other histologic types are less

clear. Follicular carcinoma increased for white and black male and females, whereas medullary carcinoma of the thyroid increased for white males. Additionally, the reasons for the increasing papillary carcinoma of the thyroid are not fully understood and the interpretations of increasing incidence rates are debated.[149,153,161–164] Several studies of the population-based SEER registry have documented increasing incidence of small cancers; however, increased incidence has been observed across all cancer sizes, including cancers ≥4 cm. Chen et al.[162] noted an 8.6% increase in cancer of the thyroid per year between 1988 and 2005 and a 5.7% increase in cancers ≥4 cm over the same time period (Fig. 4.11). Likewise, localized cancers have increased among men and women but so have distant-stage disease. Increases in the incidence of cancer of the thyroid have been detected across all race/ethnic groups but is more rapidly increasing among non-Hispanic Whites.[149] The detection of smaller cancers with ultrasonography and fine needle aspiration may account for some of the increasing incidence.[149,161,162] A European study noted an increasing incidence of cancer of the thyroid in regions with more cancer imaging[165] and US studies report a higher incidence of cancer of the thyroid among patients in higher SES zip codes.[151] Though papillary thyroid carcinoma has a good prognosis, the potential for overdiagnosis of cancer of the thyroid is important to consider given the unnecessary medical cost and emotional stress that comes with the treatment and diagnosis of cancer.

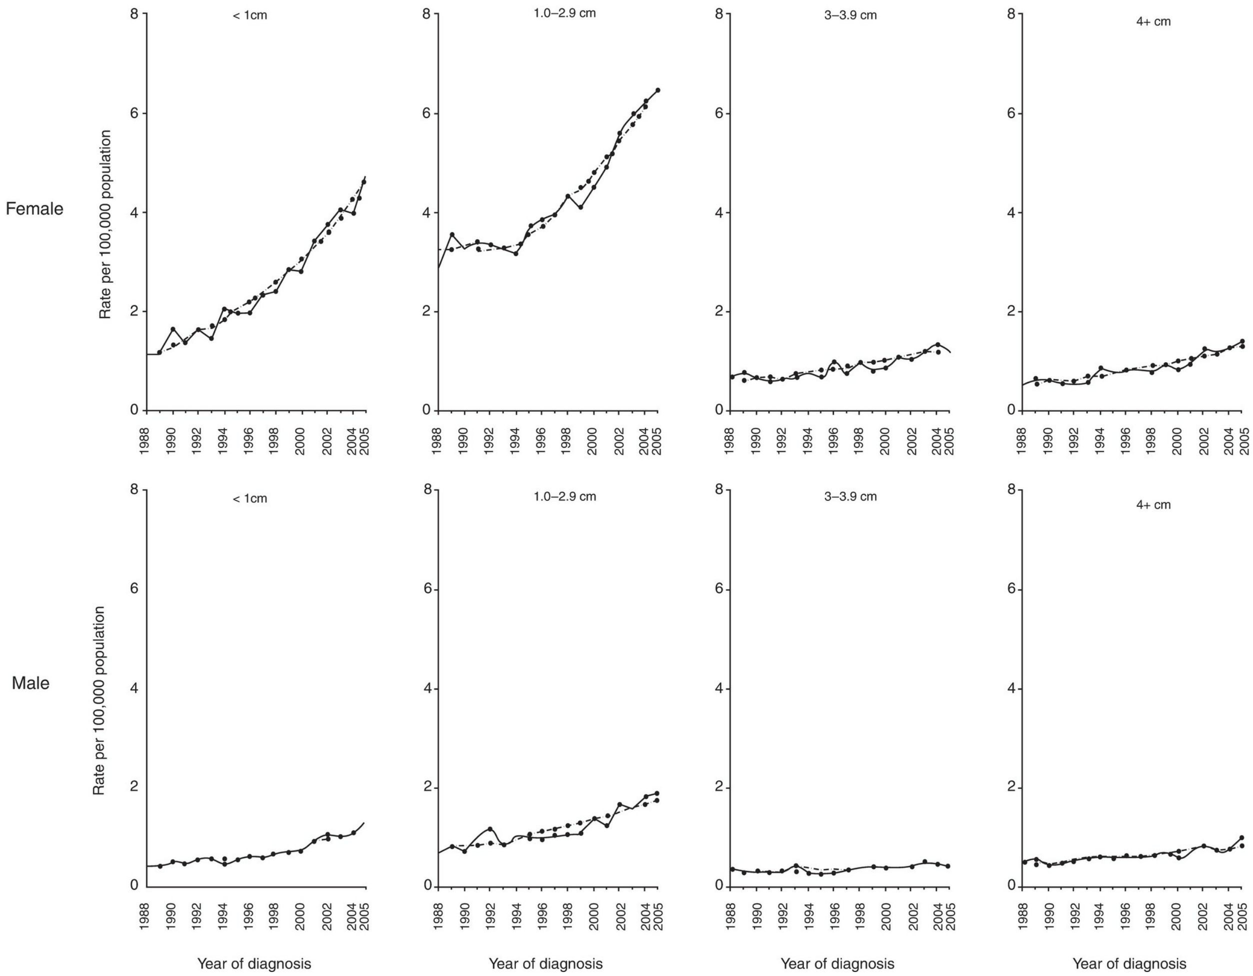

Figure 4.11. Incidence rates for cancer of the thyroid by diagnosis year, tumor size, and gender, SEER 1998–2005. (Chen AY, Jemal A, Ward EM. Increasing incidence of differentiated thyroid cancer in the United States, 1988–2005. *Cancer*. 2009;115:3801–3807.)

The detection of small cancers is not the sole contributor to the increasing incidence of cancer of the thyroid due to the increasing incidence of larger and distant-stage cancers.[149,162,164] As mentioned above, radiation in childhood is a risk factor for cancer of the thyroid; however, there are no studies measuring average radiation in childhood over time. Additionally, environmental exposures, particularly PHAHs, PBDEs, may be associated with thyroid cancer.[142]

Prognosis

The large majority of PFCs are diagnosed with early-stage disease, whereas

approximately one-half of medullary carcinomas are diagnosed at a local stage, and only a small proportion (<10%) of anaplastic carcinomas are diagnosed with localized cancer. For PFCs, tumor size varies by race/ethnicity (Figs. 4.12 and 4.13). The proportion of blacks diagnosed with papillary carcinoma ≥4 cm is higher than that of whites. Hispanics also have a higher proportion of larger papillary carcinoma compared to Whites. The prevalence of follicular carcinomas ≥4 cm is lower than that for papillary carcinoma. Findings from the NCDB indicate that black patients were more likely to be diagnosed at a later stage compared to whites adjusting for several factors including insurance.[152] SEER summary stage by race/ethnicity are shown in **Figure 4.14**. Additionally, uninsured patients were more likely to be diagnosed at a later stage compared to privately insured, adjusted for race/ethnicity and other sociodemographic factors.[152]

National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov)

As mentioned above, the 5-year survival for patients with PFC is drastically higher than medullary and anaplastic carcinoma as displayed in Figure 4.15. Survival differences among anaplastic carcinomas are difficult to assess given the rarity of the disease and overlapping confidence intervals of survival estimates. The 5-year survival among patients with medullary carcinoma varies from nearly 88% among Asians to 78.40% among Black; however, these differences are not significantly different due to overlapping confidence intervals. The 5-year relative survival for patients with follicular carcinomas is highest among Whites and Hispanics but slightly lower for blacks, and there are no discernible survival patterns by race/ethnicity for patients with papillary carcinoma. A study examining overall survival by race/ethnicity among all histologies of cancer of the thyroid noted increased observed survival among blacks compared to whites; however, after adjusting

for clinical factors, these differences diminished.[166]

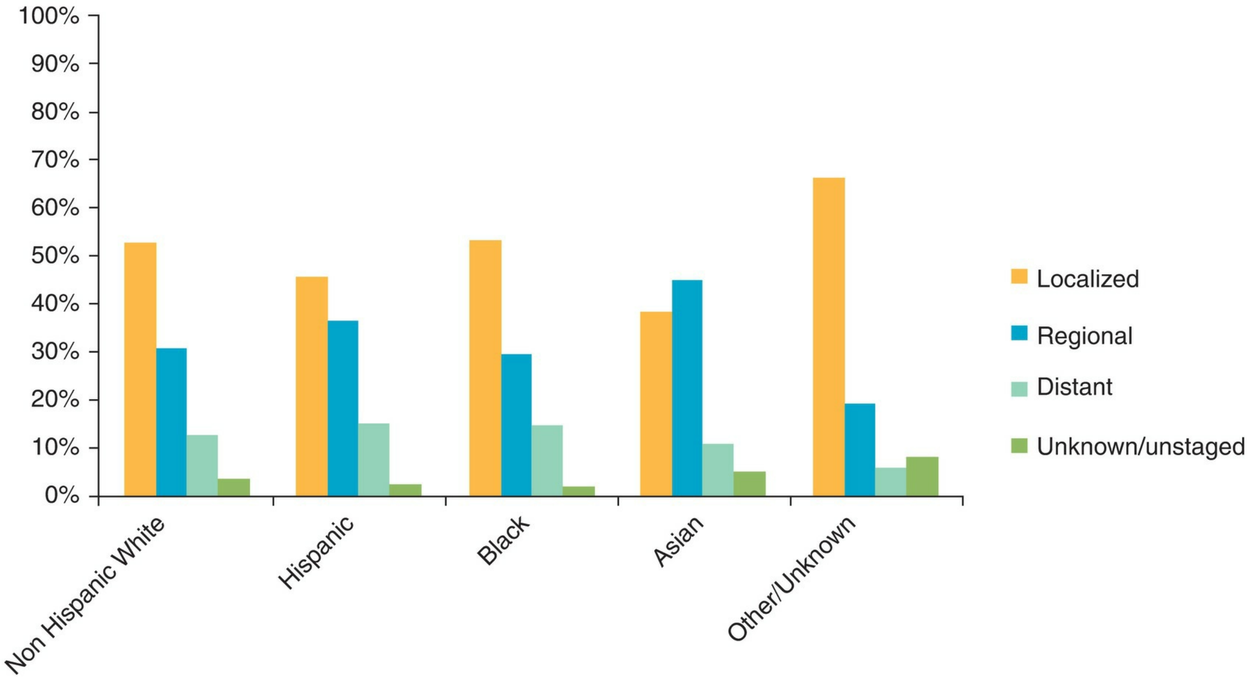

Figure 4.15. Distribution of medullary carcinoma of the thyroid by stage and race/ethnicity, SEER 18 2000–2009. (Surveillance, Epidemiology, and End Results (SEER) Program. SEER*Stat Database: Incidence—SEER 9 Regs Research Data, Nov 2011 Sub (1973–2010) <Katrina/Rita Population Adjustment>—Linked To County Attributes—Total U.S., 1969–2010 Counties. National Cancer Institute, DCCPS, Surveillance Research Program, Surveillance Systems Branch, released April 2013, based on the November 2012 submission. http://www.seer.cancer.gov)

By gender, females have a slight survival advantage for papillary and follicular cancers, but not meaningfully different given the high survival for these cancers. A study of the National Thyroid Cancer Treatment Cooperative Study Group data suggested that survival differences by gender are modified by age where women diagnosed before the age of 55 had better survival rates than did men (HR 0.33, 95% CI 0.13 to 0.81) but experienced similar survival as men past the age of 55.[167] The high survival rate of patients with papillary carcinomas is observed for most ages where relative survival remains above 95% up until age 80 where it drops slightly to ~90%. Survival rates vary more obviously across age for follicular carcinomas where 5-year relative survival rates are over 99% for those patients under the

age of 50 and decrease to 85% among ages 70 to 79 and to 74% among cases 80 years and older. The 5-year survival rates for medullary carcinomas remain at around 80% to 84% before the age of 70 and decrease to 66% among those aged 70 to 79 and further decline to around 50% for those aged 80 years and older.

OTHER CANCERS OF THE HEAD AND NECK

Cancers of the Nasal Cavity and Paranasal Sinuses

Cancers of the nasal cavity and paranasal sinuses (NCPS) are rare. By subsite, the nasal cavity (44%) is the most common site followed by the maxillary sinus (33%), ethmoid sinus (9%), accessory sinus (4%), sphenoid sinus (3%), overlapping lesion of accessory sinus (2%), and frontal sinus (1%). About one-half of these are squamous cell carcinoma followed by adenocarcinoma (13%), epithelial cell carcinoma (9%), and melanoma (7%). The median age of diagnosis is 63 years.

There are several risk factors associated with cancers of the NCPS including occupational exposures, particularly to wood, nickel, and leather dust, which IARC concluded was sufficient evidence for carcinogenity.[58,168] Other occupational exposures that are probably or possibly carcinogenic include formaldehyde and textile dust.[58] Tobacco smoking is also a risk factor, and IARC deemed it a cause in 2002 with stronger associations observed for squamous cell carcinomas.[169,170] Environmental exposure to tobacco smoke has also been shown to be related to cancer of the NCPS as the risk of cancer is elevated among spouses of smokers.[171] Consumption of alcohol has not been consistently associated with cancer of the NCPS. At least two studies have shown a positive association between alcohol and NCPS,[171] whereas another has not.[172] Dietary factors including increased intake of fruit and vegetables have been associated with a lower risk of cancer of the NCPS, whereas salted and pickled foods are associated with higher risks.[171]

As mentioned above, the incidence of cancer of the NCPS is low as the age-adjusted incidence rate is ~0.7 cases per 100,000 in the United States.

The incidence among males is slightly higher (0.9 per 100,000) compared to females (0.6 per 100,000). Incidence increases markedly with age; the incidence among those <50 years of age is <1.0 per 100,000 and increases to 3.6 per 100,000 among those aged 85 years and older. Among males, the incidence is similarly low by race where whites, blacks, and other race incidence is 0.9, 1.0, and 1.0, respectively. Among females, incidence patterns do not vary by race; the incidence for whites, blacks, and others is 0.5, 0.6, and 0.6, respectively. Over time, the overall incidence of NCPS has remained stable at around 0.7 per 100,000 from 1975 to 2009.

Most patients with NCPS are diagnosed with localized- (29%) or regional-stage (55%) cancer and 17% are diagnosed with distant stage. Stage distribution varies by race; 31% of whites are diagnosed with localized disease compared to 19% of blacks and 15% of other races. The average 5-year relative survival is 53.5%; this varies greatly by stage where the survival rate is 80.8% for localized, 47.8% for regional, and 31.5% for distant-stage cancer. Survival also varies by race where the 5-year relative survival is 54.8%, 42.8%, and 51.2% for whites, blacks, and other races, respectively. The survival for NCPS has not varied significantly over time.

Sarcomas

Sarcomas of the head and neck are rare. The large majority of sarcomas of the head and neck (80%) are in the soft tissue whereas the remaining are in bone or cartilage.[173]Due to the rarity of the disease, there are limited data on the risk factors as well as incidence and prognosis. The histology of sarcomas of the head and neck is varied. Among 802 sarcomas of the head and neck diagnosed at the University of Texas MD Anderson Cancer Center between 1970 and 1999, the most common histologic type was osteosarcoma (14.6%) followed by malignant fibrous histiocytoma (11.2%), angiosarcoma (11.2%), and rhabdomyosarcoma (11.0%).[173] A relatively high proportion (17.6%) of sarcomas were unclassified, and neural, adipose tissue, and histogenesis unclear sarcomas were all rare. It is worth noting that histologic type also varies by age as rhabdomyosarcoma is much more common in children than adults whereas osteosarcomas are more commonly diagnosed in men and women between ages 30 to 40 years and the median age at diagnosis for liposarcoma is 50 years.[173,174] The most common site was the scalp and face (31.4%) and sinonasal tract (30.5%).[173]

Li-Fraumeni syndrome, which is a germline mutation on the p53 tumor suppressor gene, is associated with sarcoma.[175] Another inheritable mutation on Rb1 is also associated with sarcomas.[176] Exposure to radiation is also associated with sarcomas of the head and neck, though the postirradiation risk of sarcomas of the head and neck is low.[177–179] A single-institution study of 229 sarcomas of the head and neck noted that only 6% had a history of exposure to radiation and among cases with a history of radiation, there was an average 12-year latency period between radiation therapy and the diagnosis of sarcoma of the head and neck.[179]

Only 5% to 10% of sarcomas are in the head and neck, and an estimated 1,000 to 1,500 cases of sarcomas of the head and neck are diagnosed in the United States each year.[180] A single-institution study from Italy of 167 patients reported 19% and 11% of patients experience local recurrence and distant metastases within a 10-year period, respectively.[181] The disease-free survival was estimated to be 26% in the same 10-year period.[181] The 5-year survival reported by the Head and Neck Sarcoma Registry varies widely by histologic type as survival from chondrosarcomas and dermatofibrosarcoma was close to 100% whereas survival from osteosarcoma was <50% as well as rhabdosarcoma.[182]

Melanomas

Cutaneous melanomas occur all over the body and one study reported that the most common location of cutaneous melanomas was on the back for men and women under the age of 50 and the most frequent location among those aged 50 and older was on the head as well as the forearm.[183] The face is the most common site in the head and neck for melanomas to occur. Among cases with a known histology, lentigo maligna melanomas are the most common histologic type followed by Spitzoid malignant melanoma and nodular.[184] Mucosal melanomas also occur in the head and neck but are very rare and have different risk factors as well as incidence patterns compared to cutaneous melanoma.[185]

Total exposure to sunlight is associated with cutaneous melanoma; however, intermittent exposure is more strongly associated with melanoma.[186] Sunburns throughout one’s lifetime is also a notable risk factor for cutaneous melanoma; a review of 29 studies found increased odds of

melanoma with sunburns in adult life (OR = 1.91), adolescents (OR = 1.73), and childhood (OR = 1.95).[186] A pooled study of 15 case–control studies examining sun exposure by latitude, with varying levels of UV radiation, found no overall association between melanomas of the head and neck with recreational exposure.[187] This study did observe an association with occupational exposure, whereas other pooled results of all melanomas, including melanomas on the trunk, arm, head and neck, as well as other sites, did not observe an association between occupational sun exposure and occurrence of the melanoma.[186] Exposure to indoor tanning is also associated with melanomas and the risk of melanoma increases with the number of years, sessions, and duration of indoor tanning.[188]There is also a particularly strong association observed among those exposed to UVA-emitting devices.[188] Other individual characteristics, including fair skin and light hair as well as family history, and presence of asymmetric nevi, are also associated with the risk for melanoma.[189]

Most melanoma incidence patterns and figures include melanomas across all locations across the body. One study examining the incidence of melanoma by subsite estimated the incidence rate of 2.0 per 100,000 for men and 1.0 per 100,000 for women melanomas occurring on the face. Cutaneous melanoma is increasing in incidence, between 1999 and 2008; incidence increased by 2.1% and 2.4% per year among men and women in the United States across all sites, respectively.[190] The incidence of cutaneous melanoma across all sites, including the trunk, back, legs, as well as other extremities, varies significantly across race/ethnicity; the incidence rate of all melanomas is ~30 times higher in white males compared to black males and 20 times higher in white females compared to black females.[42] The incidence of melanoma for Whites is also higher than that of Asian and Hispanics. A study examining the incidence of melanoma in California by site reported that ~20% to 22% of melanomas were located on the head and neck for Whites, Hispanics, and Asians but only 12% for Blacks.[191]

Approximately 75% of cutaneous head and neck melanomas are diagnosed with stage I disease and 17%, 6%, and 2% are diagnosed with stage II, III, and IV disease, respectively.[192] Prognosis of cutaneous melanoma of the head and neck is generally high. Among cases diagnosed between 2004 and 2009 in the SEER database, cause-specific survival was

90.4% for females and 87.10% for males.[192] The hazard of death increases steeply with stage and increasing age.[192] Whites have a lower hazard of death (HR 0.60, 95% CI 0.47 to 0.77) after adjusting for stage, age, gender, as well as treatment.[192]

CONCLUSION

Cancer of the head and neck encompasses many sites including the oral cavity, pharynx, larynx, salivary glands, thyroid, sinonasal tract, and skin. Site and histology vary; some of these subsites share common risk factors and others do not. Smoking is a major risk factor for most cancers of the head and neck, particularly for cancers of the *oral cavity* and *larynx*, and HPV is a risk factor for squamous cell carcinoma of the *oropharynx*. Risk factors for *cancer of the salivary glands* are less well defined. Radiation exposure appears to be the strongest risk factor for cancer *of the thyroid*.

The risk factors for cancers of the head and neck vary by site (location); therefore, the incidence of cancers of the head and neck, as shown in Tables 4.1 and 4.2, varies markedly across sites, time, and gender. In this chapter, we have presented the incidence, prognosis, and survival and discussed risk factors for each site. Cancer of the head and neck is often considered as one site, but this group of cancers is heterogeneous in pathology, risk factors, incidence rates, and survival.

5 Imaging of Head and Neck Cancer

Reza Forghani, Jason M. Johnson, and Lawrence E. Ginsberg

Over the past decades, there have been major advances and improvements in cross-sectional imaging techniques. Imaging, in particular computed tomography (CT), magnetic resonance imaging (MRI), and increasingly positron emission tomography (PET mainly combined with CT as PET/CT), now plays a central role in the management of head and neck cancer by the multidisciplinary team. Imaging can be used to identify tumor and at times suggest a differential diagnosis in order to attempt to distinguish benign from malignant lesions. However, in head and neck cancer, the determination of the specific tumor type requires biopsy for histopathology and increasingly molecular analysis, regardless of the imaging appearance of a tumor. Furthermore, not uncommonly, a diagnosis may have been already made at the time of initial imaging evaluation. Therefore, one of the most fundamental roles of imaging in head and neck cancer is to accurately determine the stage of a tumor and upstage the initial clinical assessment when appropriate. Imaging is integral in the evaluation of deep extent of tumor and lymph node levels that cannot be reliably evaluated clinically as well as in the identification of distant metastases. Following treatment, imaging is essential for surveillance and for identification of tumor recurrence, as well as for differentiating recurrence from treatment-related complications. The optimal imaging evaluation should focus on identification of tumor spread to critical structures that would alter tumor stage, determine resectability, and help with surgical and radiation therapy planning and approach.

This chapter provides an overview of current imaging modalities and emerging techniques for head and neck cancer imaging. It is neither the intention nor possible to cover such a broad topic in exhaustive detail in a single chapter. Rather, our aim is to introduce the most commonly used

techniques (CT, MRI, and PET/CT) and approach for noninvasive assessment of the common mucosal cancers of the head and neck. Imaging evaluation of sinonasal, oral cavity, oropharynx, hypopharynx, and laryngeal cancer will be discussed. A discussion of other cancer types and primary sites, including thyroid malignancies, salivary gland neoplasms, and skull base, is beyond the scope of this chapter. Ultrasound (US) and image-guided biopsies will be only briefly discussed. The chapter will begin with a discussion of the imaging techniques. This is followed by an overview of general assessment of tumors including tumor staging, spread, lymphadenopathy, and evaluation of perineural spread (PNS) of tumor. Post-treatment imaging will then be addressed. The chapter will conclude with primary site-specific considerations and a section on emerging imaging techniques.

IMAGING TECHNIQUES AND APPROACH TO HEAD AND NECK CANCER

Overview

Cross-sectional imaging techniques such as CT and MRI are the mainstay anatomic imaging modalities used for initial evaluation and follow-up of head and neck cancer. Since its invention in the 1970s, there have been remarkable advances in speed of acquisition and quality of images generated by CT scanners. MRI is another robust imaging technique that provides superb soft tissue contrast and likewise has undergone significant technical improvements enabling high-quality imaging of head and neck cancer and intracranial tumor extension. While both techniques have their strengths, currently, CT is typically the first-line imaging modality for initial evaluation of most head and neck pathologies. One exception is imaging of nasopharyngeal carcinoma (NPC), in which MRI has been shown to be superior in tumor staging,[1–6] although there can still be significant practice variations among different institutions. This will be discussed in greater detail later in the section on the nasopharynx. MRI also has certain advantages in the evaluation of sinonasal and oral cavity tumors that will be discussed in the specific sections on these primary sites. MRI is frequently used as an

adjunctive imaging modality for additional assessment of equivocal findings on CT, and has specific advantages for the evaluation of PNS and intracranial extension of tumor and is complementary to CT for evaluation of bone invasion.

Another important milestone in head and neck cancer imaging has been the introduction of molecular imaging techniques. PET, combined with anatomic/morphologic imaging techniques like CT (and more recently MRI), has emerged as an important adjunctive tool for initial evaluation and follow-up of head and neck cancers. US plays a central role in evaluation of thyroid disease, including thyroid malignancies, and is an important adjunct imaging tool in the assessment of nodal disease, particularly with its ability to facilitate image-guided biopsies. However, beyond select applications, US is not routinely used for evaluation and follow-up of the majority of mucosal head and neck malignancies in most North American institutions. Plain films and fluoroscopy have little role in routine evaluation and follow-up of head and neck cancer. The use of videofluoroscopic techniques for evaluation of swallowing and dysphagia in patients with head and neck cancer is beyond the scope of this chapter. The chapter will begin with an overview of CT, MRI, and PET before proceeding to a more specific discussion of tumor assessment.

Computed Tomography

Overview of CT Image Acquisition

CT is the first-line imaging modality for evaluation of most head and neck cancers in adults, known or suspected. Although it is not necessary to understand the complex physics and informatics behind acquisition of a CT scan, familiarity with broad principles behind image acquisition and display will enable a more effective use of the technology and recognition of its limitations. CT images are generated when x-rays transmitted through the patient's body are processed by detectors and reconstructed into a tomographic image, or slice, using sophisticated computer algorithms. The current conventional state-of-the-art CT scanners have a rotating gantry with a tube and detector opposing each other and enable acquisition of multiple slices simultaneously.[7] Current state-of-the-art scanners typically are 64-slice or higher, and the typical 64-slice scanner can generate slices with a thickness

of as little as 0.5 to 0.625 mm. For the standard neck CT, images should be typically reconstructed at a section thickness between 1 and 3 mm. The spatial resolution of the images in the axial (X to Y) plane, that is, the ability to resolve fine detail or the smallest distance at which two separate objects can be distinguished on an image, ranges between 0.33 and 0.47 mm. Because of their high resolution, the axial acquisitions on modern CT scanners can be used to generate "reformatted" images in the coronal and sagittal planes. This can be very useful for evaluation of head and neck cancer. In addition to the improvements in image quality, technical advances in CT have also resulted in significantly reduced patient exposure to ionizing radiation on modern CT scanners compared to their earlier counterparts.

Tissue Characterization and Image Display in CT

On CT, different tissues are characterized and distinguished based on their ability to attenuate x-ray beams passing through. The density of a structure can be quantified, and the standard measure used for quantification is the Hounsfield unit (HU), named after the British engineer who built the first CT scanner in the 1970s. By convention, the attenuation of x-rays by water is used as a standard reference and arbitrarily set at 0 (zero) HU. All other attenuations are reported in reference to that of water. The basic densities typically used as reference points on CT are air, fat, water, soft tissue, and bone, each having a higher attenuation (i.e., density or brightness) than the preceding, respectively (Fig. 5.1; Table 5.1), spanning a range of densities typically between −1,000 and +3,000 HU. Increased iodine content of a tissue also results in increased density of that tissue, which forms the basis of contrast-enhanced CT images.

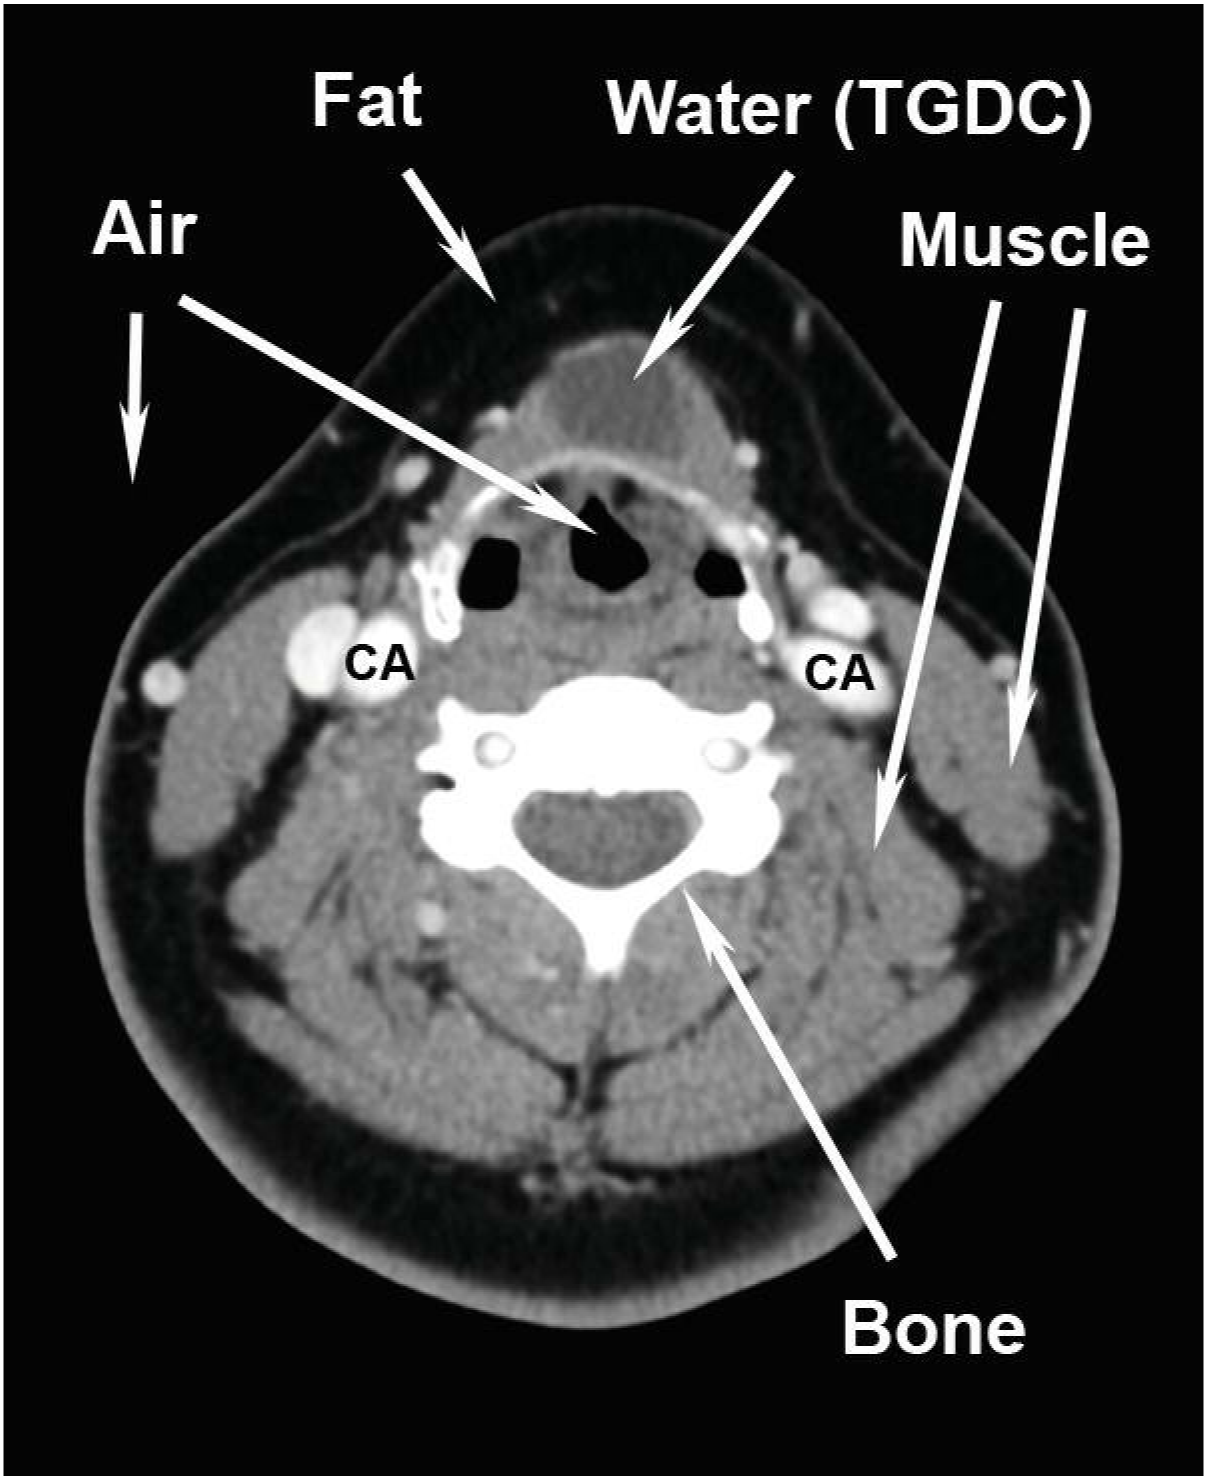

Figure 5.1. Axial contrast-enhanced CT image from a patient with a thyroglossal duct cyst (TGDC) demonstrates the basic tissue densities on CT. As discussed in greater detail in the text, there is progressively increasing density of air (*dark black*), subcutaneous fat, fluid or water (within the TGDC), muscle (soft tissue), and bone. Various intermediate densities are

seen, such as the brightly opacified carotid arteries (CA), secondary to a higher concentration of intravenous iodinated contrast, with density much higher than muscle but less than bone.

Table 5.1 Basic Tissue and Tumor Characteristics on Contrast-enhanced CT

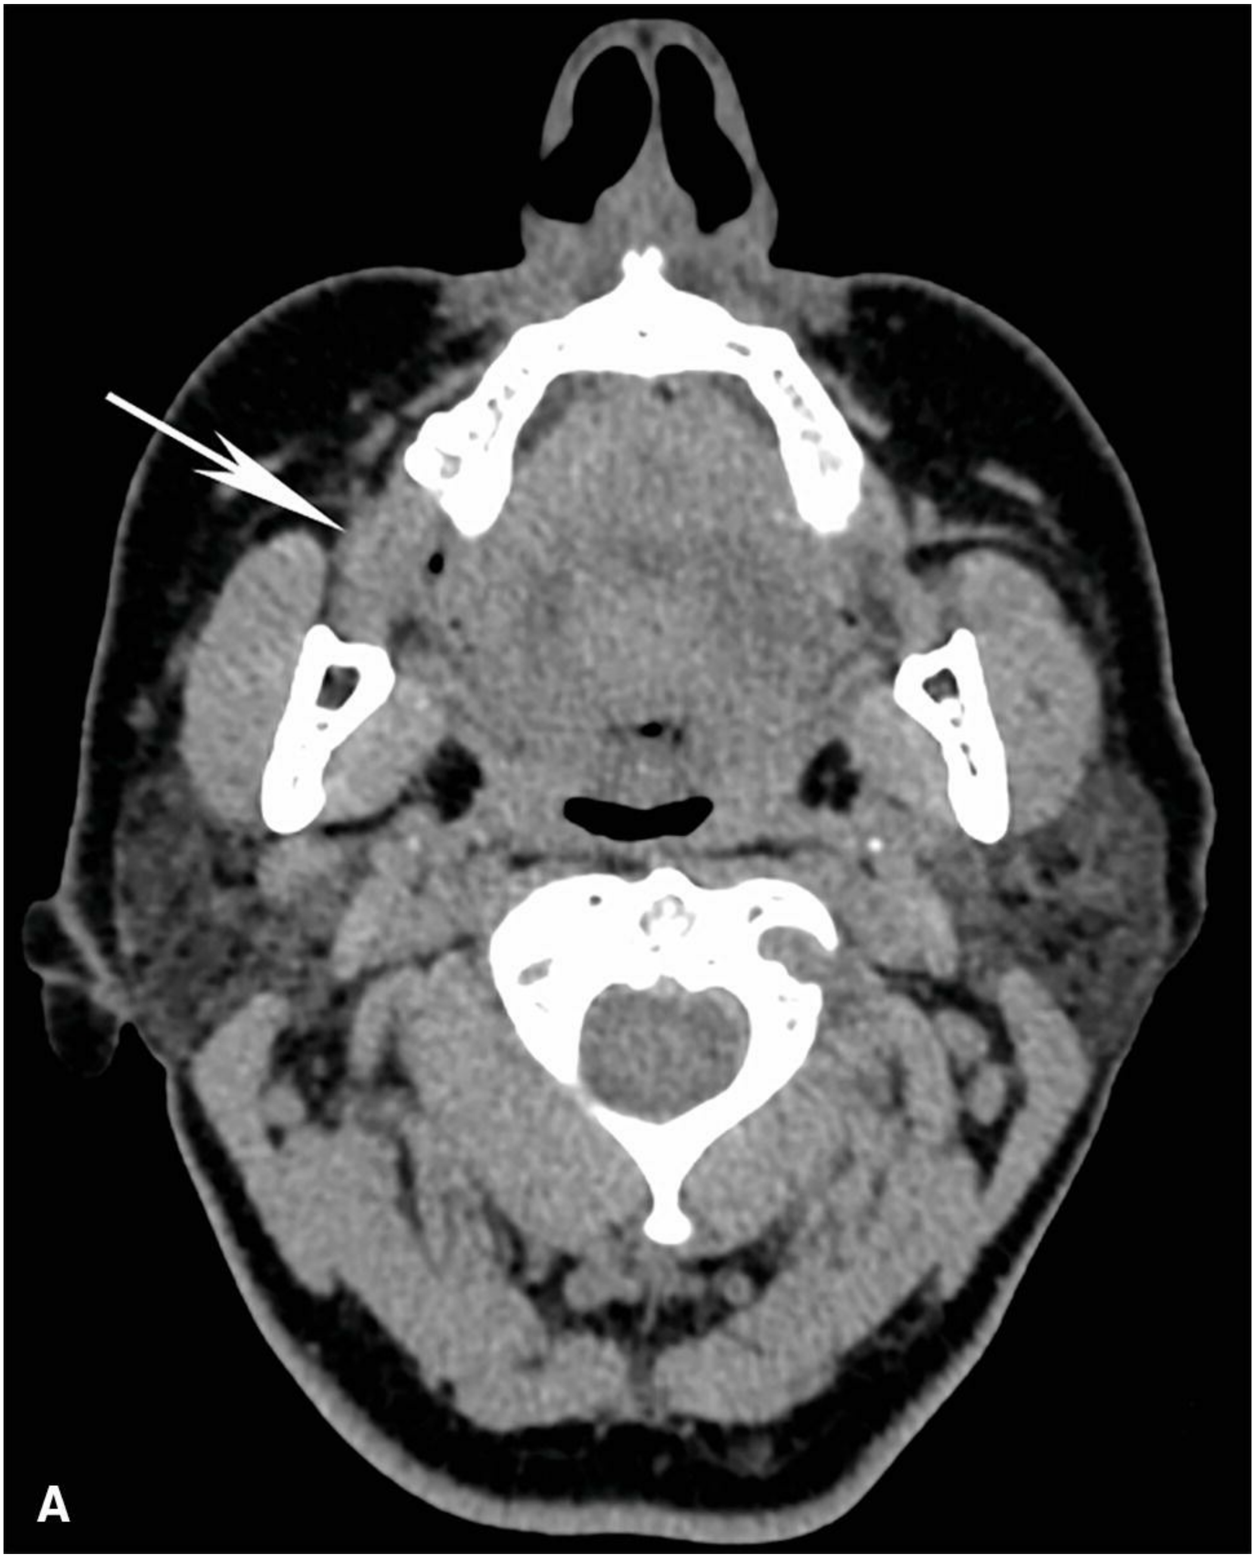
Tissue or Lesion	Relative Density and Approximate Hounsfield Unit (HU) Measurement	Comments
Air	Dark black; –1,000 HU range	
Fat	Darker than fluid; –180 to –30 HU	Macroscopic fat has a distinctive appearance and is readily recognized on CT. Fat is an important source of "intrinsic contrast," readily distinguishable from normal soft tissues such as muscle and most (nonlipomatous) tumors.
Water and other simple fluids	–30 to +20 HU	Simple cystic lesions, such as thyroglossal ducts cysts, have this density. However, areas of cystic change and necrosis within a tumor or lymph node can also approach the density of water on CT.
Normal soft tissues (e.g., muscle), tumor, complex fluid or cystic lesions (i.e., proteinaceous or hemorrhagic)	Typically +20 HU to +70/+100 HU; may be as dense as +300 HU or higher	Most tumors and soft tissues have densities less than +100 HU on contrast-enhanced CT. However, very vascular tumors (e.g., paraganglioma) with large iodine content can have higher density. Vessels with high iodine content can approach or even exceed +300 HU depending on the phase of the study, for example, in angiographic studies.
Bone, metal implants	Range close to +3,000 HU or higher for metal implants	Bone is very dense on CT, and this further varies based on the type of bone (i.e., cortical bone is denser than cancellous bone). Metallic devices can be even denser than bone, exceeding +3,000 HU, and appear very bright on CT.

On CT, tissue density can be quantified, measured by its Hounsfield unit (HU) density value. By convention, the attenuation of x-rays by water is used as standard reference and arbitrarily set at 0 (zero) HU. Greater HU value indicates greater density or brightness on CT.

Air essentially does not attenuate x-ray transmission and would have densities in the −1,000 HU range, appearing black on a CT image displayed with soft tissue settings, or "window" (discussed further below) (Fig. 5.1). Fat typically has densities between −180 and −30 HU and visually appears black on soft tissue "windows." Water and other simple fluids have densities ranging between −30 and +20 HU. More complex (i.e., proteinaceous or hemorrhagic) fluid and soft tissue (in the absence of IV contrast) have densities higher than +20 HU and may approach densities up to +70 to +100 HU. However, after administration of IV iodinated contrast, these could have densities as high as +300 HU, particularly in a structure with a high concentration of contrast such as a vessel (Fig. 5.1), if properly timed. Bone is very dense on CT, and the density further varies based on the type of bone

(i.e., cancellous vs. cortical bone) and can have attenuations of up to +3,000 HU.

To recapitulate, the ability to distinguish both normal and pathologic structures on CT is based on their density/attenuation. Therefore, spaces or tissues with largely different densities, such as soft tissue tumor invading a normally fat containing area or tumor extension into air containing sinus, are easy to distinguish on CT. However, this “inherent” tissue contrast by itself is insufficient for optimal imaging of head and neck cancer. The reason is that proper staging of tumor extent and lymphadenopathy frequently requires distinction from adjacent soft tissues, such as muscle, which can have very similar density to tumor on an unenhanced CT scan (Fig. 5.2). Therefore, in order to improve soft tissue contrast and help distinguish tumor from normal soft tissues or vital structures such as vessels, neck CTs are almost always performed after administration of iodinated IV contrast unless contraindicated. Administration of iodinated contrast agents results in increased tissue contrast and improves detection and delineation of tumors based on differences in their composition and vascularity, resulting in different enhancement patterns compared to normal soft tissue structures (Figs. 5.2 and 5.3). Sometimes, there can be early or increased enhancement of the tumor margins, presumably because of the higher vascularity of the tumor periphery[8] (Fig. 5.3). There is no need for routinely obtaining a precontrast study before the contrast-enhanced scan. However, a second set of contrast-enhanced images in a plane with a slightly different angle should be obtained through the oral cavity to improve visualization of areas obscured by dental artifact on the standard acquisition. Absolute and relative contraindications to the use of IV iodinated contrast agents are most frequently due to a history of allergic reactions or impaired renal function, a more detailed discussion of which is beyond the scope of this chapter.



A

Figure 5.2. Contrast-enhanced neck CT for tumor evaluation. Axial CT images obtained **(A)** before and **(B)** after administration of IV contrast from a 59-year-old woman with a right buccal squamous cell carcinoma (*arrow*) are

shown. **A:**Without IV contrast, there is asymmetry at the site of tumor, but the density is nearly identical (isodense) to muscle, and it is very difficult to clearly visualize the tumor margins. **B:** After administration of IV contrast, there is differential enhancement of tumor compared to adjacent soft tissues with better delineation of tumor margins.

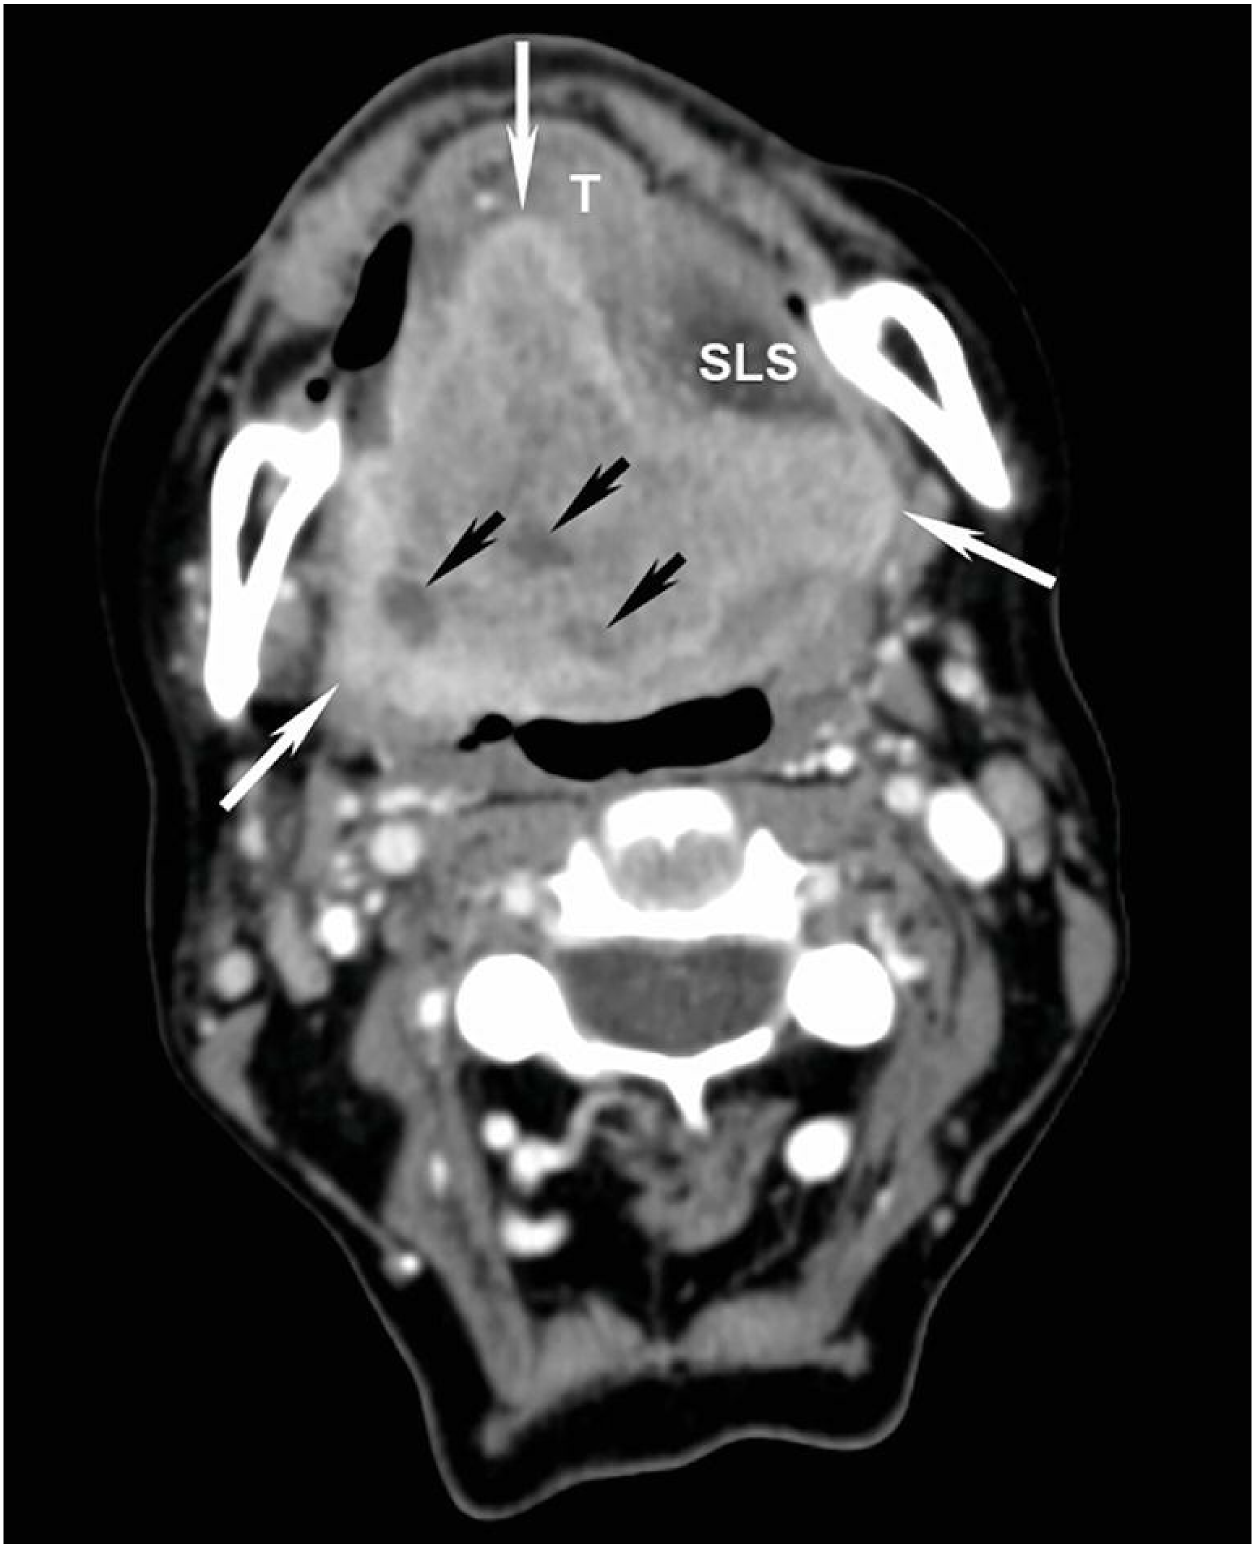


Figure 5.3. Contrast-enhanced neck CT for tumor evaluation and delineation. Axial contrast-enhanced CT image from a 56-year-old woman with a large invasive oral tongue cancer is shown. Because of differences in tumor vascularity compared to normal tissues, contrast-enhanced images are used to

distinguish tumor from otherwise similar density soft tissues such as muscle. Note the clear demarcation of the enhancing edge of tumor (*white arrows*). The small low-density areas within the tumor represent areas of cystic change and necrosis (*small black arrows*). T, tongue muscles; SLS, sublingual space.

Clinicians should be aware that for optimal viewing of specific structures, different display parameters, referred to as “windows,” are used. Windows routinely used during evaluation of a neck CT include soft tissues, bones, and lung windows (because the lung apices are scanned as part of standard neck acquisition). Failure to use the proper window may result in overlooking an abnormality. For example, failure to use bone windows may result in overlooking bone invasion (Fig. 5.4) or a bone metastasis. Commonly used display windows are also usually preprogrammed using different function keys for easy and rapid access.

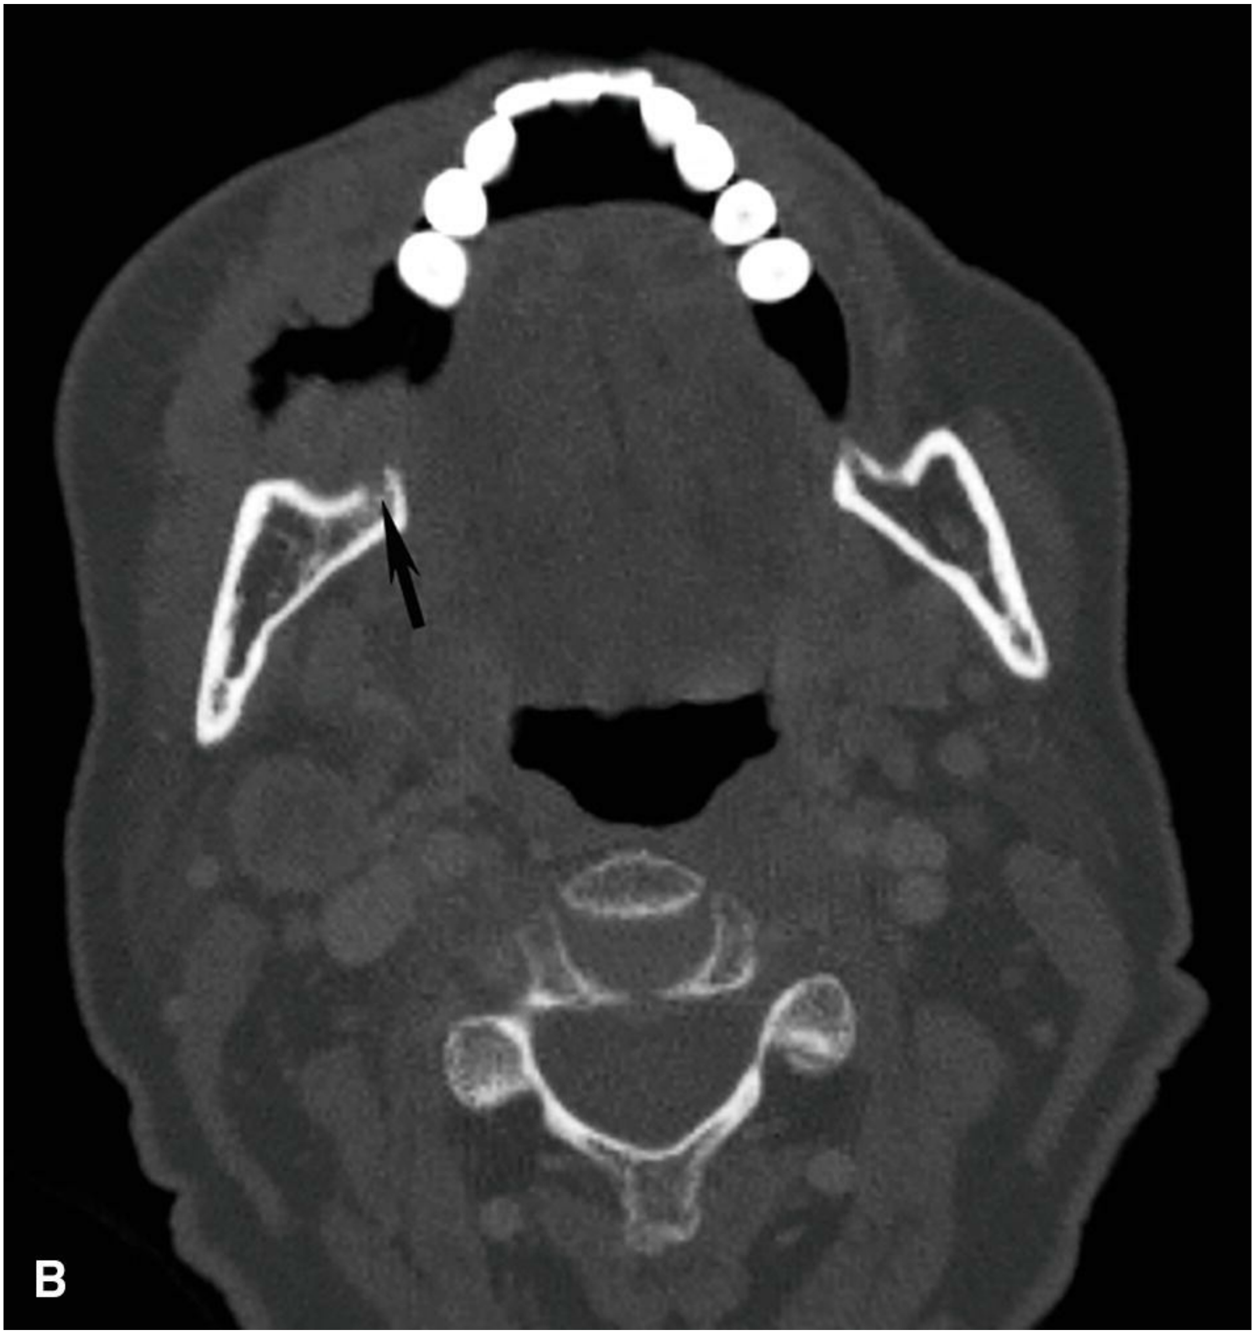

Figure 5.4. Optimal window display for evaluation of bones on CT. Axial contrast-enhanced CT images are shown from a 67-year-old woman with squamous cell carcinoma of the right gingivobuccal sulcus with extension to the retromolar trigone. The same slice is shown using two different reconstruction algorithms and display windows. **A:** Image displayed using narrow soft tissue windows is used for demonstration and evaluation of the mass (*white arrows*) and adjacent soft tissues. Notice how the cortex of the mandible is very bright when displayed in soft tissue windows with poor

visualization of bone architecture (*black arrow*). This image is not diagnostic of cortical invasion. **B:** The same slice reconstructed and displayed in bone "algorithm" demonstrates a small defect (*arrow*) corresponding to a pathologically proven focal cortical invasion of the mandible, resulting in a T4 stage designation. Note that although the bone windows demonstrate cortical invasion to better advantage, the soft tissue mass itself is poorly seen using these display parameters.

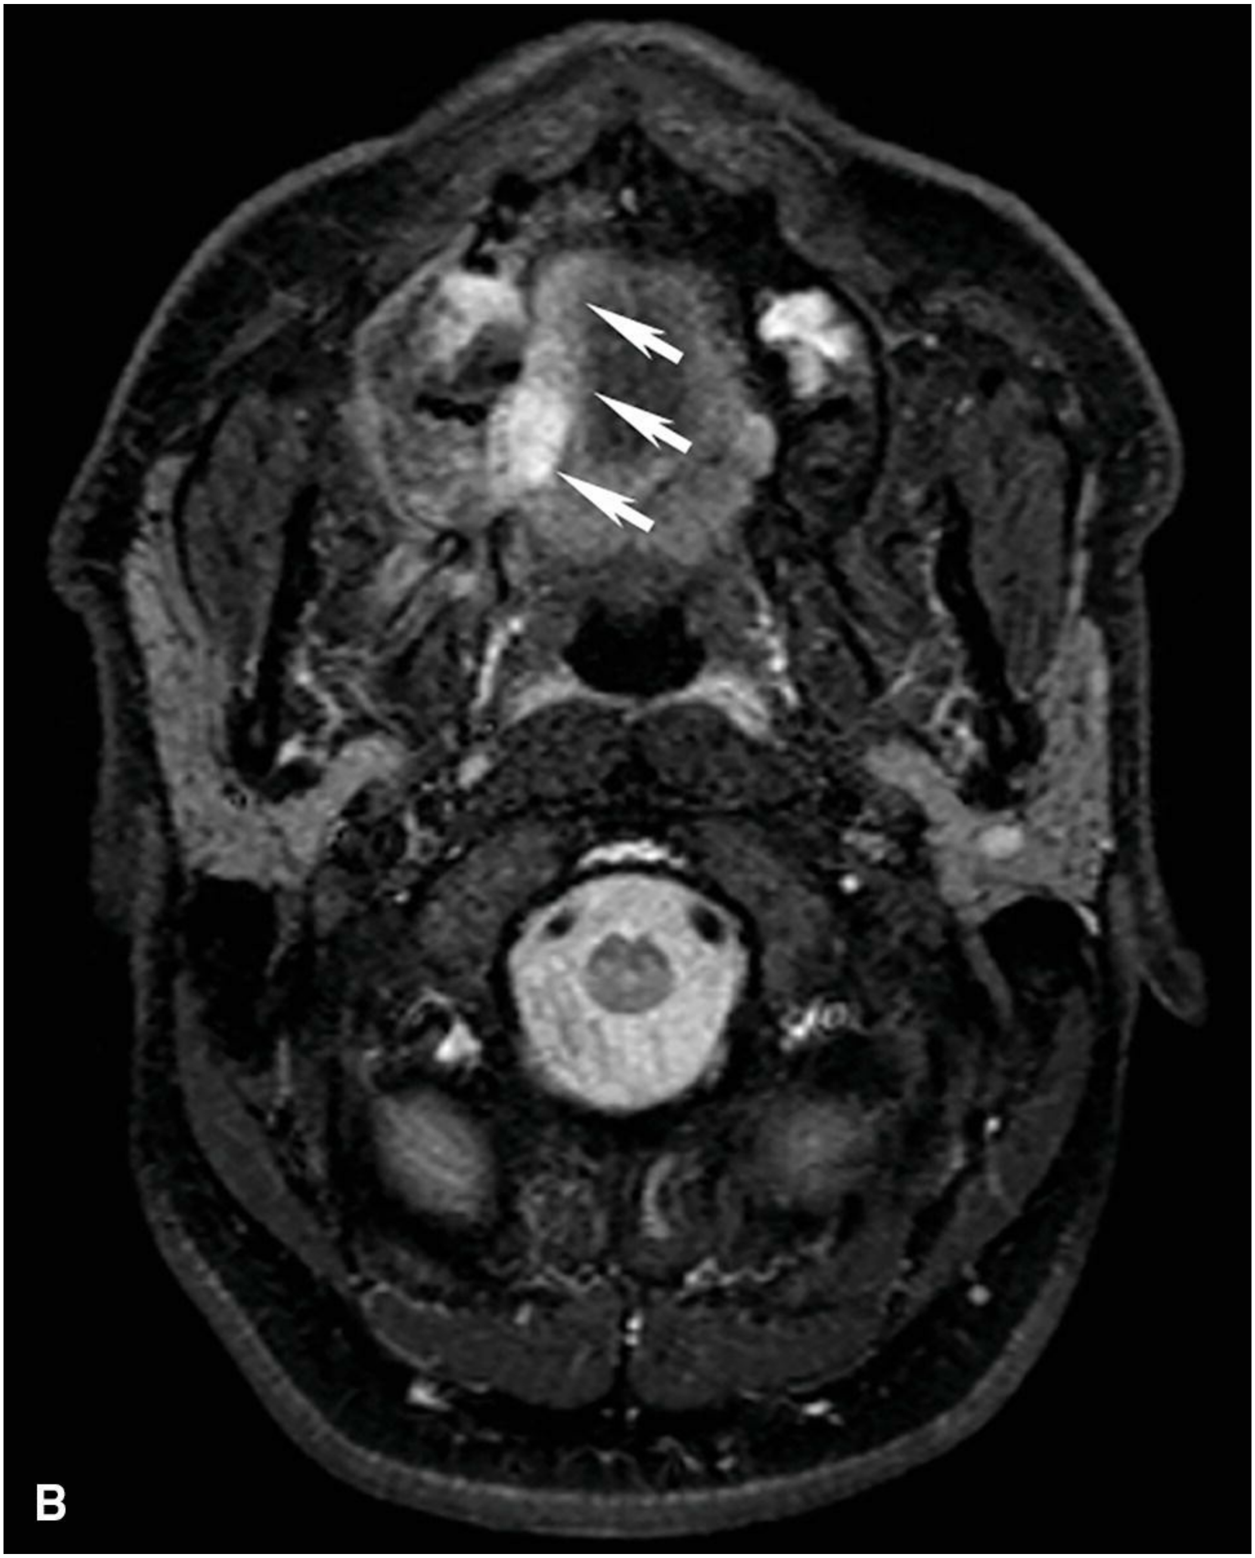
Magnetic Resonance Imaging

Basics of MRI

Whereas CT relies on differences in attenuation of x-ray beams by different tissues and tumor for distinction, MRI relies on entirely different properties of tissues. MRI is a powerful imaging technique based on the application of a uniform external magnetic field coupled with use of radiofrequency (RF) excitation pulses. Placement into an external magnetic field results in alignment of some of the protons within the tissues of the body. An RF pulse is then applied to perturb and result in a change in alignment of some of those protons, which subsequently return to their original alignment upon discontinuation of the RF pulse. This process produces signals that are ultimately reconstructed into images. Using different parameters, multiple "sequences" are acquired, each demonstrating different tissue characteristics and typically in different planes. These are then interpreted for characterization of normal tissues and pathology.

In general, MRI has superb soft tissue contrast that is superior to CT. Therefore, although CT provides an excellent evaluation of most head and neck cancers, in certain cases MRI may be able to identify tumor not seen on CT (Fig. 5.5). However, one disadvantage of MRI for head and neck cancer imaging is the relatively long scan times of at least 20 to 30 minutes or longer. Patients with head and neck cancer may have difficulty undergoing an MRI because of their inability to handle secretions and remain motionless during the scan, decreasing the diagnostic quality of the examination. This results in increased propensity to motion artifact, particularly below the hard palate, where there can also be image degradation secondary to swallowing artifact. A more detailed comparison of the two techniques will be provided later.

A



B

Figure 5.5. Superior soft tissue contrast of MRI compared to CT. Axial CT **(A)** and MRI **(B, C)** images are shown from a patient with an adenoid cystic carcinoma involving the right hard palate. On the contrast-enhanced CT

image, the approximate area of the lesion is marked by the *arrows*. The lesion is not clearly visible on CT, and only mild asymmetry and minimal heterogeneous density are seen in the region of the tumor. STIR **(B)** and contrast-enhanced T1w fat-suppressed MR images **(C)**, on the other hand, demonstrate abnormal high signal and heterogeneous enhancement in the right hard palate (*arrows*, **B** and **C**, respectively). Although CT typically enables excellent tumor delineation, occasionally, such as in this case, the lesion is much better seen on MRI because of MRI's superior soft tissue contrast.

There are trade-offs between key parameters affecting the quality of a scan and length of acquisition, which can both positively and negatively affect image quality. This is particularly relevant for MRI given the long scan times. Spatial resolution (e.g., when high-resolution imaging is required to look at a small structure of interest such as skull base neural foramina) comes partly at the expense of signal-to-noise ratio and ability to evaluate soft tissue contrast (i.e., ability to distinguish tumor from adjacent normal soft tissues), unless the duration of acquisition of a sequence is increased. However, while increasing the length of a scan improves signal to noise, it also predisposes to motion artifact, which can degrade image quality. Therefore, the MRI protocols are designed carefully and optimized to achieve the best result taking into account these variables. When detailed evaluation of a small area of interest, such as skull base foramina, is required, this is best performed as a targeted exam focusing on the area of interest, rather than an evaluation of the entire neck, if possible. An optimal examination is designed to achieve reasonable scan times that can be tolerated by the patient and also enable acquisition of high-quality images without significant motion degradation and image distortion.

Basic Sequences Used for MRI and Evaluation of Tissue Signal Characteristics

As discussed earlier, an MRI examination consists of different "sequences," typically obtained in different planes. Unlike CT, MRI of head and neck cancer is obtained without and with administration of IV contrast. For MRI, paramagnetic gadolinium (Gd)-based contrast agents are used, different from iodinated contrast agents used in CT. The basic sequences that can be used

for head and neck imaging are T1-weighted images (T1w), T2-weighted images (T2w), and short tau inversion recovery (STIR) images. T1w and T2w images can be obtained with fat suppression (T1FS and T2FS) to suppress the bright signal of fat and highlight pathologies such as tumor (see below for more explanations). T1w/T1FS or similar type sequences are used for evaluation of enhancement characteristics of a tumor, because Gd-based MRI contrast agents result in signal change and appear bright (white in color, or "hyperintense") on these sequences. It should be noted that the names and certain technical parameters for the sequences can vary depending on the specific scanner and vendor.

On MRI, lesions are characterized based on their signal or brightness. Lesions with higher signal are described as "hyperintense," those with signal similar to a reference structure are described as "isointense," and those with lower signal than the reference are described as "hypointense." The signal is typically compared to a standard or specific structure of interest. The reference used varies depending on body site (or the reader may specifically select a reference for comparison when appropriate), but in head and neck, the standard reference is frequently muscle. The typical sequences used for MRI evaluation of the neck and tissue and tumor characteristics on these sequences are summarized in Table 5.2 and are also further discussed below. Other sequences, such as head and neck applications of diffusion-weighted imaging, will be discussed in the section on emerging techniques.

Table 5.2 Basic MRI Sequences and Tissue Characteristics

Sequence	Basic Tissue Signal	Comments
T1w, without fat suppression	High signal: fat (including fat in the bone marrow), paramagnetic contrast, subacute hematoma (methemoglobin), mineralization	Good for depicting tissue architecture and anatomy. Enhancing tumor not as conspicuous as T1w images with fat suppression
	Intermediate signal: muscle, tumor	Fat can act as intrinsic contrast agent and help identify invasion of fatty structures by tumor by demonstrating replacement of high signal fat by intermediate signal of tumor
	Low signal: fluid, edema (low to intermediate)	Necrotic part of tumor or lymph node would have lower signal approaching that of fluid
	Very low signal/dark black: cortical bone, calcium	Hemorrhage or proteinaceous fluid can be bright—compare with precontrast images in order not to misinterpret as tissue enhancement
T1w, with fat suppression (standard sequence used to evaluate enhancement characteristics of tissues and tumor)	Fat has low, dark signal. Although not identical, other tissue signal patterns generally follow the trends described for T1w image without fat suppression.	Used to evaluate tumor enhancement, appearing as increased signal Better demonstrates tumor enhancement and allows clearer distinction from bright signal of normal structures such as fat
		Always compare to precontrast images to make sure bright signal is true enhancement (and not increased signal from proteinacious secretions and content or hemorrhage)
		Longer acquisition time than non–fat-suppressed T1 images may increase propensity to motion artifact
		Increased propensity to susceptibility artifact (at interfaces between air-containing paranasal sinuses and bones at the skull base or dental filling and implant artifact)
		Inhomogeneity of fat suppression can occur and should not be misinterpreted as bright signal from abnormal enhancement
		Enables diagnosis and confirmation of lesions with macroscopic fat content (e.g., a dermoid or lipoma or fat within a liposarcoma)
T2w images (fast spin-echo technique)	High signal: fluid, edema, fat (but less bright than fluid and not as bright as fat on T1w images)	Fat-suppressed T2w images accentuate high signal of tumor and edema by suppressing the bright signal of fat
	Intermediate signal: muscle (intermediate to low signal)	There may be areas of inhomogeneous or incomplete fat suppression (particularly superficially or in areas prone to susceptibility): should not be misinterpreted as abnormal
	Very low signal/dark black: cortical bone, calcium	Tumor usually has intermediate to high signal, and this sequence typically provides good contrast between tumor and muscle
		Higher cellularity tightly packed tumors may have relatively lower signal than lower cellularity loosely packed tumors
		Reactive tumor-associated edema typically appears brighter than the tumor itself
		Distinction from other structures such as salivary gland tissue may not be as clear based on signal alone and requires evaluation of subtle detailed anatomic features and/or correlation with other sequences
STIR	Although not identical, tissue signal patterns generally follow the trends described for fat-suppressed T2w images.	Typically has lower signal-to-noise than fast spin-echo T2w images, but practically, that is compensated for by greater soft tissue contrast and more uniform suppression of bright fat signal
	Fluid is even brighter than on T2w images.	Very good sequence for demonstrating tumor-associated edema or edema secondary to denervation change; see above comments and caveats for T2w images

T1w Images and Contrast-Enhanced Imaging.

T1w images can be performed without or with fat suppression and are also the sequences used for evaluation of contrast enhancement as described earlier. Standard, non–fat-suppressed T1w images have relatively short scanning times and are good for evaluating normal anatomy and tissue

architecture (Fig. 5.6). On this sequence, fat is very bright, muscle has intermediate signal, and simple fluid has low signal. Cortical bone has a very dark signal. The signal of the medullary portion of bones varies depending on the extent of their fat and hematopoietic elements. Fatty marrow appears bright, whereas significant cellular infiltration of marrow, including marrow invasion by tumor, has intermediate signal.

T
C

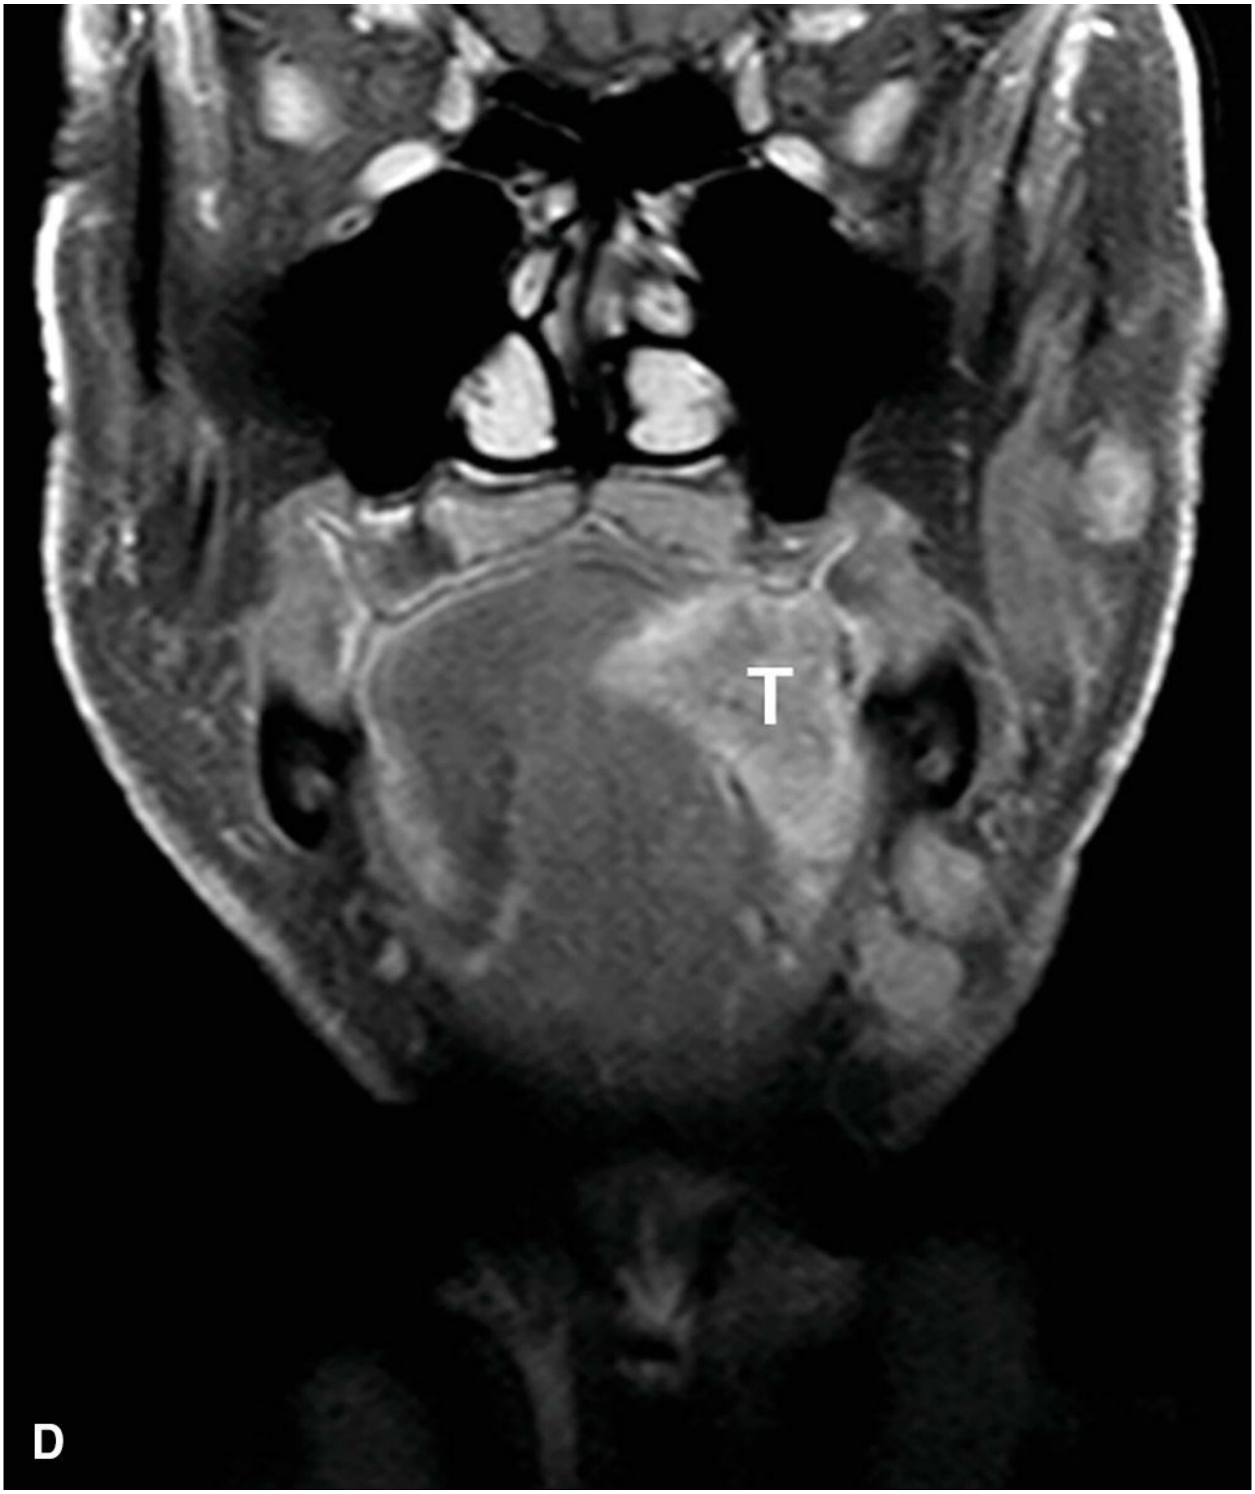

Figure 5.6. T1w and contrast-enhanced imaging for evaluation of cancer of the head and neck. Images are shown from a 59-year-old man with oral tongue squamous cell carcinoma. **A:** Axial T1w image without fat suppression. As discussed in the text, there is good depiction of normal anatomy. Muscle has intermediate signal (e.g., MS, *masseter*), and fat is very

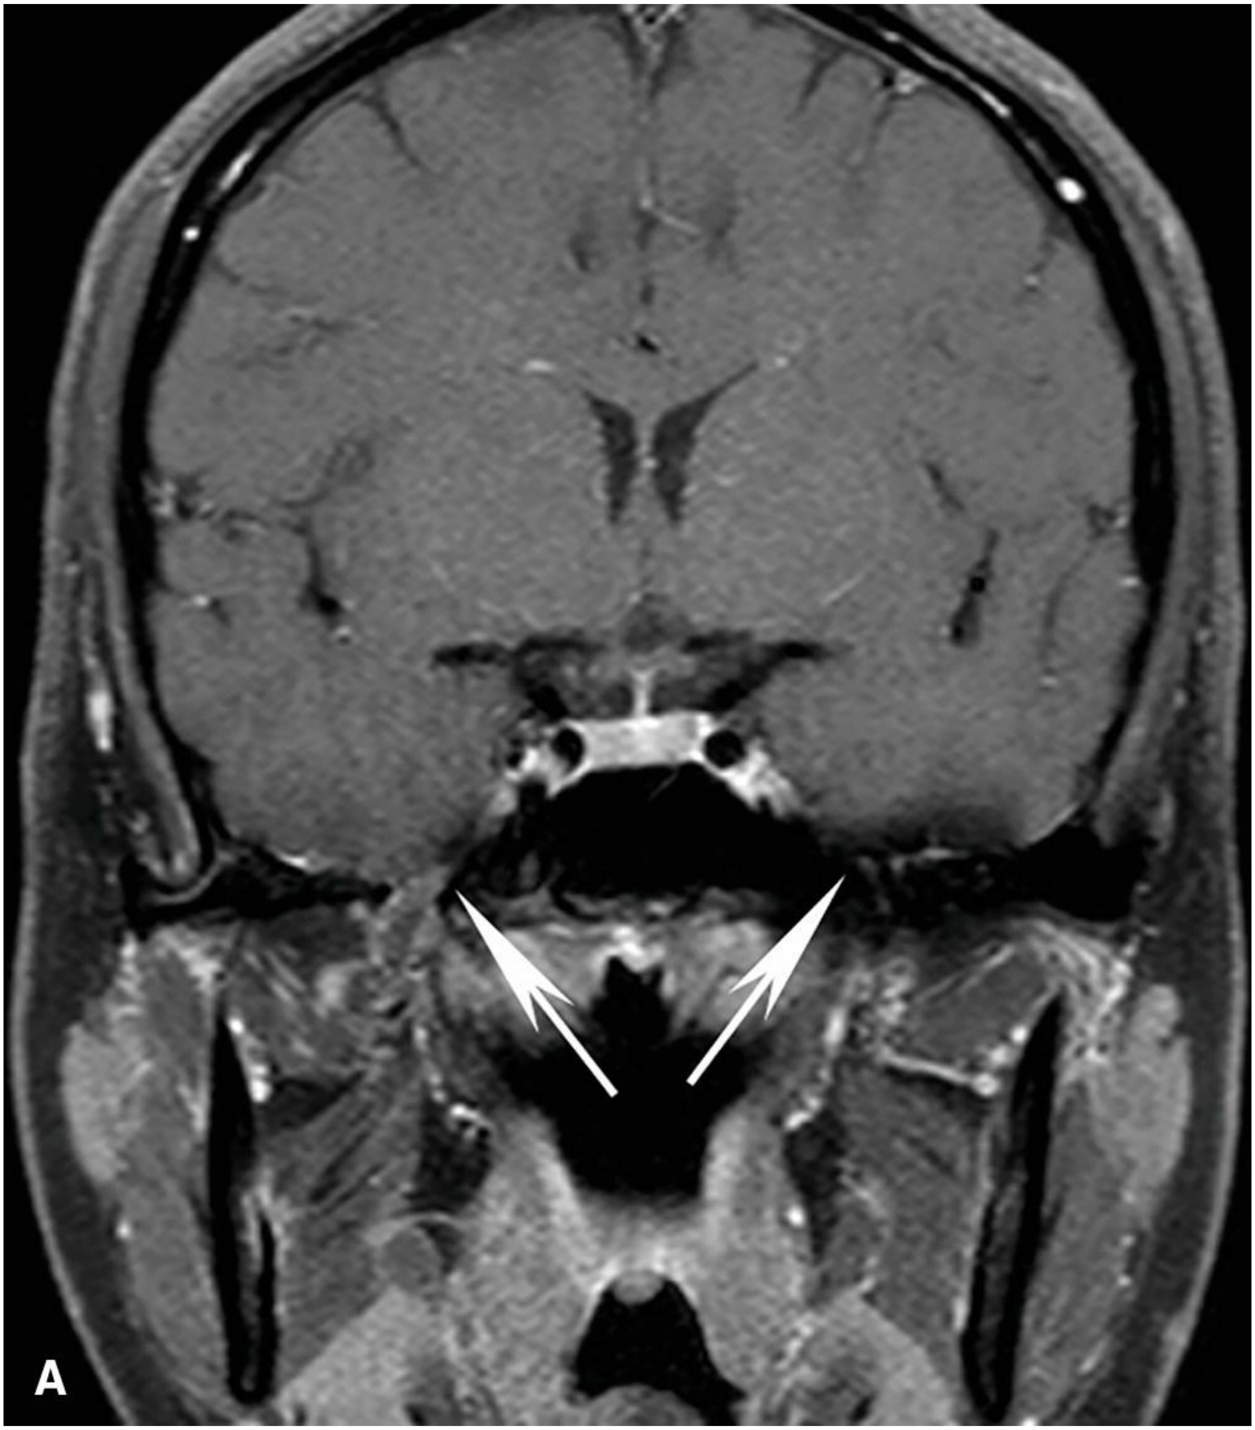
bright (or hyperintense), for example, the subcutaneous fat (*black asterisk*). Cortical bone is dark, whereas the fatty marrow is bright (**A**, e.g., *white circle* around the right mandibular ramus). The tumor (T) has intermediate signal on the unenhanced T1w image and is not very conspicuous. Because this patient has a relatively fatty tongue, the tumor margins are still visible. **B:** Postcontrast axial T1w image without fat suppression. Because of the intrinsically bright signal associated with the fat in the tongue, this sequence does not show the enhancing tumor (T) well. Postcontrast axial **(C)** and coronal T1w image **(D)**, both with fat suppression. Note how the enhancing tumor (T) is much more conspicuous on the fat-suppressed images compared to the non–fat-suppressed image **(B)**.

Contrast-enhanced images are key for tumor evaluation and should be obtained in all head and neck MRIs unless contraindicated. Paramagnetic contrast agents have bright signal on T1w images, and therefore, T1w images are the main sequence used for evaluation of contrast enhancement. In order to better depict tissue enhancement, contrast-enhanced T1w images are obtained as fat-suppressed sequences (T1FS). On these sequences, the bright signal of fat is suppressed and the fat appears dark, accentuating the enhancement characteristics of normal tissues and tumors (Fig. 5.6). All head and neck MRIs should include contrast-enhanced T1FS images. However, it is noteworthy that fat-saturated images are more prone to artifacts, particularly at air–bone interfaces such as the skull base or at sites of metal implants, dental fillings, or dental implants (Table 5.2; Fig. 5.7). Therefore, at some institutions and for select applications, one or more sets of postcontrast T1w images without fat suppression may also be obtained, in addition to fat-suppressed images (Fig. 5.7). On non–fat-suppressed contrast-enhanced T1w images, tumor has a grayish hue, which is typically distinguishable from the brighter signal of fat although the enhancement is not as conspicuous as on T1FS images.



A

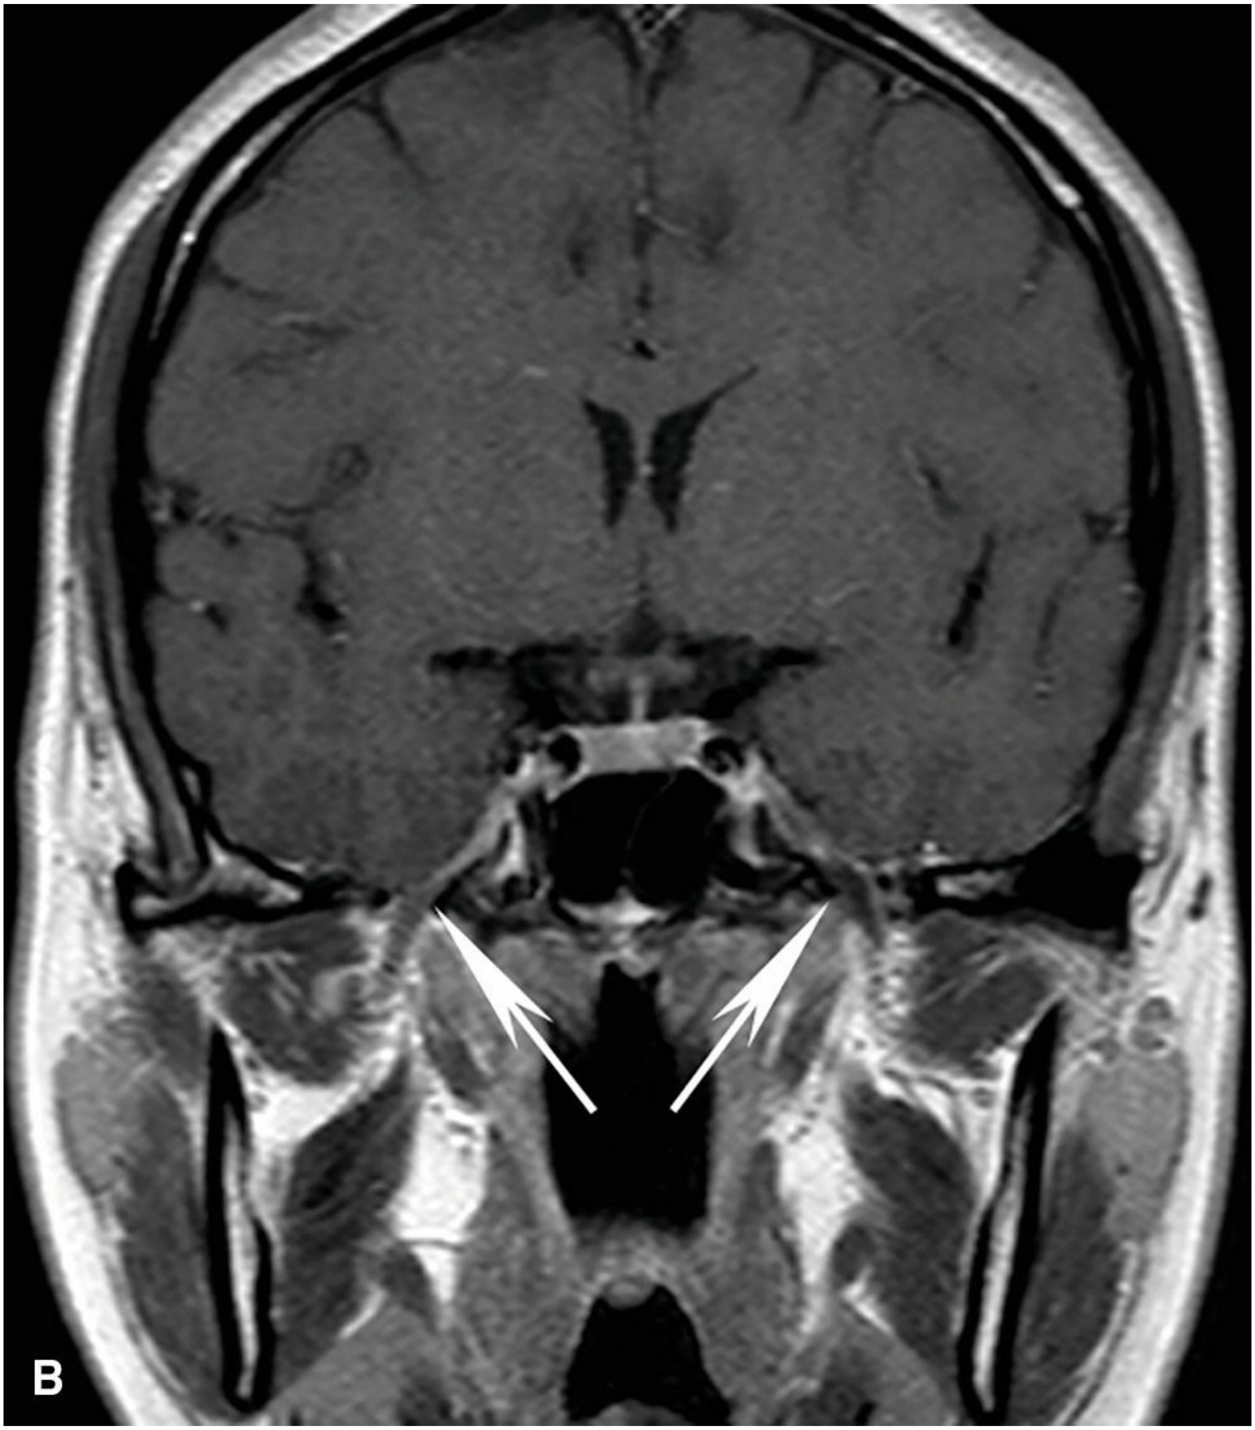


Figure 5.7. Effects of fat suppression on artifacts at the skull base. Coronal postcontrast T1w images with fat suppression **(A)** and without fat suppression **(B)** are shown. On the fat-suppressed image **(A)**, the foramen ovale (*arrows*) is partly obscured bilaterally, especially on the left side. On the other hand, the foramen ovale is well seen bilaterally on the T1w image obtained without fat suppression (**B**, *arrows*), and a normal intermediate

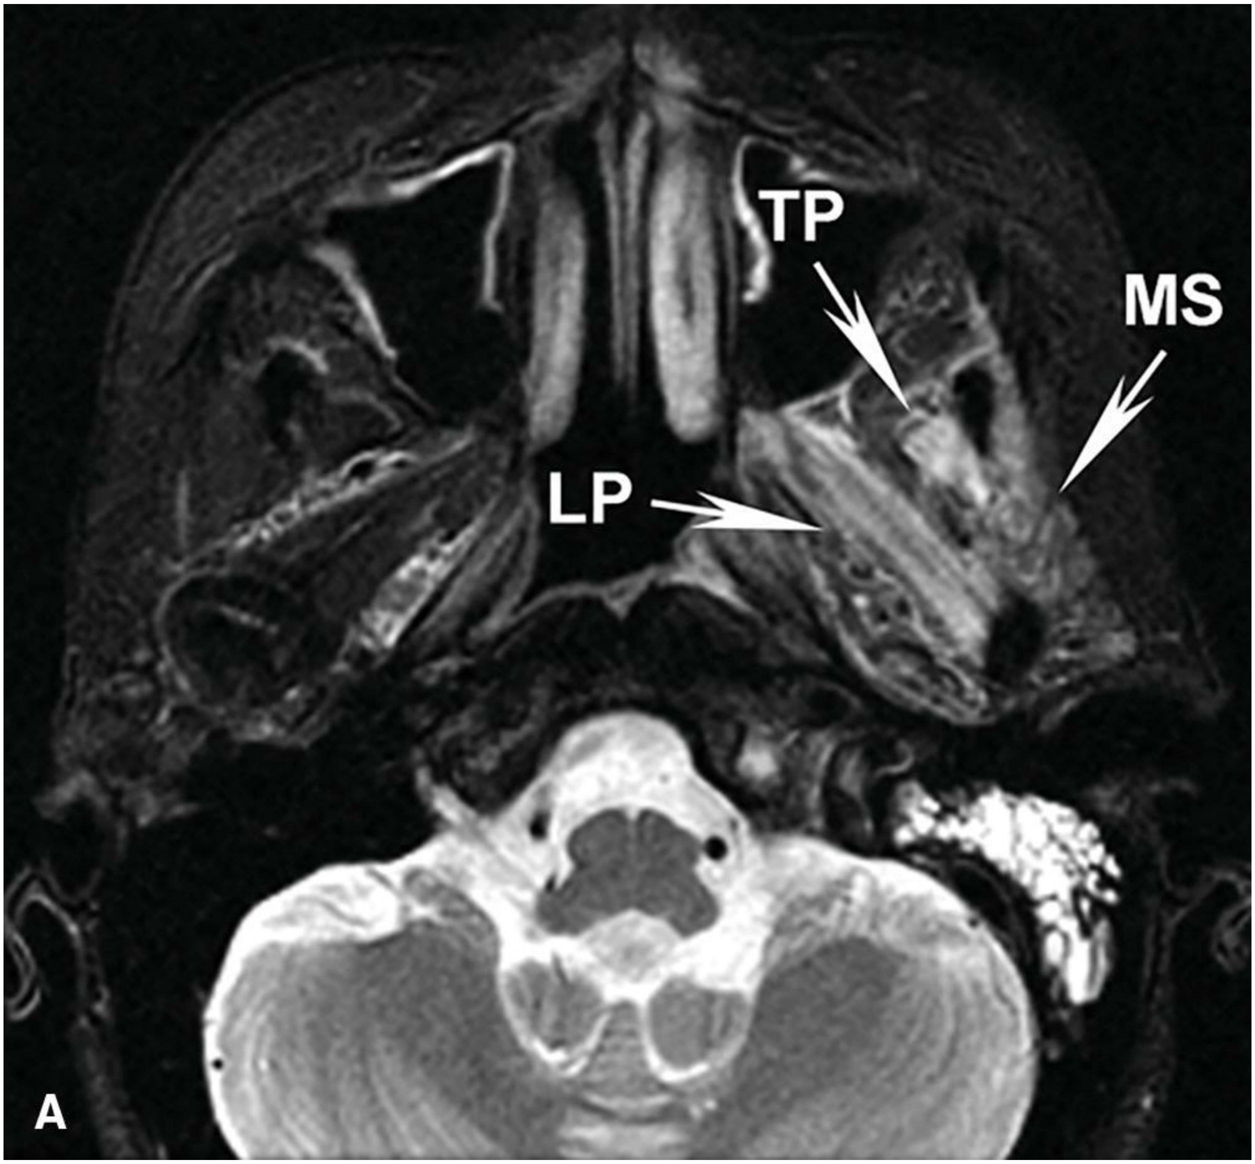
signal V3 branch is well seen on both sides. Therefore, although fat-suppressed T1w images are the primary sequence for evaluation of lesion enhancement, in select cases, addition of a non–fat-suppressed T1w sequence can improve diagnostic evaluation.

T2w and STIR Images.

T2w and/or STIR images are important sequences and are routinely obtained during head and neck imaging. On T2w images, fat is bright, although typically not as bright as T1 images, and muscle has intermediate to low signal (Table 5.2). Unlike T1 images, fluid is very bright on T2w images. On T2w images, tumor typically has intermediate signal, but this can vary from hypointense to hyperintense relative to muscle depending on the specific tumor type and tumor cellularity. This sequence typically provides good contrast between tumor and muscle. Tumor-associated edema also has high signal, typically higher than the signal of cellular tumor itself, which needs to be taken into account when evaluating invasion of anatomic structures such as marrow, when distinction between reactive edema and tumor invasion is important. Tumors with high cellularity tend to have relatively lower signal on T2w images compared to less cellular and more loosely packed tumors. As would be expected, the necrotic part of a tumor would have higher signal approaching that of fluid, and T2w images are a good sequence for identification of nodal inhomogeneity or necrosis, confirmed by demonstration of lack of internal enhancement on postcontrast T1w images (necrotic tumor components do not enhance). T2w images can also be obtained with fat suppression, to subdue the bright signal of fat and accentuate relatively hyperintense tumor and edema (Fig. 5.8). Fat-suppressed T2w images and STIR images (discussed next) are especially important for the evaluation of skull base and nasopharynx and are also very useful for demonstrating edema associated with denervation changes (Fig. 5.8).



TP
MS
LP
A

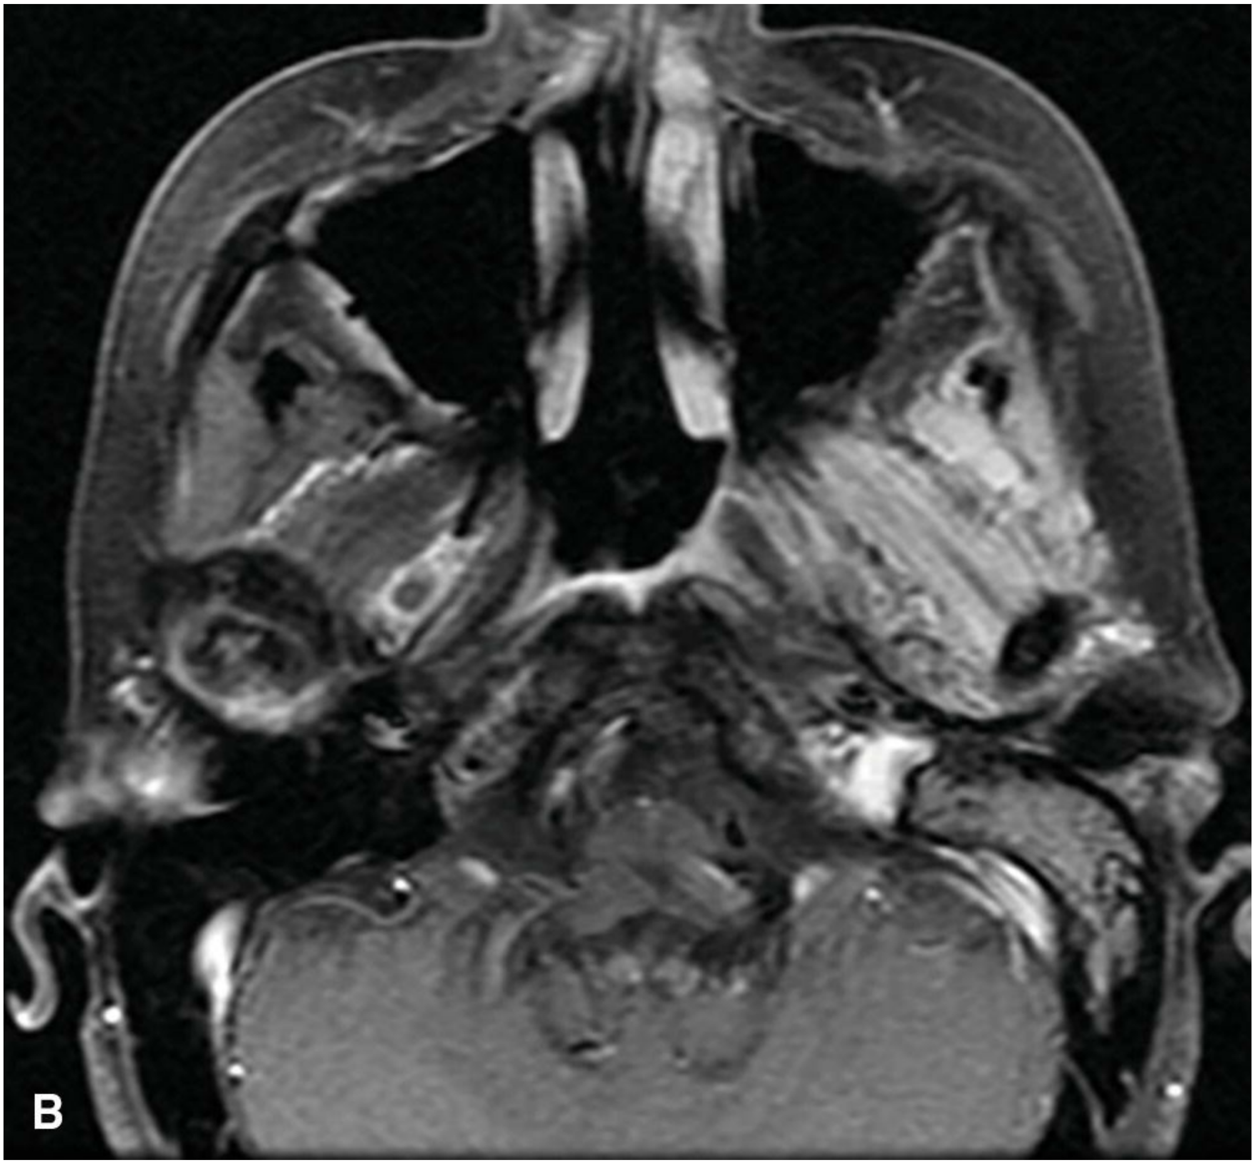


Figure 5.8. Denervation changes on MRI and utility of fat-suppressed T2w images. Axial fat-suppressed T2w **(A)** and contrast enhanced T1w **(B)** images are shown from a 43-year-old woman with recurrent nasopharyngeal cancer to the left Meckel cave (not shown). There are typical denervation changes in the distribution of the mandibular division of the left trigeminal nerve (V3) with hyperintense T2 signal **(A)** and abnormal enhancement **(B)** in the lateral pterygoid (LP), temporalis (TP), and masseter (MS) muscles. Note the preservation of muscle architecture with striations that is typical of denervation change and should not be mistaken for tumor. Fat-suppressed T2w images (or STIR images—not shown) are excellent for demonstrating edema.

Although technically different, the signal characteristics of tissues on STIR images (Fig. 5.9) are in many ways similar to, and follow what is seen on, fat-suppressed T2w images. Although the signal to noise of a typical STIR image is lower than that of T2w images, this is made up for by the increased soft tissue contrast. STIR has very good soft tissue contrast, has more uniform suppression of fat signal, and is excellent for demonstrating high signal from soft tissue tumors or edema[9,10] (Fig. 5.9; Table 5.2). Similar to fat-saturated T2w images, fat is dark on STIR images. Simple fluid and edema are even brighter on STIR than T2w images, and these sequences are excellent for demonstrating edema or necrosis within the tumor or pathologic lymph nodes. Tumor also tends to be brighter on STIR compared to T2w images. It is noteworthy that normal mucosal surfaces may have high signal intensity on STIR images, and this should not be mistaken for pathology.[11] All head and neck MRIs should include at least one set of fat-suppressed T2w or STIR images. Please refer to Table 5.2 for a more detailed description of tissue signal on different MRI sequences.

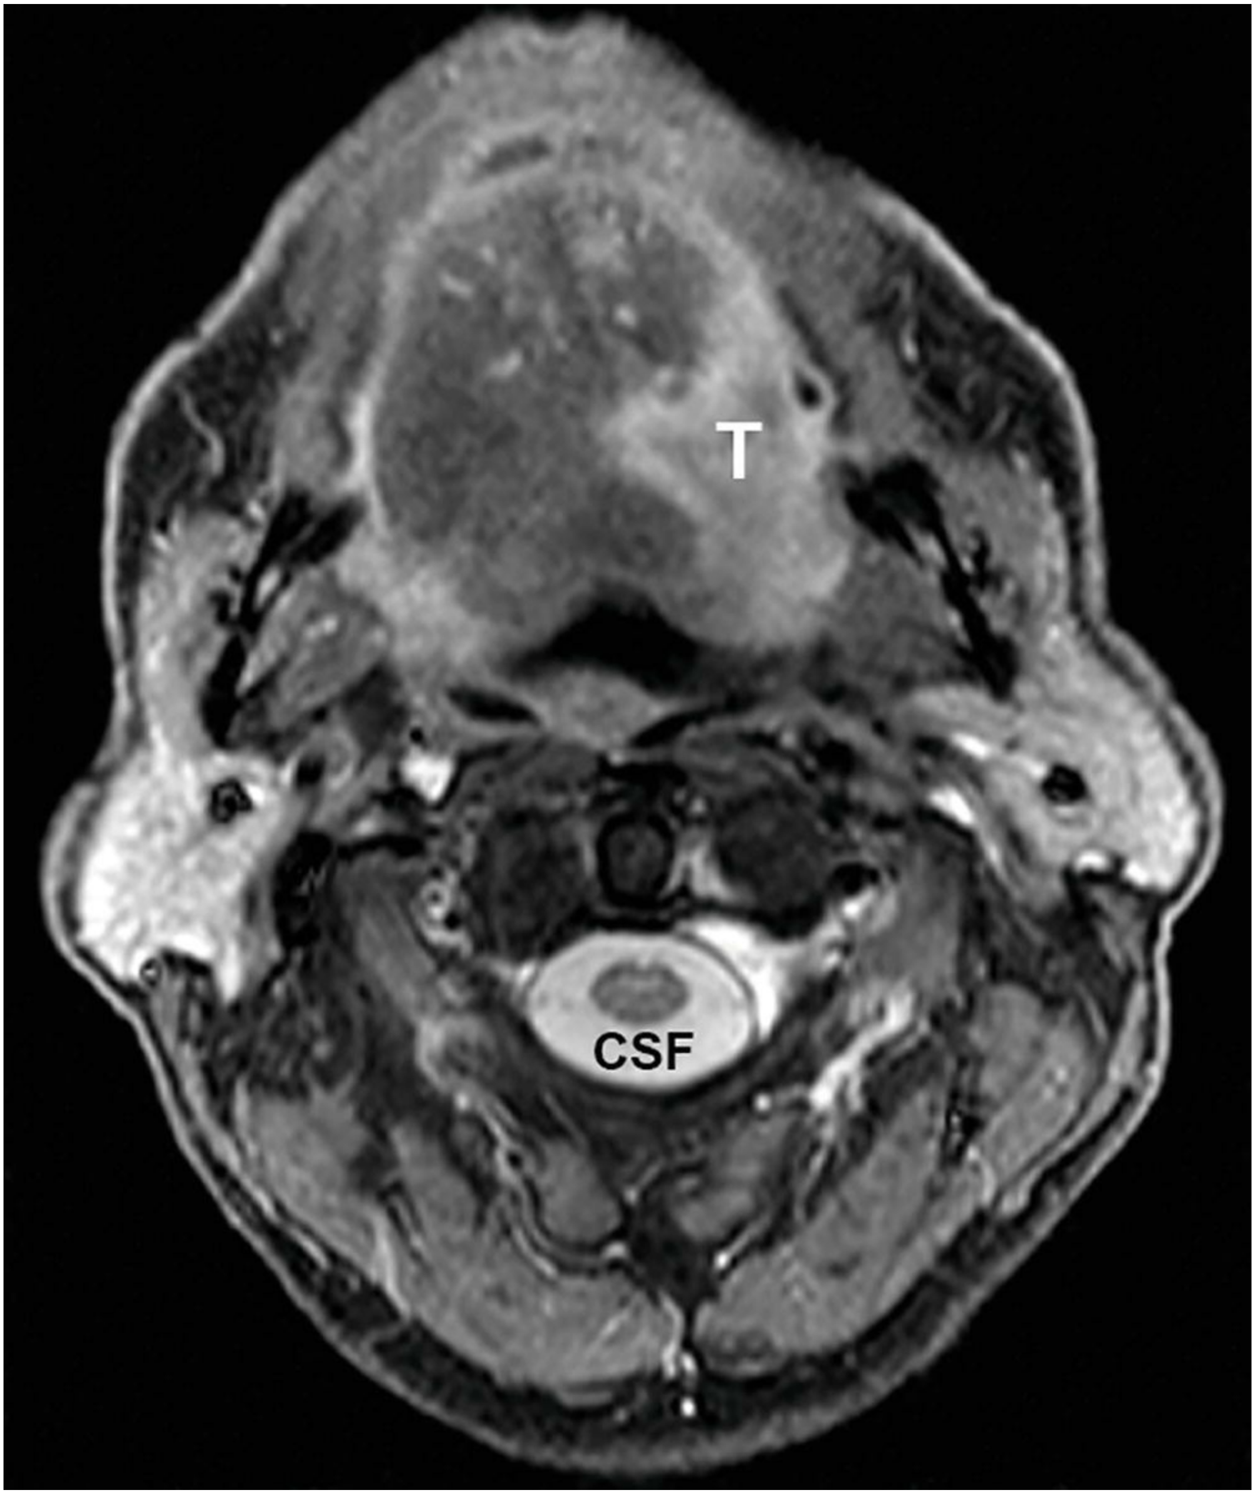

Figure 5.9. Tumor appearance on STIR images. STIR image is shown from the same case displayed in Figure 5.6. Note the bright signal of the tongue cancer (T) compared to adjacent tissues. Fluid, such as that of cerebrospinal fluid (CSF), is very bright on STIR.

Comparative Overview of Strengths and Weaknesses of CT Technique for Head and Neck Cancer Imaging

Some of the advantages of CT and MRI were discussed in the preceding sections, and the techniques are also compared in greater detail in Table 5.3. Briefly, advantages of CT accounting for its popularity include rapid image acquisition, widespread availability, and relatively lower cost compared to MRI. On the typical modern CT scanner with 64 or more slices, a neck CT is obtained in <10 seconds. As a result, CT is generally better tolerated by patients compared to MRI where the typical scan times will be 20 to 30 minutes or even more in specialized applications. Imaging of the head and neck, particularly below the level of the hard palate, is prone to motion artifact that may result from swallowing or other motion if the patient cannot remain still. The problem is further exacerbated in patients having difficulty breathing or difficulty clearing secretions. Therefore, from a diagnostic image quality perspective, the short scan times of CT represent a considerable advantage over MRI for cancers below the level of the hard palate. CT is also a safer environment for the evaluation of acutely ill patients or patients with respiratory difficulties who would have difficulty lying still in the supine position for a prolonged period of time.

Table 5.3 Comparison of Relative Strengths of CT and MRI for Head and Neck Cancer Imaging

	CT	MRI
Diagnostic and image quality, artifact	■ Less prone to motion degradation and swallowing artifact, particularly below the level of the hard palate ■ Complementary to MRI for evaluation of bone, better visualization of bone architecture, and early cortical invasion ■ Single plane acquisition disadvantage for certain areas such as palate but at least in part offset by the ability to generate high-quality reformats in sagittal and coronal planes on modern scanners	■ Higher soft tissue contrast ■ Typically less prone to dental implant and metallic hardware-related artifact ■ Prone to artifact at interfaces between soft tissues or bone and air ■ Complementary to CT for evaluation of bones, better visualization of marrow edema, and marrow invasion ■ Multiplanar acquisition
Patient tolerance, safety, and exposure to ionizing radiation	■ Rapid acquisition (actual scan time within seconds) is better tolerated by patients, particularly patients who are ill and patients with respiratory problems or difficulty clearing secretions who may have a hard time remaining motionless for a prolonged period of time ■ Higher likelihood of occurrence and severity of anaphylactoid and anaphylactic reactions compared to MRI contrast agents ■ Exposure to ionizing radiation	■ No exposure to ionizing radiation although practically this is not a significant or determining factor in the typical adult head and neck cancer population ■ Risk of rare but potentially fatal adverse reaction of nephrogenic systemic fibrosis in patients with significantly impaired renal function
Accessibility and cost	■ Generally more accessible ■ Costs less than MRI	■ Less accessible, especially outside large centers ■ Typically costs more than CT

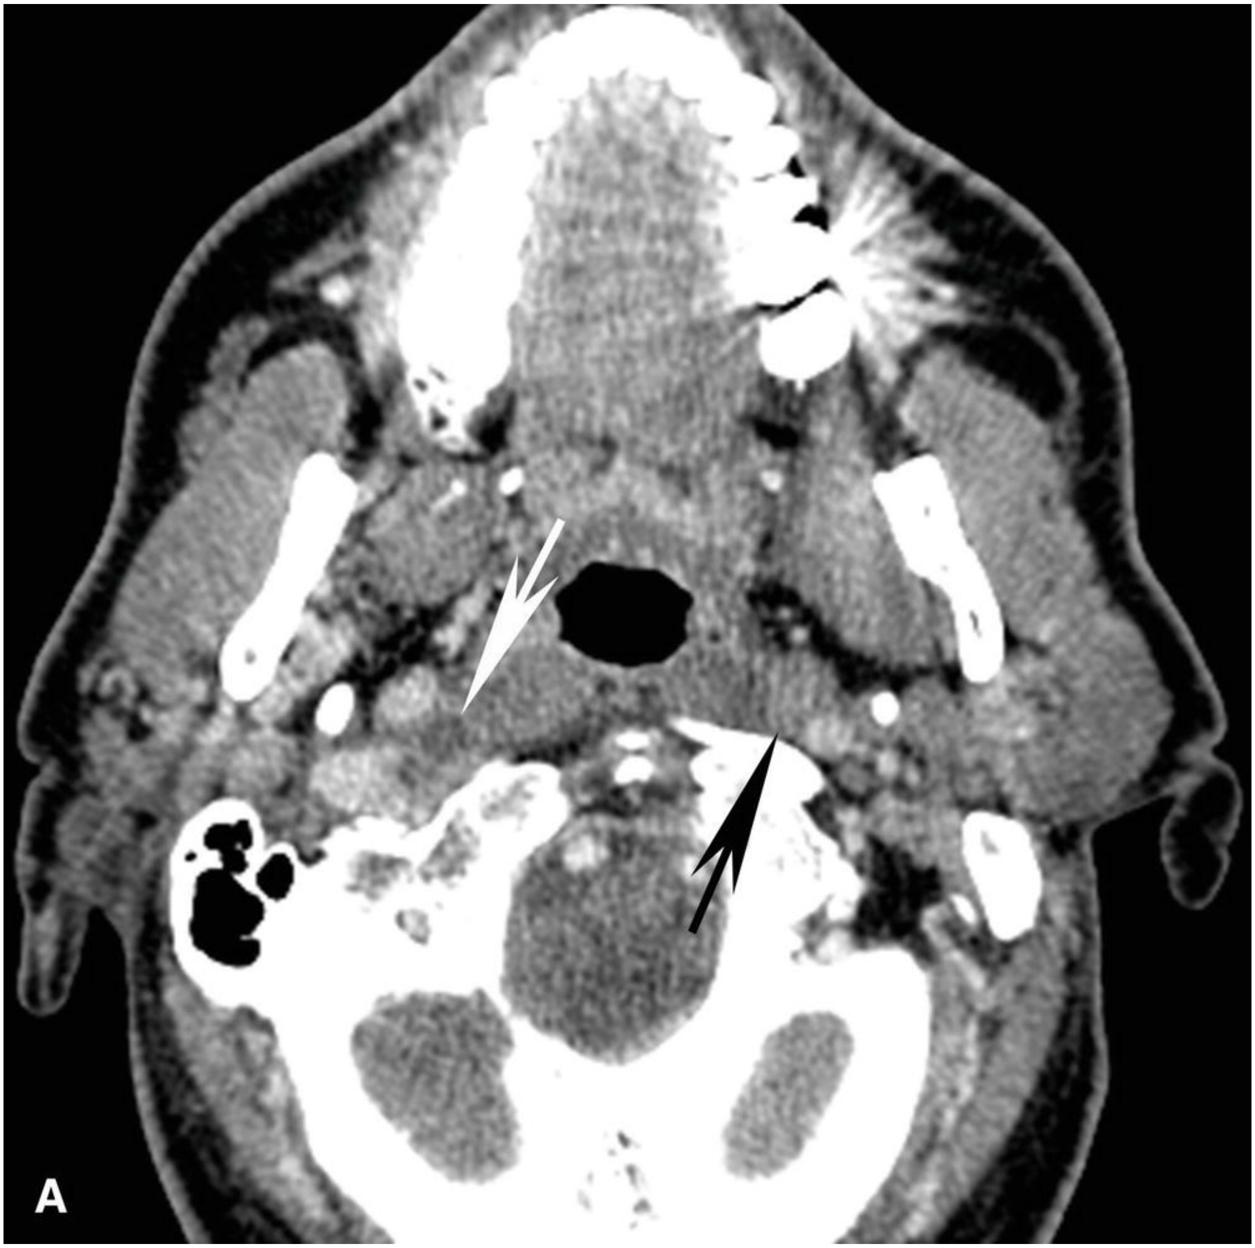
MRI is frequently used as an adjunctive tool for better delineation of lesions not clearly seen on CT and for specialized applications such as evaluation of PNS of tumor or intracranial extension. There is also typically less dental artifact on MRI compared to CT, although this is not always predictable. CT and MRI are generally considered complementary for the evaluation of bone invasion. CT is superior for detection of cortical erosion (Fig. 5.4), whereas MRI is superior for determination of marrow invasion, such as infiltration by nasopharyngeal cancer. Additional site-specific advantages of each modality are discussed later in this chapter. There is greater risk of adverse reactions such as anaphylactic reactions with iodinated contrast agents used for CT compared to MRI contrast agents. There is also a risk of impaired renal function with CT contrast agents, mainly in patients with preexisting renal failure. However, although MRI contrast agents do not induce renal failure, there is a rare but potentially fatal complication of nephrogenic systemic fibrosis associated with gadolinium-based MRI contrast agents in patients with severely impaired renal function,[12] and an estimated glomerular filtration rate (eGFR) of <30 mL/min/1.73 m^2 is generally considered an absolute contraindication to administration of gadolinium. MRI is also contraindicated in patients with certain metallic implants, accidental foreign bodies, and most patients with pacemakers, although newer pacemakers with conditional MRI compatibility are increasingly becoming available and may no longer represent an absolute contraindication in the future. A more detailed discussion of potential adverse reactions and safety is beyond the scope of this chapter. A summary comparison of strengths and relative disadvantages of CT and MRI is provided in Table 5.3.

Molecular Functional Imaging: Positron Emission Tomography in Head and Neck Cancer

Overview of PET Principles and Acquisition

PET has emerged as an essential adjunctive modality for evaluation of head and neck cancer.[13,14] PET is a functional technique that evaluates cellular metabolism. This is achieved by “tagging” metabolites of interest with specific radiopharmaceuticals, which in turn can be detected and localized with a PET scanner. When integrated with an anatomic technique like CT,

this provides a robust functional evaluation while enabling accurate anatomic localization, which is very important given the complex anatomy in the head and neck. Therefore, current standard practice is to perform a combined PET/CT for evaluation of head and neck cancer.[13,14] Most PET/CTs for head and neck cancer are performed using the radiopharmaceutical 2-18F-fluoro-2-deoxy-D-glucose (FDG), a glucose analog that is taken up by cells but is not metabolized.[13,14] The rationale for FDG–PET cancer imaging is that in general, cancer cells have greater uptake on PET than do normal tissues (known as Warburg effect) (Fig. 5.10). However, one must take into account that increased FDG uptake is not specific to cancer cells and may be seen in context of inflammation/infection including biopsy sites, some benign neoplasms, or increased muscular activity under certain circumstances. This needs to be taken into account when interpreting PET scans; to be discussed later.



A

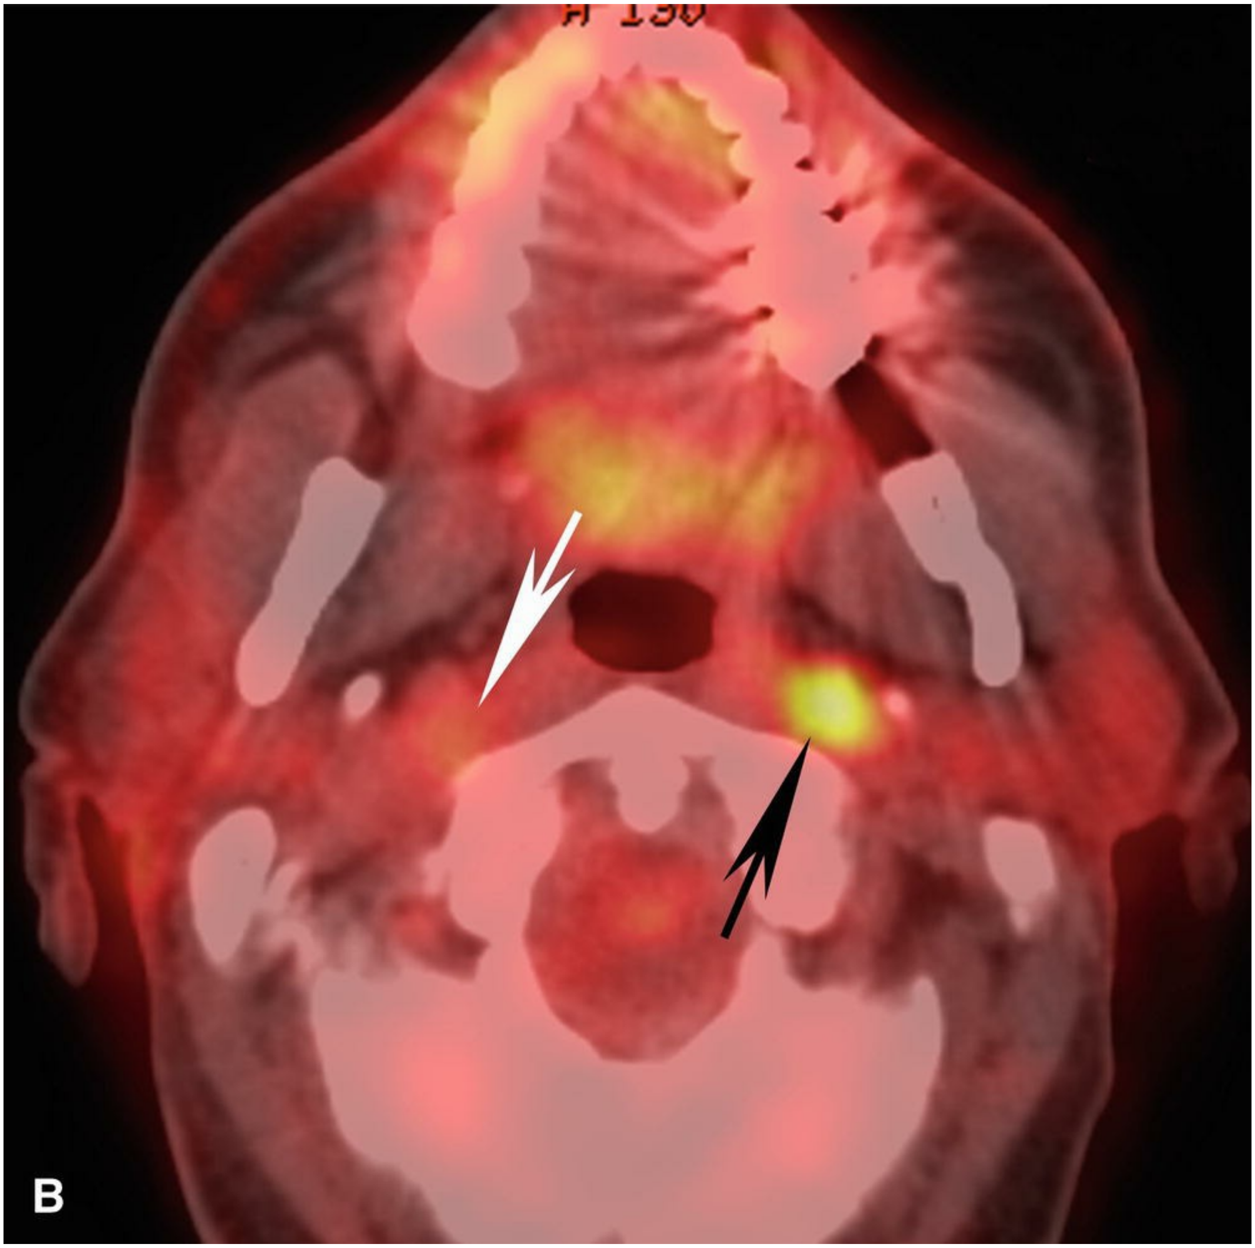


Figure 5.10. Advantages and pitfalls of PET for detection of metastatic lymph nodes. Axial contrast-enhanced CT scan **(A)** and fused PET image **(B)** are shown from a 60-year-old man with squamous cell carcinoma of the left lateral pharyngeal wall (not shown). There is abnormal, markedly increased uptake in the left lateral retropharyngeal lymph node (*black arrow*) that on the CT is barely visible and cannot be convincingly characterized as abnormal but which is quite evident on the PET study. This illustrates the increased sensitivity of PET compared to CT. On the other hand, there is a subtle but clearly necrotic, pathologic right lateral retropharyngeal lymph node seen on CT without significant uptake on PET (*white arrow*). Necrotic

nodes are a known potential pitfall of PET because there may be insufficient metabolically active tissue to permit visual detection. This case highlights the importance of combined interpretation of a diagnostic CT and PET scan.

Currently, the CT portion of a PET/CT can be performed using two techniques. In one approach, a low-dose CT is obtained without IV contrast. This provides adequate anatomic localization, but the CT portion is otherwise not considered a diagnostic study. When this is done, the standard practice would be to interpret the PET/CT scan in conjunction with a dedicated contrast-enhanced CT obtained in a separate session. It is important to interpret these scans in conjunction with a dedicated contrast-enhanced neck CT because the contrast-enhanced CT provides superior anatomic information for tumor delineation and invasion of critical structures, including vessels.[13,15] This is the approach used at our institutions, although in practice, the two exams may end up temporally separated. The contrast-enhanced study is also important for identification of necrotic lymph nodes, which may not demonstrate significant uptake on the PET scan (Fig. 5.10). The other approach is to perform combined PET/CT scanning with a diagnostic quality contrast-enhanced CT. The advantage of this approach is that both tests are obtained in a single session. However, the use of CT contrast media in PET/CT has the potential to introduce artifacts and may result in an overestimation of PET attenuation factors. The clinical significance of this is unclear at this time with some authors suggesting that the effect is not clinically significant whereas others suggesting that interpretation can be adversely affected.[15–18] There are in addition other limitations to this approach such as an excessively large CT field of view, and inability to angle the gantry so as to avoid artifact from dental fillings.

PET/CT Interpretation

The FDG uptake by a tumor is typically displayed with a color overlay map to demonstrate metabolic activity (Figs. 5.10 to 5.13). The overlay map can also be fused with the CT part of the exam for display for easier anatomic colocalization (Figs. 5.10 to 5.13). The uptake on PET can also be evaluated semiquantitatively using the standard uptake value (SUV), a measure of the radioactivity within a region of interest (e.g., tumor) corrected for the amount of radioactivity injected and the patient’s body weight. The SUV by itself is

not specific, and a number of benign processes can result in false-positive uptake on a PET scan, as discussed below. Nonetheless, SUV is a useful indicator of the potential of a lesion to represent a malignancy.[13]

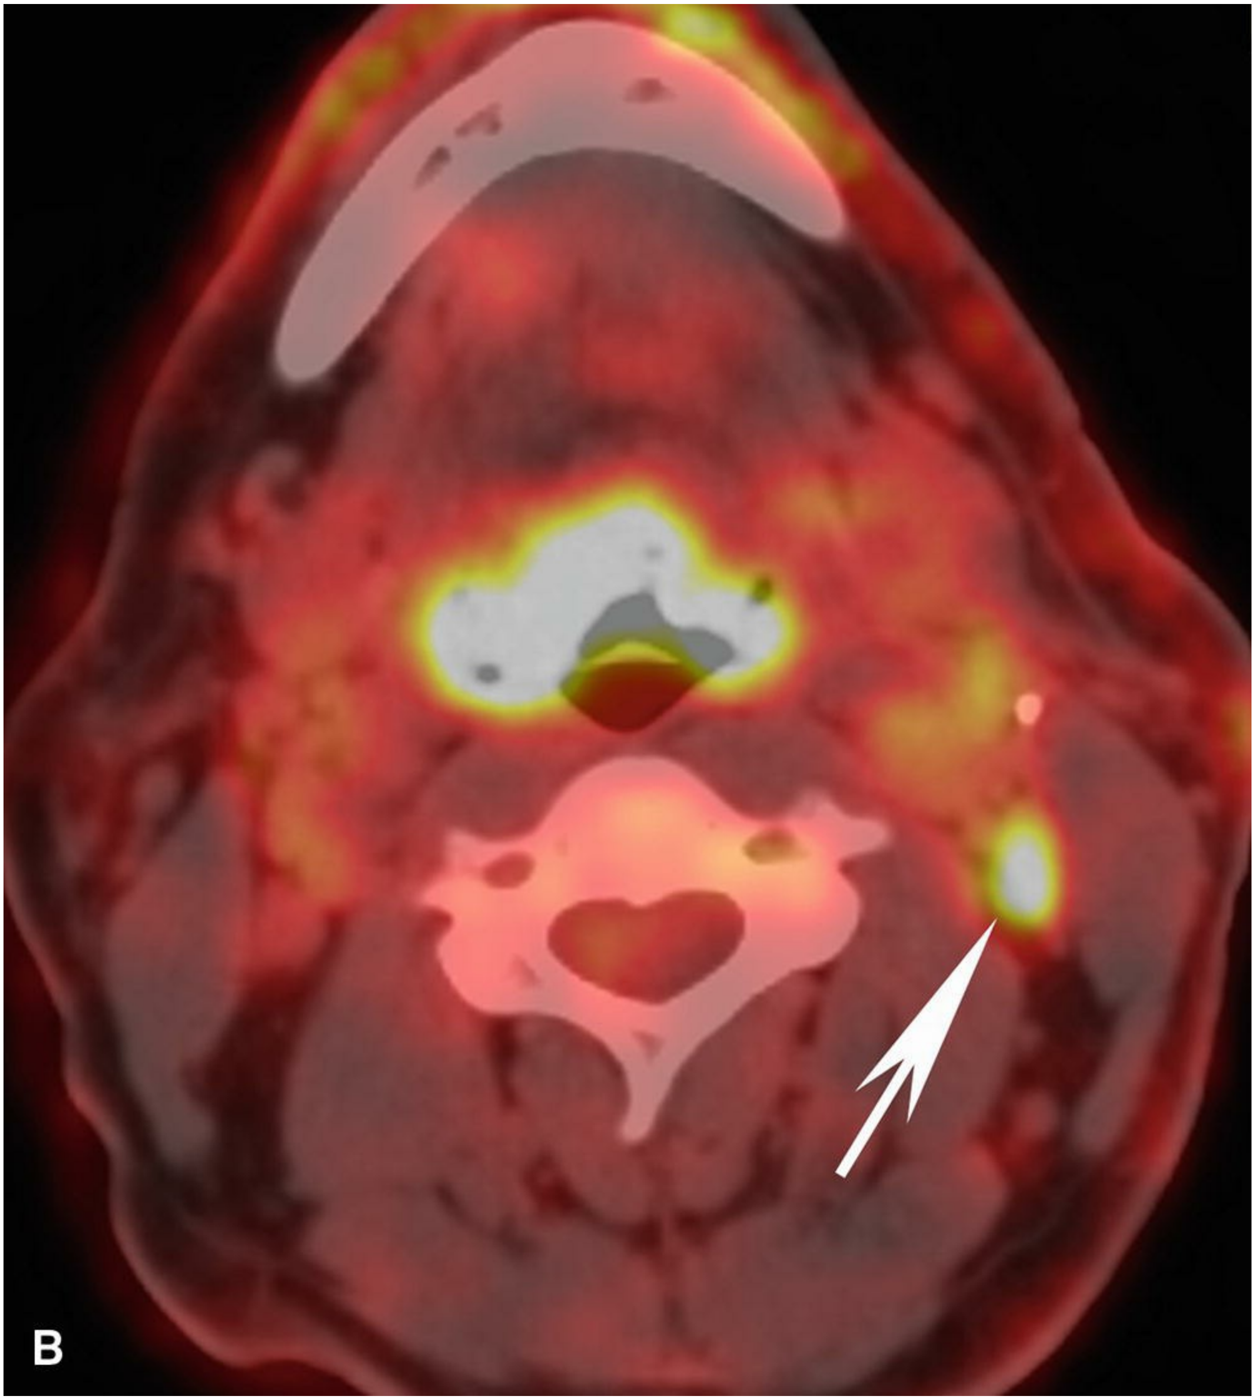

Figure 5.11. Pitfalls and false positives in PET: lymphoid tissues of the Waldeyer ring. Axial contrast-enhanced CT scan **(A)** and fused PET image **(B)** are shown from a 50-year-old with carcinoma of unknown primary who presented with an N2C neck. On CT, there are enlarged lingual tonsils at the base of the tongue without a focal enhancing mass. On PET, there is diffusely increased uptake of this lymphoid tissue. However, all base of tongue biopsies were negative. Note the pathologic level IIb node detected on PET

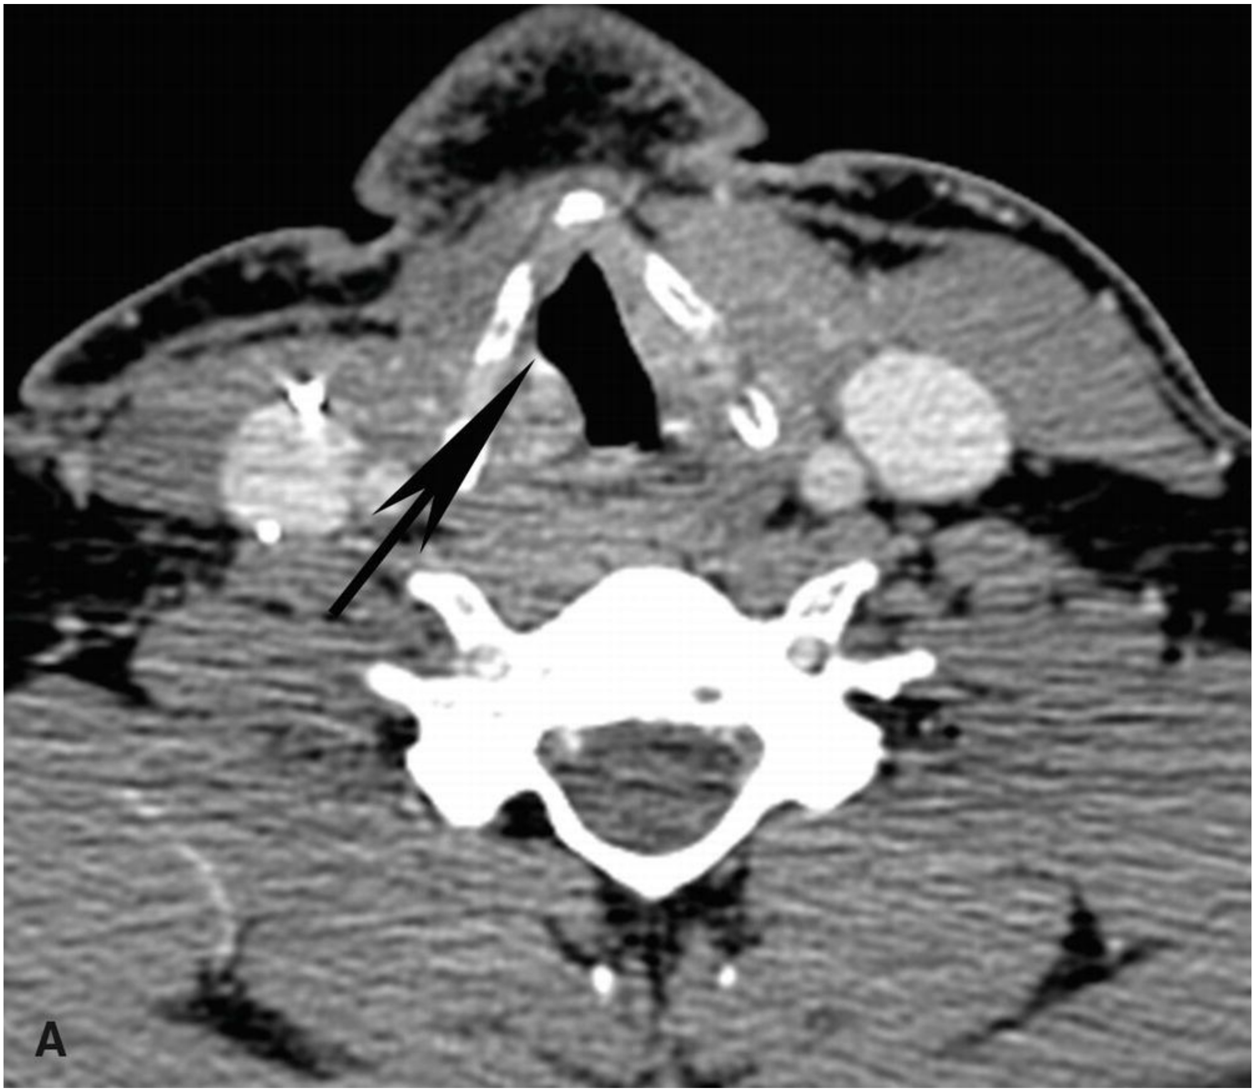
(*arrow*). On CT, the node is prominent but cannot be characterized as abnormal by anatomic imaging criteria.

Figure 5.12. Pitfalls and false positives in PET: lymphoid tissues of the Waldeyer ring. Axial contrast-enhanced CT scan **(A)** and fused PET image **(B)** are shown from a 52-year-old with biopsy-proven squamous cell carcinoma of the right base of the tongue. Similar to the case in Figure 5.11, there is diffuse uptake at the base of the tongue without clear focally increased uptake at the site of tumor on the right (*long arrow*). On CT, there is asymmetric enlargement of the right base of tongue tissues (*long arrow*). Although by itself this is insufficient for a confident diagnosis, it is useful for directing the biopsy, which demonstrated cancer at that site. Note the large,

partly necrotic, right level II pathologic nodal mass with diffusely increased uptake on PET (*short arrows*).



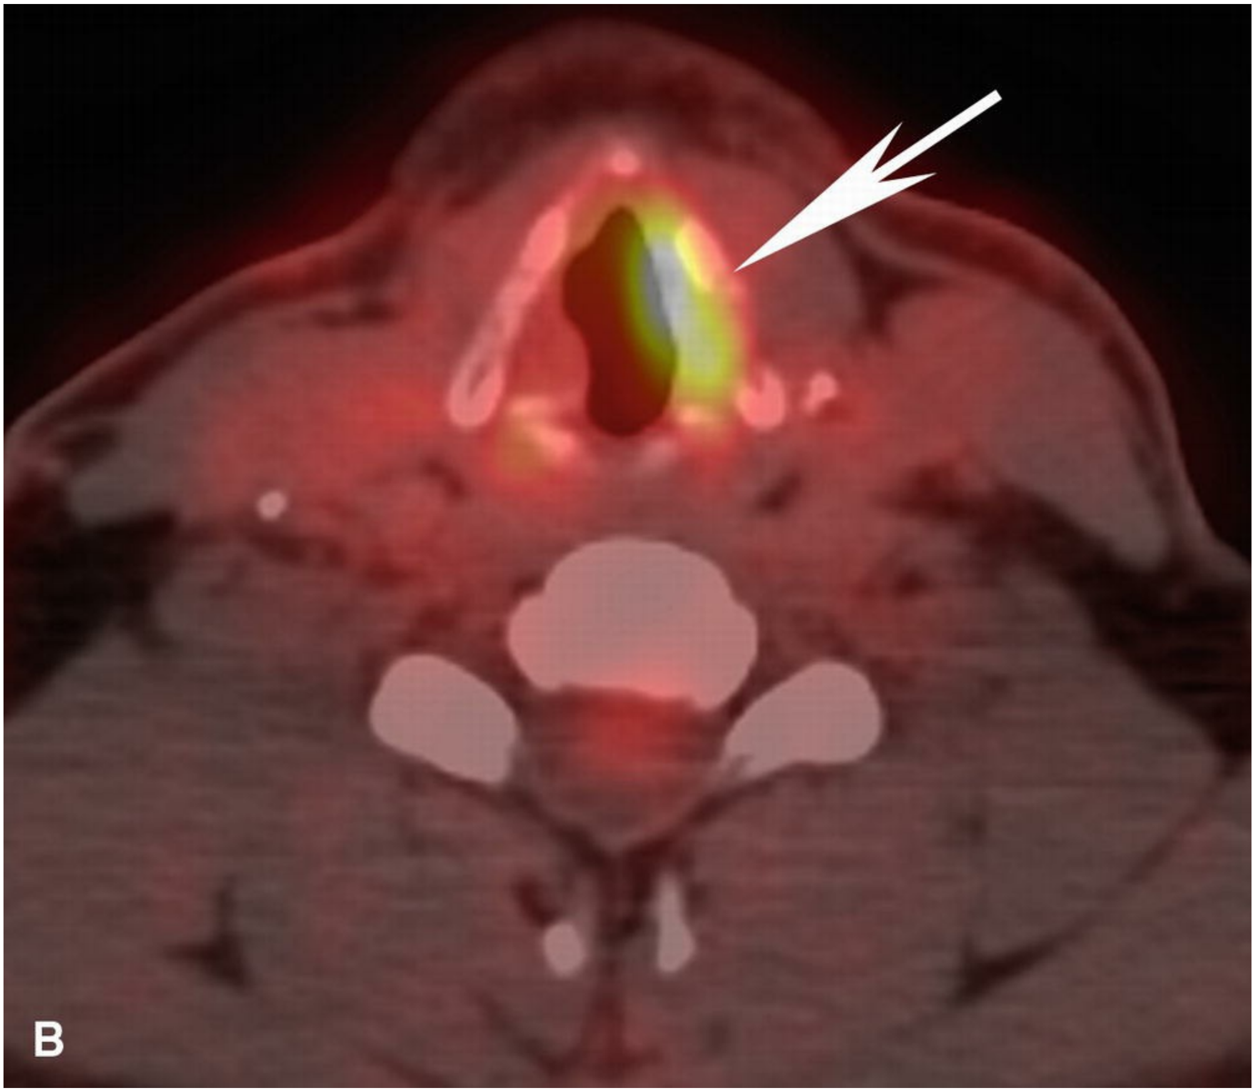


Figure 5.13. Pitfalls and false positives in PET: asymmetric muscle uptake associated with vocal cord paralysis. Axial contrast-enhanced CT scan **(A)** and fused PET image **(B)** are shown from a 33-year-old patient operated for thyroid cancer with right vocal cord paralysis. The CT image demonstrates a patulous laryngeal ventricle on the right (*black arrow*) typical of vocal cord paralysis. The PET image demonstrates typical compensatory increased activity in the normal left true vocal cord (*white arrow*). This should not be mistaken for tumor.

The most common SUV used as a threshold between a benign and potentially malignant lesion is 2.5. This value has been extrapolated from a study of pulmonary lesions performed in 1993[19] and has been used by some for evaluation of head and neck cancer.[20] Therefore, although it is useful as a

reference for potential pathology, there is no clear evidence that this threshold can be extrapolated to lymph nodes or tissues and lesions outside the thorax. For example, others have used an SUV of 3.5 to 4 as threshold for evaluation of lymphadenopathy,[21] and one study showed that the greatest specificity for determination of metastatic nodal disease in squamous cell carcinoma (SCC) was achieved when a threshold of 5 was used.[22] As discussed by Escott,[13] another pitfall of using strict SUV criteria for determination of lymphadenopathy is that small pathologic lymph nodes may have an SUV value below an accepted threshold and thus be visually difficult to call abnormal. This highlights the importance of using the SUV as a guide, rather than absolute determining value, and carefully correlating with findings on the contrast-enhanced CT for determination of pathologic lesions and lymphadenopathy.

Pitfalls, Artifacts, and False Positives in PET Imaging

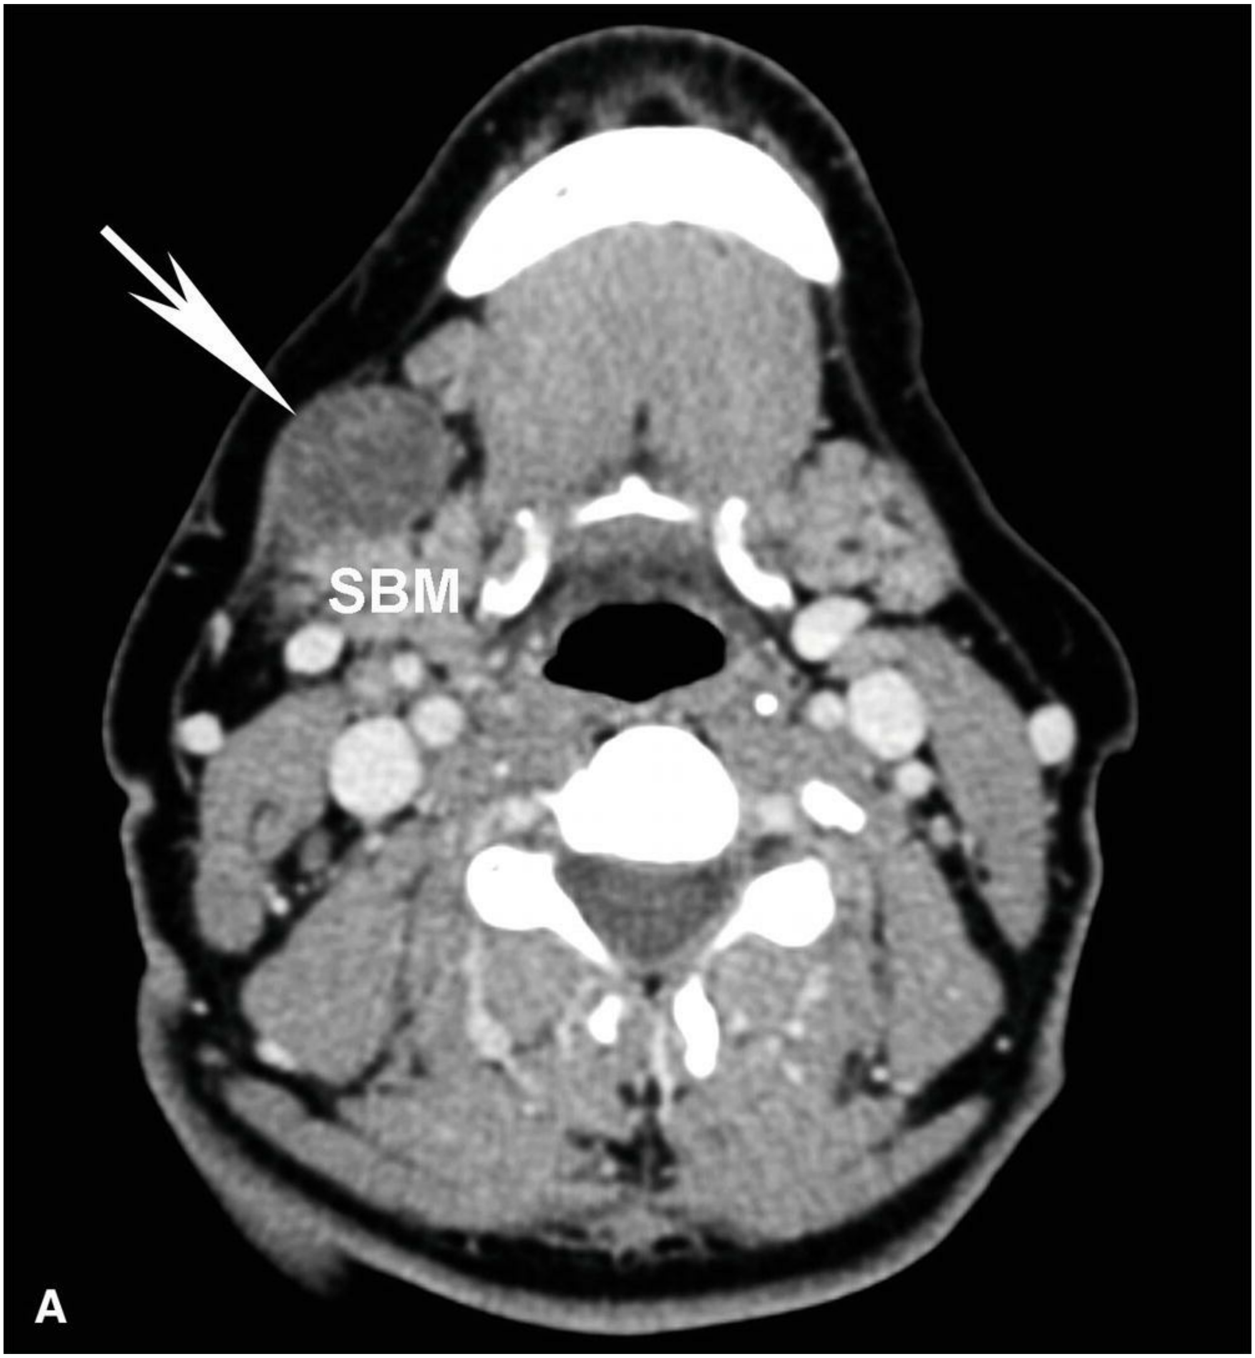
It is also important to be aware of general pitfalls, potential false positives, and artifacts during PET/CT interpretation. An exhaustive list of false-positive and false-negative findings is beyond the scope of this chapter, but increased FDG uptake can be seen in a variety of nonneoplastic pathologies such as inflammatory and infectious processes, including that seen after radiation therapy, as well as uptake from normal anatomic structures such as muscle, brown fat, salivary glands, and lymphoid tissue, particularly the tissues of Waldeyer ring[13,23] (Figs. 5.11 and 5.12). Asymmetric uptake can occur with vocal cord paralysis (Fig. 5.13) or after surgery or other posttreatment changes resulting in asymmetric muscle uptake. A number of benign lesions can also result in increased FDG uptake including thyroid adenomas, Paget disease, and fibrous dysplasia. Thyroiditis and Graves disease can also result in increased FDG uptake. One must also be aware of different artifacts including those secondary to metallic implants or dense IV or enteric contrast falsely appearing as hypermetabolic areas.

EVALUATION OF TUMORS—GENERAL CONSIDERATIONS

Overview

Although there are important differences in tumor behavior, spread pattern, and consequently imaging evaluation according to the primary site, the general approach to interpreting head and neck cancer studies is similar regardless of specific tumor or primary location. A careful, systematic evaluation is essential for optimal imaging assessment and should parallel the American Joint Committee on Cancer (AJCC) tumor, node, metastasis (TNM) staging system.[24] Using this approach, the report will follow a logical and clinically relevant structure for optimal communication of results. In this regard, it is not absolutely necessary to provide the specific radiologic tumor stage in the report, the pros and cons of which are beyond the scope of this chapter. What is important is to evaluate and identify involvement of critical structures that would alter tumor stage and consequently patient management.

As discussed earlier, one role of imaging is to evaluate a lesion's characteristics, provide a differential diagnosis, and when necessary help with biopsy planning. Imaging can also be helpful in clinically misleading presentations, and sometimes the radiologist is the first to suggest the presence and site of a head and neck cancer (Fig. 5.14). However, frequently, at the time of initial evaluation, the diagnosis has already been made, and the main role of imaging is to stage the tumor. The added value of imaging in that scenario is typically to upstage the clinical assessment by identifying involvement of critical structures, lymph nodes, or distant metastases that are not reliably identified clinically. Imaging can also guide biopsy when there are potentially important equivocal findings. Furthermore, imaging plays a key role in follow-up and surveillance of cancers to evaluate response to treatment, progression of disease, and tumor recurrence.



SBM
A

Figure 5.14. Nodal metastasis from squamous cell carcinoma presenting clinically as a submandibular region mass. Axial contrast-enhanced CT images in a patient referred for evaluation of a new right submandibular mass demonstrate an inhomogeneous enlarged level IB node (*large arrow*; **A**) anterior to the submandibular gland (SBM), compressing and displacing the gland posteriorly. Images more superiorly demonstrate a small buccal mucosal primary cancer (*small arrows*; **B**). The *small black arrows* mark the medial margin of the tumor. The *small white arrow* marks the lateral margin

of the tumor, resulting in partial obliteration and asymmetry of adjacent buccal space fat. Evaluation of subtle loss of symmetry is very useful for detection of small lesions in the neck.

Tumors can spread by direct extension with encroachment and invasion of nearby structures, lymphatic dissemination, and hematogenous dissemination to distant sites, as reflected in the TNM staging.[24] A less common but important route of spread for head and neck cancer is along the nerve bundles, referred to as PNS of tumor.[25,26] In addition, head and neck cancer patients are also at risk for the presence of a second primary cancer, which can arise from the upper aerodigestive tract, the lungs, or less frequently other organs.[27–32] A thorough evaluation will lead to proper staging at the time of diagnosis and, in turn, will help determine the appropriate treatment regimen.[24] The following sections will provide an overview of imaging characteristics and approach to evaluation of head and neck cancer.

Approach to Evaluation and General Characteristics of Head and Neck Cancer on CT, MRI, and PET

The majority of head and neck cancers are SCCs. Although it is not always possible to distinguish different malignancies based on imaging alone, SCCs, especially when large, tend to have a more invasive or aggressive appearance with irregular enhancing margins, invasion rather than displacement of adjacent normal anatomic structures, and areas of internal heterogeneity/necrosis or ulceration (Figs. 5.3, 5.4, and 5.6). More indolent or benign neoplasms such as benign salivary gland tumors tend to have more homogenous appearance with smooth rounded margins, however, biopsy is typically required for definitive diagnosis. Malignant salivary gland neoplasms may have a similar appearance as SCC on imaging and require biopsy for diagnosis (Fig. 5.15). For necrotic or cystic lesions, nodularity and irregularity of the margins of the lesion favors a malignant process over benign cystic lesions or abscesses,[8] but there can be overlap in appearance, and without clinical information or biopsy, the imaging appearance may not be sufficient for a definitive distinction from inflammatory or infectious lesions.

A

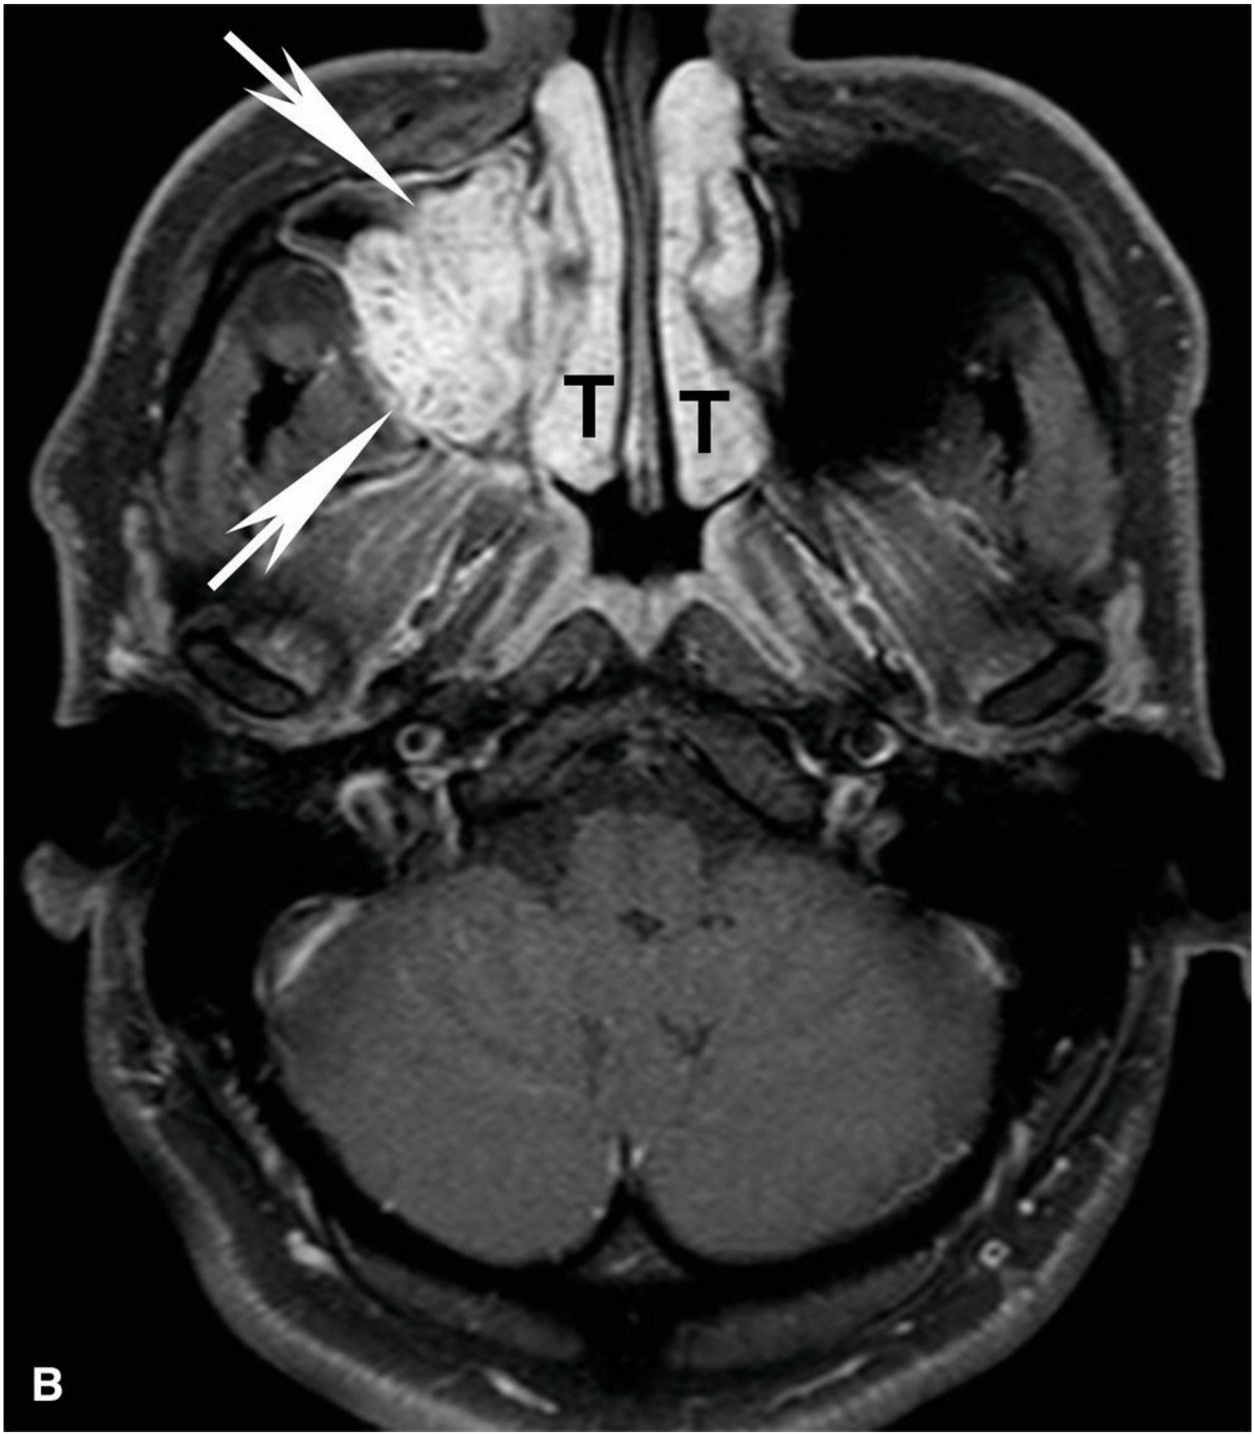


Figure 5.15. Adenoid cystic carcinoma of the maxillary sinus. Coronal T2w **(A)** and axial postcontrast T1w **(B)** fat-suppressed images from a 26-year-old patient. On T2w images, the tumor (*arrows*) is hyperintense to muscle but not strikingly bright. There is only a small amount of secretions and inflammatory mucosal changes on either sides (*arrowheads*), with higher signal than the tumor on T2w images **(A)**. There is heterogeneous but robust

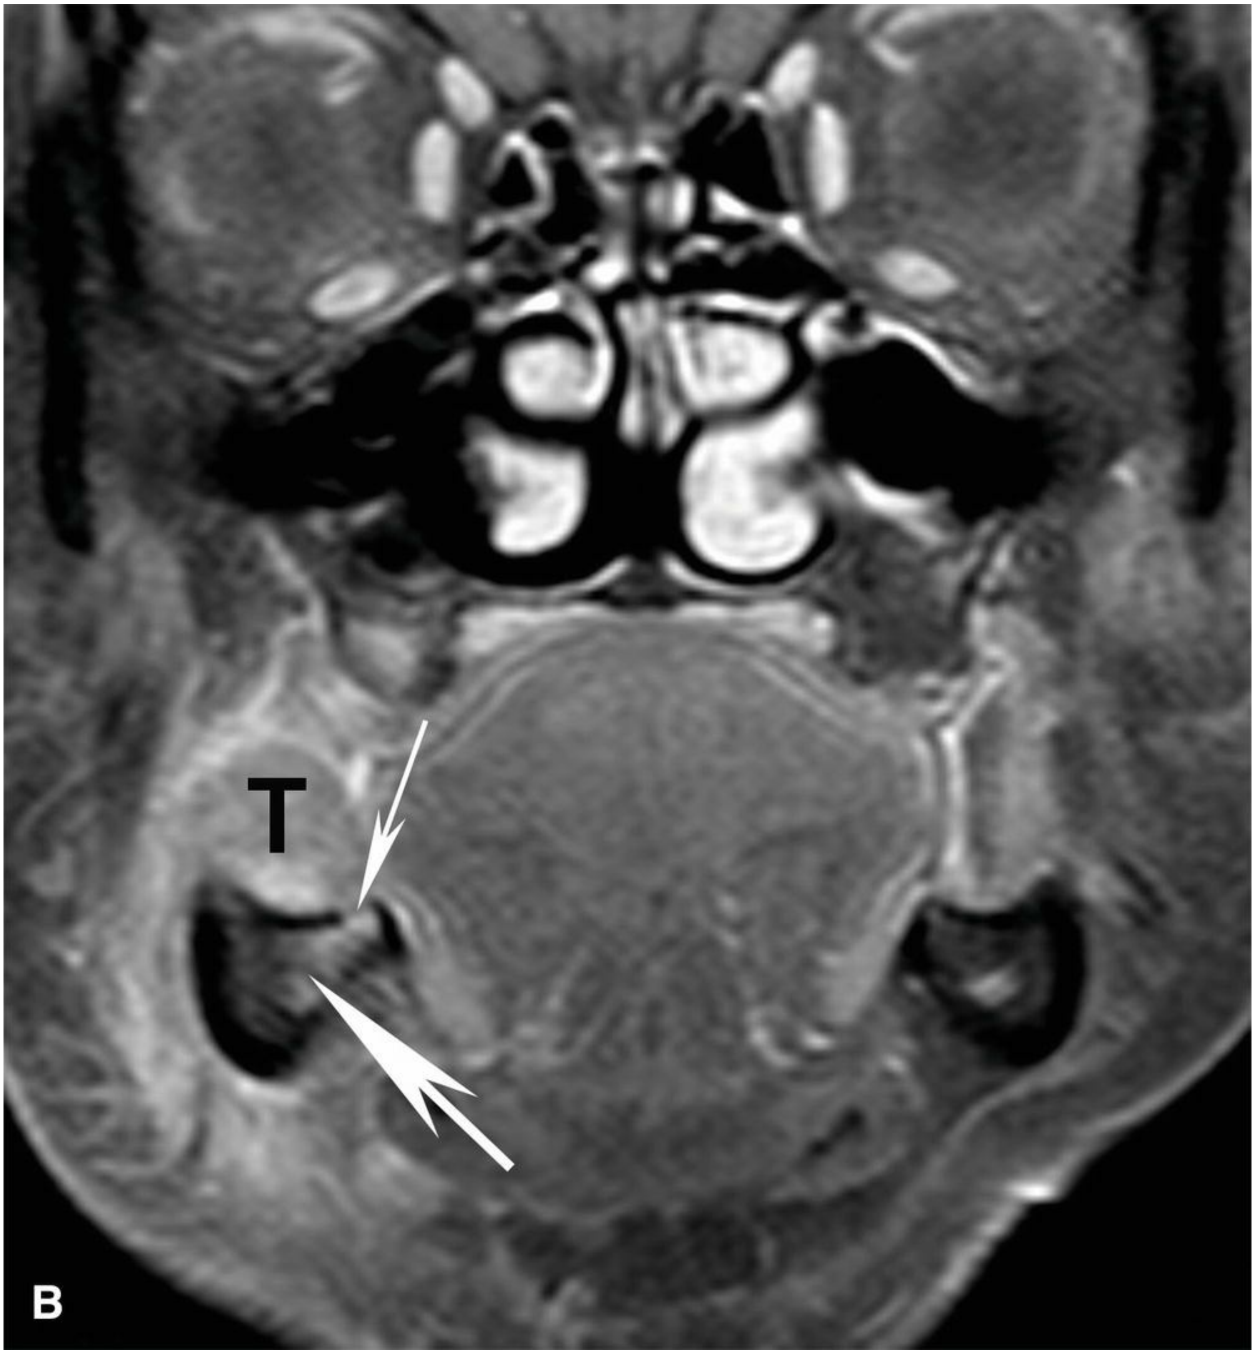
enhancement of the tumor *arrows* in **(B)**. The normal enhancement of the lining of nasal turbinates (T) should not be mistaken for tumor. In cases when tumor abuts the turbinates, this distinction may be more difficult, but careful evaluation of contiguity with the main tumor mass and subtle signal changes on all sequences may be helpful for making the distinction.

On CT, SCCs can appear as homogenous or heterogeneous soft tissue attenuation lesions with variable enhancement[33,34] (Figs. 5.2 to 5.4). There can be areas of internal heterogeneity or necrosis with low attenuation, particularly in larger lesions (Fig. 5.3). On MRI, the soft tissue extent of a tumor may be better seen because of MRI's superior soft tissue contrast compared to CT. On conventional T1w images without fat suppression, SCC has intermediate signal intensity and is generally isointense or hypointense to muscles[35–38] (Fig. 5.6), although rarely it may be slightly hyperintense.[38] On T2w images, SCC is typically isointense to hyperintense relative to normal muscle (but may be hypointense depending on the specific tumor type and cellularity) and can appear heterogeneous[35,37,38] (Fig. 5.16). Similar to CT, SCC has variable enhancement on contrast-enhanced MRI and typically well seen on fat-suppressed T1w images[35–37] (Figs. 5.6, 5.16, and 5.17). It is important to confirm that the high signal represents true enhancement by comparing to the similar sequence obtained before fat suppression.

A

Figure 5.16. Buccal squamous cell carcinoma. Coronal T2w **(A)** and contrast-enhanced fat-suppressed T1w **(B)** images. The mass is heterogeneous and appears hyperintense to muscle on T2w images with heterogeneous enhancement that is greatest around its margins.

T
A



T
B

T
C

Figure 5.17. Superficial invasion of the mandibular cortex with reactive marrow edema on MRI. Axial STIR **(A)**, coronal contrast-enhanced fat-suppressed T1w **(B)**, axial T1w **(C)**, and coronal T2w **(D)** MRI images are shown from the same patient whose CT is shown in Figure 5.4. Corresponding to the small focal cortical break seen on CT, there is a potential defect (*thin arrow*), although the MRI is less convincing than the CT. There is also mildly increased signal within the marrow (*thick arrow*) on the STIR **(A)** and contrast-enhanced **(B)** images, demonstrating the increased

sensitivity of MRI for detecting subtle marrow changes. However, in this case, the fat within the marrow is preserved on the T1w image (**C**; *thick arrow*) and the signal is normal on the T2w image (**D**; *thick arrow*). This suggests that the mild signal abnormality represents reactive marrow edema and not true marrow invasion. Pathology confirmed superficial cortical invasion without marrow invasion.

Assessment of tumor density on CT and signal on MRI is only part of the evaluation used to detect tumor and delineate its extent. Assessment for presence of asymmetry is also key for detection of subtle small tumors that may have density or signal similar to adjacent structures (Fig. 5.14). Loss of symmetry in or around a structure can be an important clue to the presence of pathology in that region. Fat represents an important source of intrinsic contrast on both CT and MRI and is clearly distinguishable from soft tissue characteristics of most nonlipomatous tumors. Careful evaluation of infiltration and obliteration/asymmetry in the fat within and fat planes separating various structures and spaces in the neck will enable identification of small tumors and areas of tumor infiltration (Fig. 5.14). Familiarity with the detailed anatomy of the neck is an essential asset to help evaluation. Disruption of normal tissue architecture is also important for evaluating tumor infiltration. For example, the preserved striated architecture of denervated muscle should enable distinction from tumor invasion despite the abnormal signal (Fig. 5.8). By taking into account all the different characteristics, an optimal imaging evaluation and lesion characterization can be performed. Information from the PET scan complements the anatomic information provided on CT and MRI and can increase sensitivity for detection of tumor, lymphadenopathy, and recurrence in head and neck squamous cell carcinoma (HNSCC).[13]

Evaluation of the Primary Site and Local Extent of Tumor (T Stage)

General Evaluation

After identification of the primary tumor, the initial key task of the radiologist is to determine the anatomic extent of the tumor. The T stage indicating the extent of primary tumor will vary depending on the primary

site, and important site-specific determinants of T stage are discussed later for individual primary sites or can be found in the AJCC manual[24] and elsewhere in this book. In this regard, familiarity with the AJCC tumor staging classification and factors altering management, including those important for selection of organ preservation and surgical therapies, is an essential asset for the head and neck radiologist and will enable the radiologist to provide an optimal, clinically relevant imaging evaluation. Regardless of particularities of each primary site, certain general principles apply to all sites.

Evaluation of Bone Invasion

CT and MRI are generally considered complementary in the evaluation of bone invasion by tumor. CT better demonstrates bone detail and architecture and is excellent for evaluation of cortical bone. CT is particularly useful for assessment of subtle cortical bone destruction or periosteal reaction (Figs. 5.4 and 5.18). CT also shows bony landmarks, including those used for surgical planning and intraoperative guidance during sinonasal and skull base surgery. On the other hand, MRI is more sensitive than CT for detection of early marrow invasion and better depicts marrow invasion by tumor (Fig. 5.18). MRI has superior sensitivity to CT in demonstrating marrow edema. This can be an advantage, but care should be taken to make sure the signal is similar to the actual tumor in order not to overcall marrow invasion (Figs. 5.17 and 5.18).

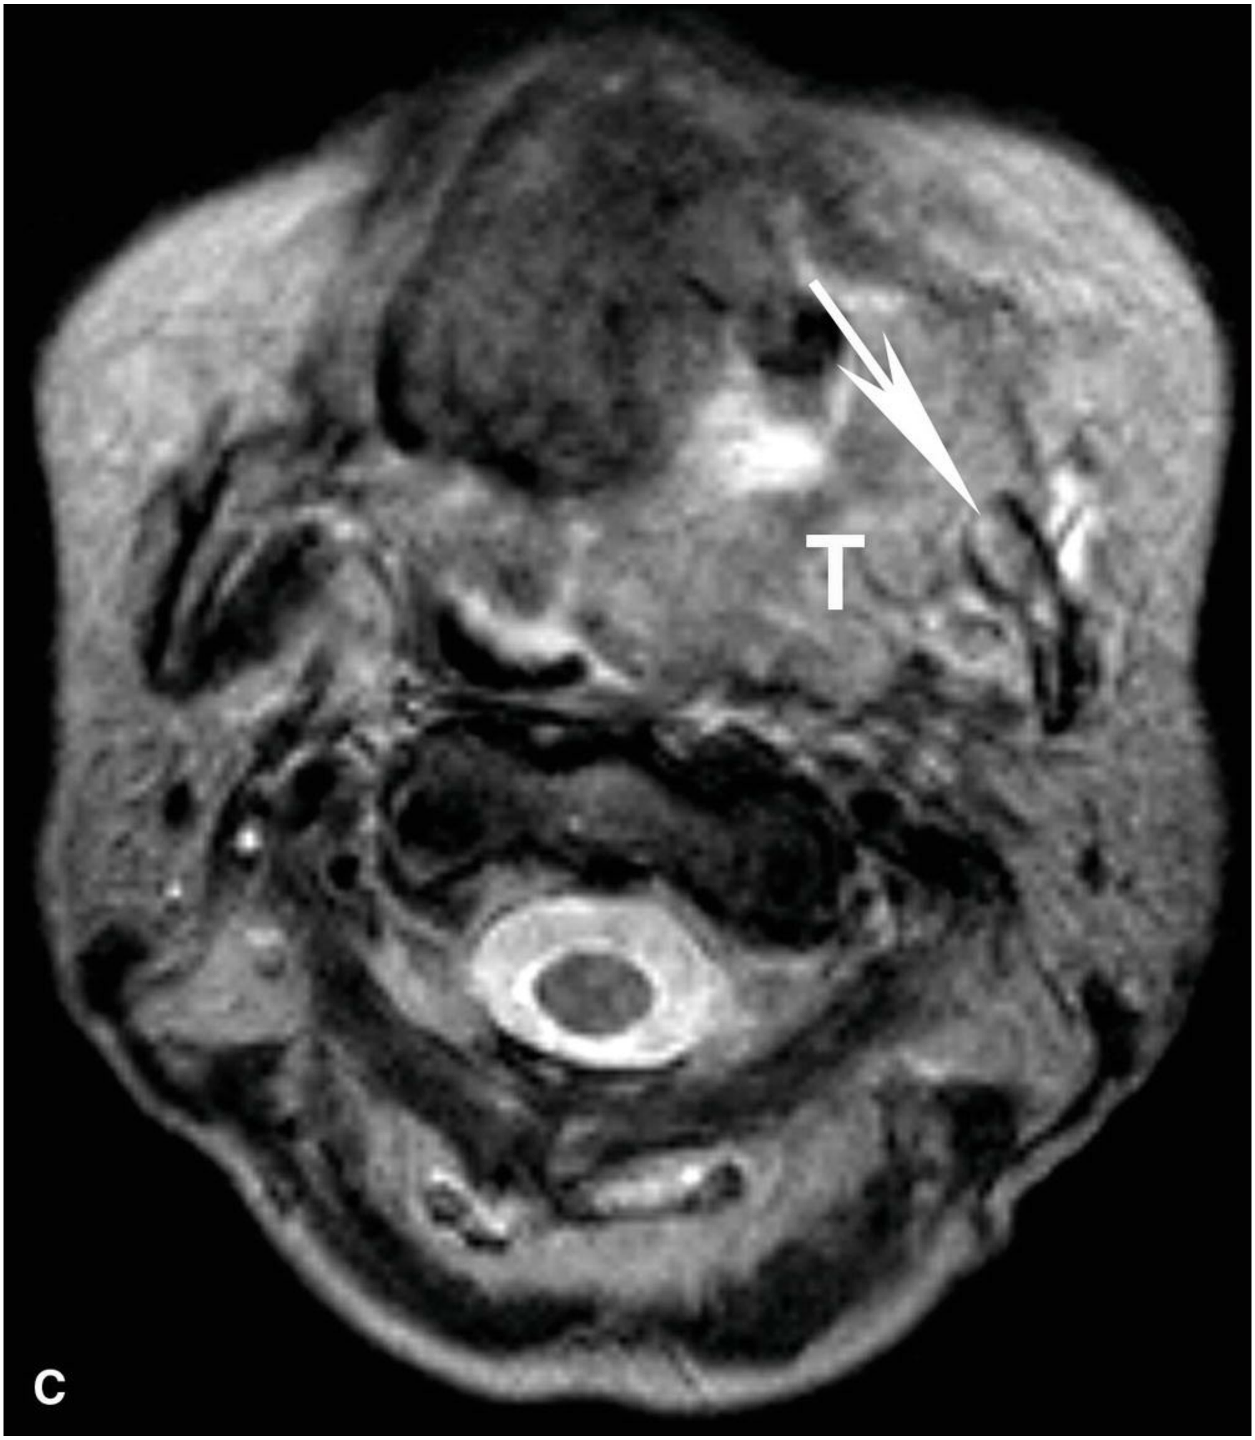
T
B



T
C

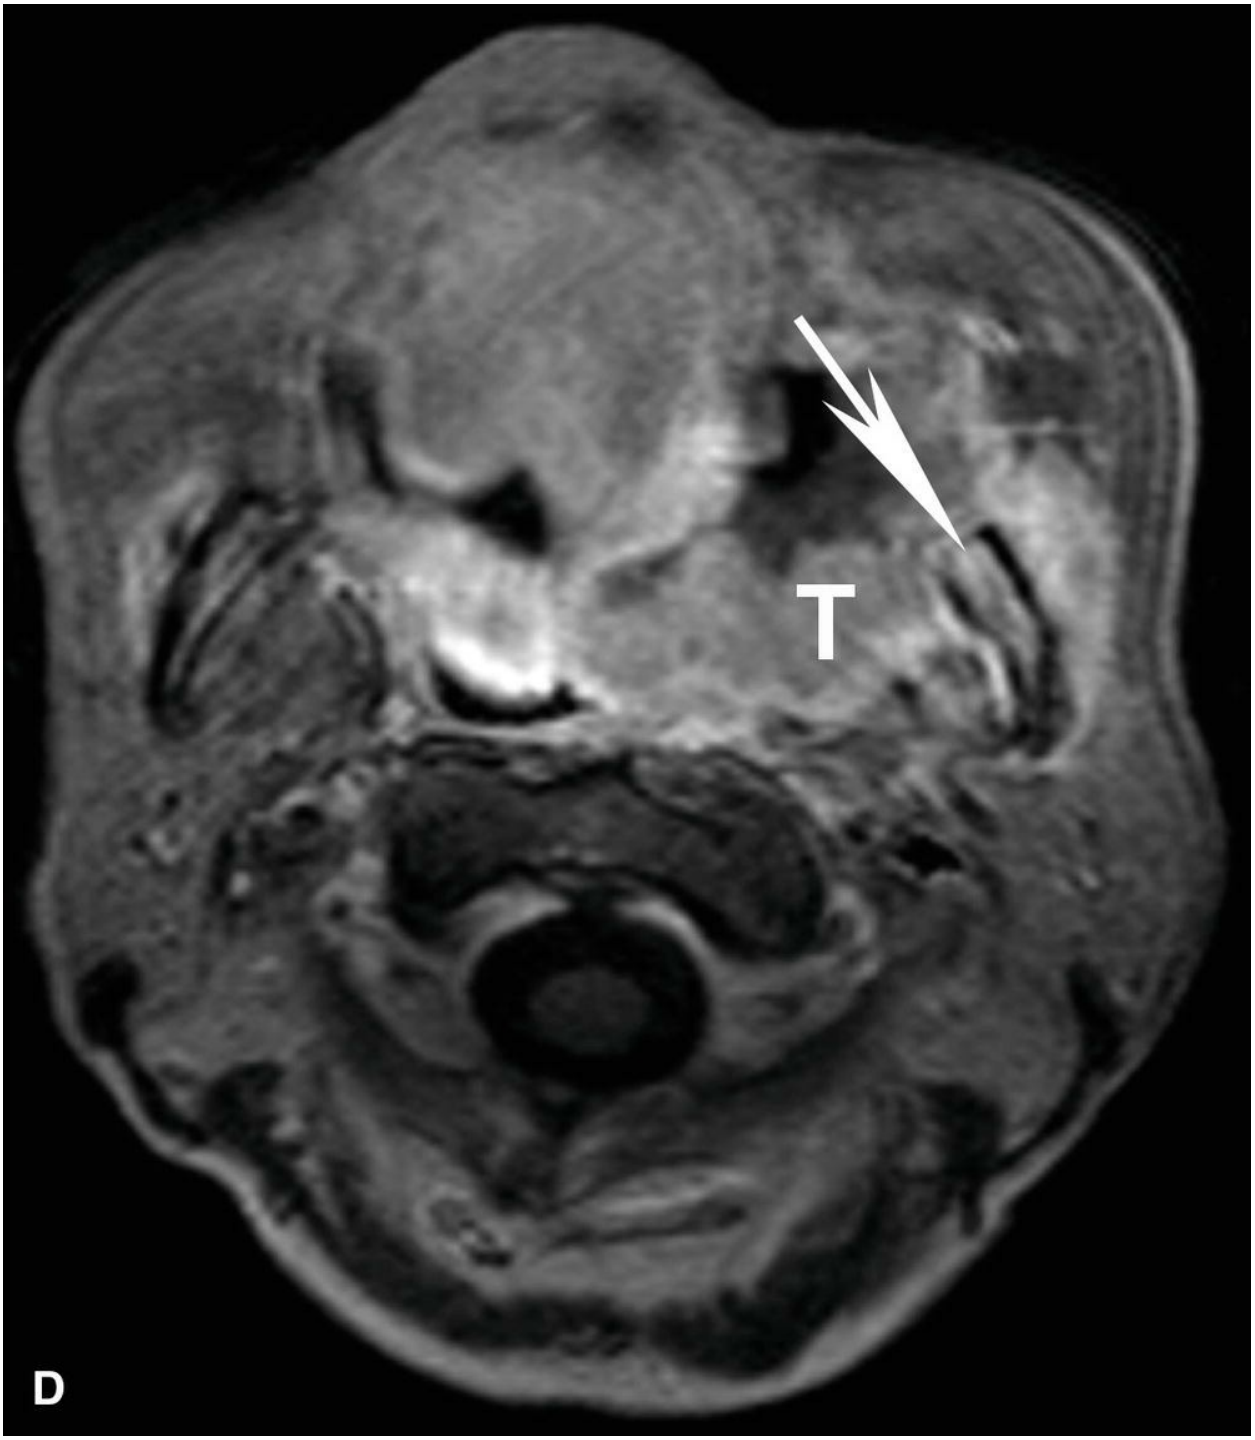


Figure 5.18. Increased sensitivity of MRI for determination of invasion of the bone marrow compared to CT. Axial CT displayed in bone windows **(A)** and unenhanced T1w **(B)**, T2w **(C)**, and contrast-enhanced fat-suppressed T1w **(D)** MRI images are shown from a patient with an advanced squamous cell carcinoma of the retromolar trigone (T) with invasion of multiple adjacent spaces including the buccal space, masticator space, and

oropharynx. On CT, the cortical invasion of the left mandible is subtly evident (*arrowhead*). However, the marrow invasion is not clearly demonstrated. On the MRI, however, there is clear invasion of the marrow with replacement of the normal marrow fat in the mandibular ramus with tumor (*white arrow*). Note the difference compared to the normal marrow of the contralateral mandibular ramus, particularly well seen on the unenhanced T1w image (**B**, *black arrow*). Unlike reactive marrow edema shown in Figure 5.17, the marrow signal abnormality follows the signal of large extraosseous tumor mass on all sequences, a key feature for differentiating the two on imaging.

Evaluation of Arterial Invasion

Invasion of the carotid artery in head and neck cancer portends a poor prognosis[39] and alters management, including surgical approach and assessment for resectability of a lesion. Different imaging criteria have been evaluated for prediction of arterial invasion by tumor.[40–44] In general, if there is >180 degree encasement of the circumference of the artery with loss of fat plane, the possibility of invasion needs to be raised and there is high likelihood of invasion if there is >270 degree encasement.[40]

Role of FDG-PET in the Evaluation of Untreated Primary Tumor Local Extent and T Stage

Most HNSCCs are well visualized by CT and MRI during initial tumor evaluation, and CT and MRI are superior to PET alone for evaluation of detailed anatomy and tumor extent. Therefore, even though PET has high accuracy in detecting the primary lesion, typically, it does not add significant clinically useful information to CT/MRI for determination of the local anatomic extent/T stage of the tumor.[14] However, in cases of equivocal findings, PET may be helpful and should be considered. In cases of carcinomas of unknown primary, there is currently no consensus on the role of PET. Although some studies have reported that the addition of PET improves detection of the occult primary HNSCC,[20] PET does not have sufficient sensitivity or negative predictive value to exclude a primary. In particular, PET has low sensitivity for detection of primary cancers arising in the oropharynx because of the relatively high background physiologic

activity within the Waldeyer ring structures[14] (Figs. 5.11 and 5.12).

Evaluation of Lymphatic Spread of Tumor (N Stage)

Overview

Determination of the presence of nodal metastasis is also essential for proper staging and surveillance of head and neck cancer. In the AJCC classification, there is a uniform N classification system for cervical lymph node metastasis from all primary sites except for those arising from the nasopharynx, thyroid, and skin cancers; nasopharyngeal carcinoma has a separate nodal staging classification.[24] Imaging plays an important role in evaluation of lymph nodes, enabling confirmation of clinically suspected lymphadenopathy and evaluation of deeper nodal levels that cannot be reliably evaluated on clinical examination.[45–47] Optimal evaluation for the presence of lymphadenopathy requires an understanding of the strengths and limitations of imaging criteria used for determination of nodal metastases. In equivocal cases, image-guided (usually US) biopsy can be used for a more definitive assessment. In addition, it is important to be aware that although imaging is useful for staging a tumor, imaging cannot reliably exclude micrometastases to lymph nodes, especially for tumors of the oral cavity. It is worth emphasizing that potentially abnormal nodes should be interpreted in the context of their location with respect to a known or suspected primary malignancy; their size, shape, and number; or presence of focal internal defect. As such, isolated interpretation based solely on the appearance of lymph nodes on an imaging study is fraught with pitfalls and is discouraged.[45–47]

Imaging-Based Anatomic Classification of Lymph Nodes

When evaluating cervical lymph nodes, the first step is the proper anatomic localization of a lymph node. Earlier lymph node classification systems were based on clinical landmarks.[45–48] However, with improvements in imaging techniques enabling accurate identification of enlarged lymph nodes and a shift in treatment paradigm in which many cancers were not treated surgically, an imaging-based classification system represented the most practical and logical approach. The imaging-based classification system

proposed by Som et al.[49] is a level-based classification and has received widespread acceptance, including adoption by the AJCC. The rationale behind this classification system is to provide a reproducible, widely applicable framework based on readily identifiable imaging landmarks.

In the imaging-based classification, the cervical nodal chains are divided into seven levels.[45]–[49] The levels and the landmarks used for the classification are described in detail in Table 5.4 and illustrated in Figure 5.19. Briefly, level I consists of submental (IA) and submandibular (IB) nodes. Levels II to IV consist of internal jugular nodes. Level II nodes extend from the skull base to the level of the lower body of the hyoid bone. Level II is further subclassified into levels IIA (anterior) and IIB (posterior to the internal jugular vein and separated from it by a fat plane). Level III nodes consist of those nodes that are around the internal jugular vein, between the level of the lower body of the hyoid bone and the level of the lower margin of the cricoid cartilage arch. Level IV nodes are internal jugular chain nodes that extend from the level of the lower margin of the cricoid cartilage arch to the level of the top of the manubrium. Level V nodes are posteriorly located lymph nodes that are subdivided into levels VA and VB. Level VI nodes are the visceral nodes, and level VII nodes are those that lie caudal to the top of the manubrium, located between the medial margins of the left and right common carotid arteries in the substernal region[45]–[47] (Fig. 5.19; Table 5.4). Please refer to Table 5.4 for a detailed description of the anatomic landmarks used for the imaging classification.

Table 5.4 Landmarks Used for Cervical Lymph Node Localization Using the Imaging-based Classification

Node Levels	Major Landmarks	Sub-Classifications
Level I	All of the nodes below the mylohyoid muscles, anterior to a transverse line drawn through the posterior edge of the submandibular gland in the axial plane, and above the bottom of the body of the hyoid bone.	*Level IA* Nodes that lie between the medial margins of the anterior bellies of the digastric muscles (previously classified as submental nodes)
	These include previously classified submental and submandibular nodes.	*Level IB* Nodes that lie posterior and lateral to the medial edge of the anterior belly of the digastric muscle (previously classified as submandibular nodes)
Level II	Nodes around the internal jugular vein extending from the lower bony margin of the jugular fossa at the skull base to the level of the lower body of the hyoid bone.	*Level IIA* Nodes that lie anterior, lateral, or medial to the internal jugular vein (previously classified as upper internal jugular nodes) as well as nodes that lie posterior to the internal jugular vein and are *inseparable* from the vein
	Nodes that lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle, and posterior to a transverse line drawn on each axial scan through the posterior edge of the submandibular gland.	
	In the area within 2–3 cm of the skull base, a node located anterior, lateral, or posterior to the internal carotid artery is classified as a level II node. However, if the node lies medial to the internal carotid artery, it is classified as a retropharyngeal node. More caudally, level II nodes include those located anterior, lateral, medial, or posterior to the internal jugular vein.	*Level IIB* Nodes that lie posterior to the internal jugular vein and are separated from the vein by a fat plane (previously classified as upper spinal accessory nodes). These nodes are located in the fat deep to the sternocleidomastoid muscle.
Level III	Nodes around the internal jugular vein between the level of the lower body of the hyoid bone and the level of the lower margin of the cricoid cartilage arch.	
	These nodes lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle.	
	Level III nodes also lie lateral to the medial margin of either the common carotid artery or the internal carotid artery. On each side of the neck, the medial margin of carotid arteries separates level III nodes (located laterally) from level VI nodes (located medially).	
Level IV	Nodes around the internal jugular vein between the level of the lower margin of the cricoid cartilage arch and the level of the top of the manubrium.	
	These nodes lie anterior and medial to an oblique line drawn through the posterior edge of the sternocleidomastoid muscle and the lateral posterior edge of the anterior scalene muscle.	
	The medial margin of the common carotid artery is the landmark that separates level IV nodes (located laterally) from level VI nodes (located medially).	
Level V	Nodes extending from the skull base, at the posterior border of the attachment of the sternocleidomastoid muscle, to the level of the clavicle, as seen on each axial scan.	*Level VA* Nodes between the skull base and the level of the lower margin of the cricoid cartilage arch, behind the posterior edge of the sternocleidomastoid muscle
	All these nodes lie anterior to a transverse line through the anterior edge of the trapezius muscle in the axial plane.	
	From the skull base to the bottom of the cricoid arch, these nodes are located posterior to a transverse line through the posterior edge of the sternocleidomastoid muscle in the axial plane (VA). More caudally, between the level of the bottom of the cricoid arch and top of the manubrium, they lie posterior and lateral to an oblique line through the posterior edge of the sternocleidomastoid muscle and the lateral posterior edge of the anterior scalene muscle (VB).	*Level VB* Nodes between the lower margin of the cricoid cartilage arch and the level of the clavicle, as seen on each axial scan. They are behind an oblique line through the posterior edge of the sternocleidomastoid muscle and the lateral posterior edge of the anterior scalene muscle.
Level VI	Nodes located between the medial margins of the left and right common carotid or internal carotid arteries, extending from the level of the lower body of the hyoid bone to the level superior to the top of the manubrium. These are the visceral nodes.	
Level VII	Nodes in the substernal region extending from the level of the top of the manubrium to the level of the innominate vein, between the medial margins of the left and right common carotid arteries

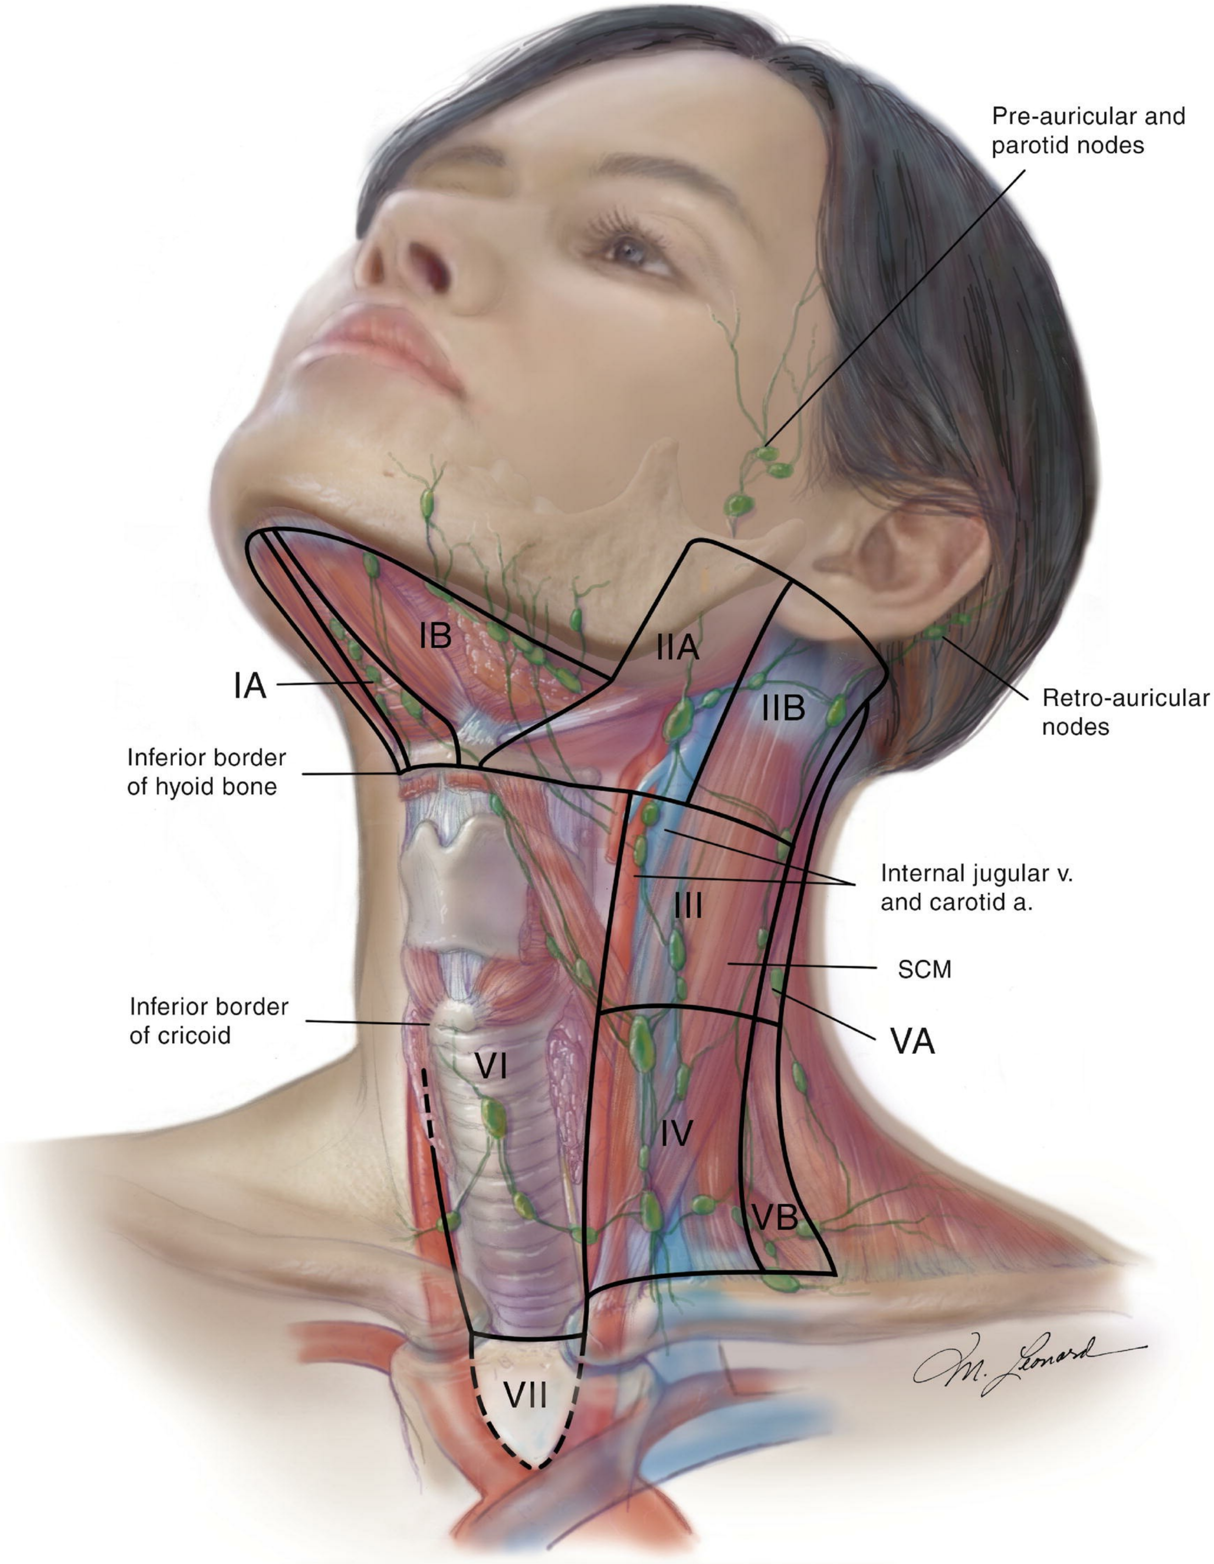

Figure 5.19. Illustration demonstrating the imaging-based classification of cervical lymph nodes. (Illustration is based on the classification proposed by Som PM, Curtin HD, Mancuso AA. An imaging-based classification for the

cervical nodes designed as an adjunct to recent clinically based nodal classifications. *Arch Otolaryngol Head Neck Surg.* 1999;125:388–396; reproduced with permission from Forghani Medical Services Inc.)

It is noteworthy that surgically, levels IIA and IIB are separated by the spinal accessory nerve, the preservation of which reduces morbidity associated with level II compartment dissection.[50] As such, there is some controversy regarding the clinical applicability of separation of level II into radiologic sublevels IIA and IIB.[32] Outside node levels I to VII, other lymph nodes are referred to by their anatomic names. These include the retropharyngeal nodes and the superficial nodes of the neck including the parotid (periparotid and intraparotid), buccinator (facial), suboccipital, and preauricular nodes, among others. The supraclavicular nodes are still frequently referred to by their classic anatomic names because the terminology is deeply entrenched in clinical practice. The supraclavicular fossa is difficult to precisely identify in the axial plane because it is oblique to that plane and not seen in its entirety on a single section. However, it can be approximated on axial images whenever any portion of the clavicle is identified on one side of the neck, provided the patient's shoulders are as low as possible. Using the imaging classification, this would include the caudal portions of the level IV and VB nodes.[45–47]

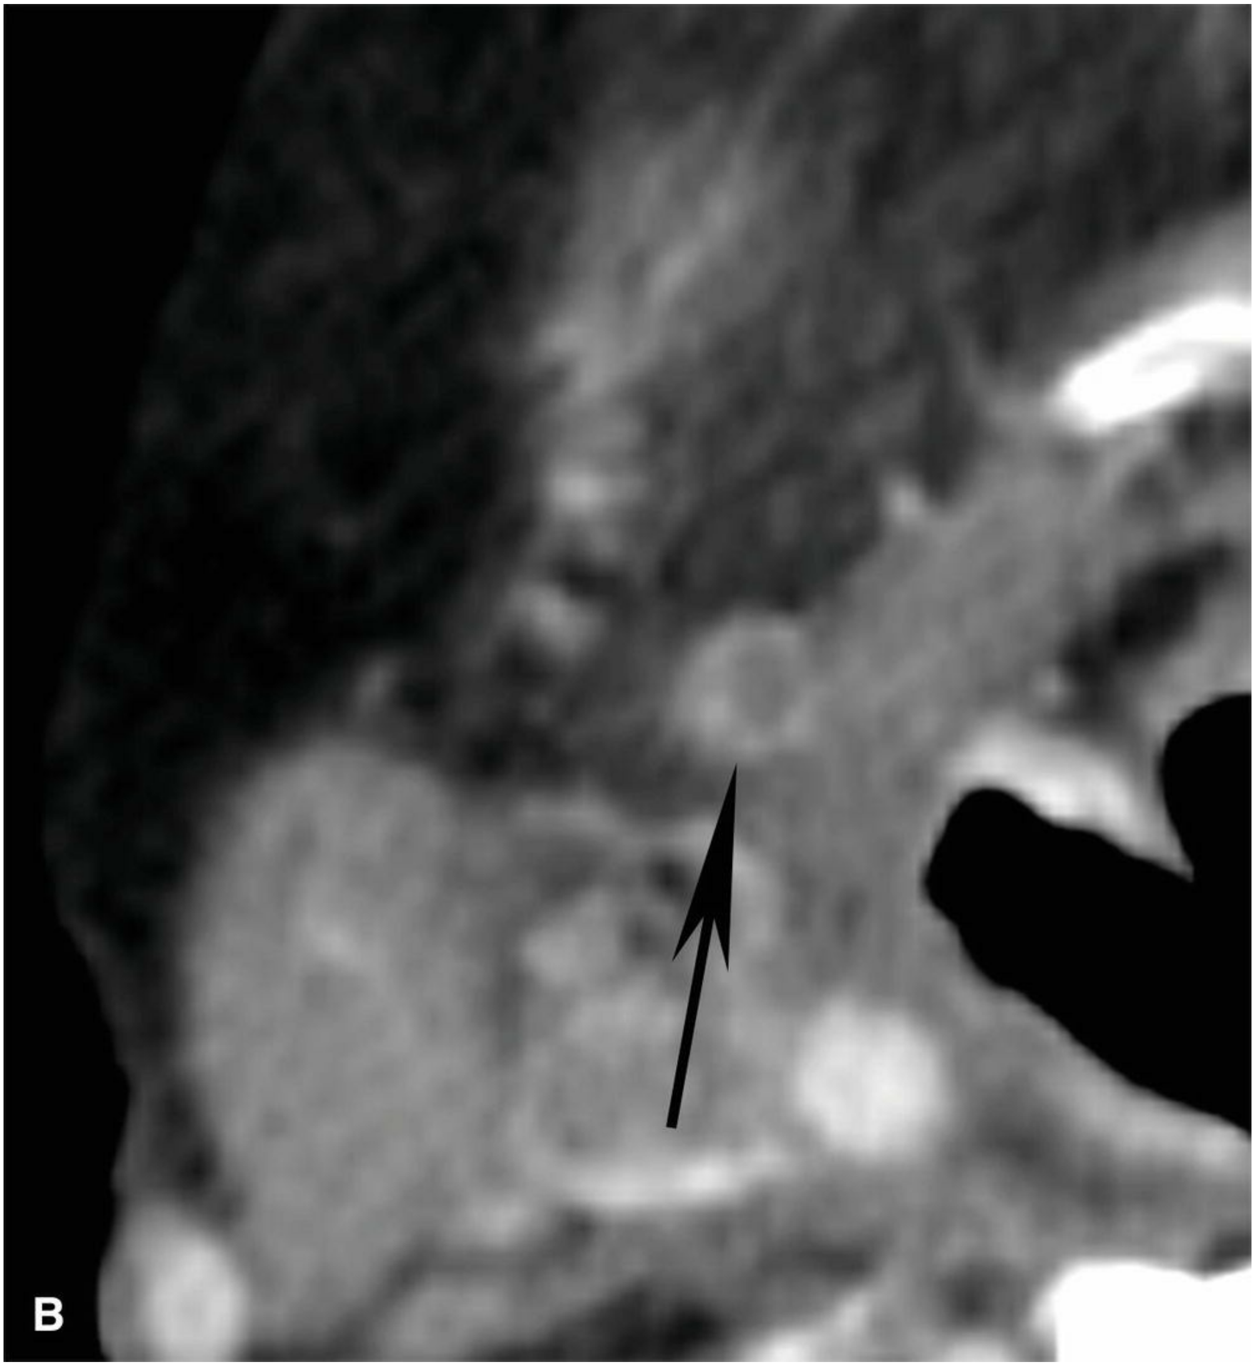
Imaging Approach and Morphologic Criteria for Assessment of Metastatic Nodes

CT and MRI are almost equivalent for evaluation of metastatic lymphadenopathy, although at least one study has suggested that CT may be slightly superior.[51] In practice, the selection of the imaging modality is based on the primary site and was discussed earlier. US has also been used for evaluation of cervical lymphadenopathy but is operator dependent and does not provide a reliable evaluation of deep nodal levels. As a result, except for thyroid cancer, US is not routinely used for staging of head and neck cancers, though in some centers, it is considered complimentary or useful for cases in which other imaging is equivocal. However, US-guided biopsy is very useful for evaluation of indeterminate nodes. In general, the morphologic criteria used for identification of metastatic nodes are applicable to all three imaging modalities.

Normal nodes are only a few millimeters in size and have smooth well-defined borders on imaging.[45–47] Normal nodes are usually lima bean shaped, although this may not be clearly evident for small nodes and depending on the plane of section used to evaluate that lymph node. Normal nodes also have a fatty hilum, and depending on its size, it may or may not be seen on CT and MRI. Nodes at levels IIA and IB constitute the primary drainage routes of the oral cavity and oropharynx and as a result are frequently exposed to the numerous infections that occur at those sites. Therefore, these nodes are in general larger than other cervical lymph nodes.

The main imaging criteria used for identification of metastatic nodes are node size, internal nodal architecture, nodal grouping or clustering, and node shape and contour[45–47] (Fig. 5.20; Tables 5.5 and 5.6). An optimal evaluation of lymph nodes is performed only when all of these parameters are taken into account, as well as the clinical context, and one should try to avoid focusing excessively on a single parameter such as size in isolation.

A



B

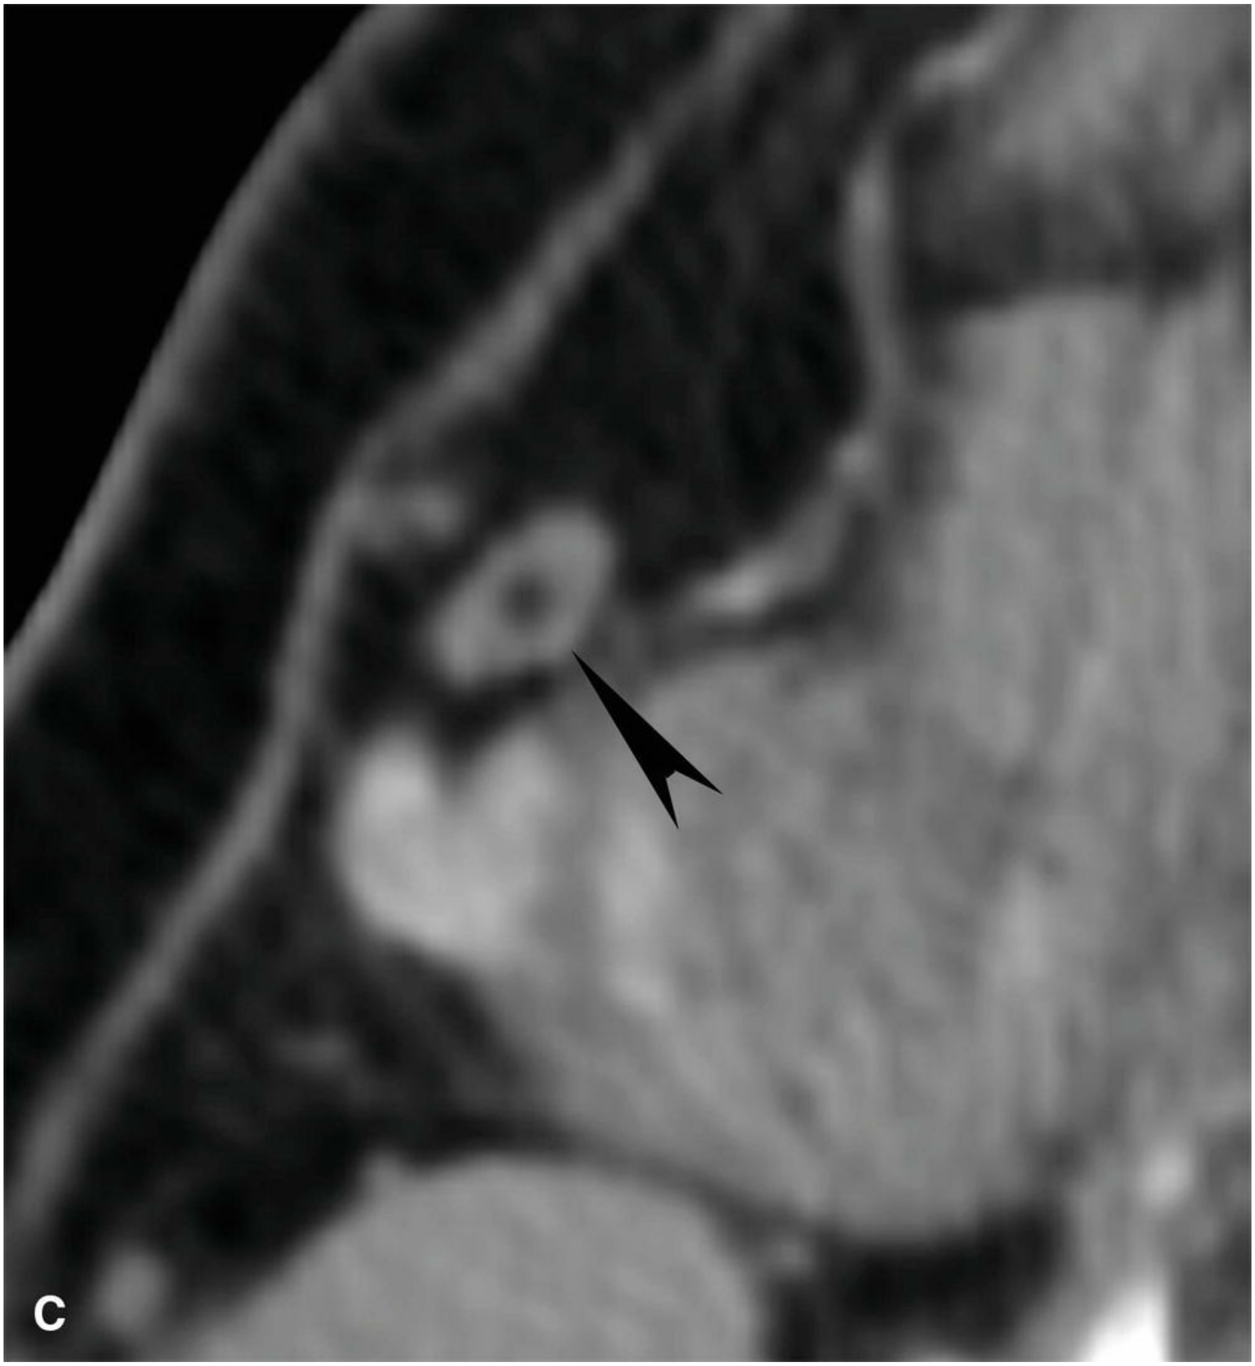


Figure 5.20. Characteristics of metastatic nodes as well as normal fatty hilum. **A:** Axial contrast-enhanced CT image demonstrates different features of pathologic nodes. The large midline node (*arrow*) is rounded and has internal inhomogeneity/necrosis and irregular margins. The more laterally located node (*arrowhead*) on the right is rounded. **B:** Example of small necrotic lymph node (*arrow*). **C:** Example of normal fatty hilum (*arrow*). At this size, the density is clearly identifiable as that of fat (compare to adjacent

subcutaneous fat), and this should not be misinterpreted as nodal necrosis.

Table 5.5 Commonly Used Size Criteria for Distinction of Pathologic from Normal or Benign Reactive Lymph Nodes on Axial Images for Single Homogenous Sharply Delineated Nodes

Short-axis diameter for individual, nonclustered lymph nodes:
Jugulodigastric (level II) nodes Abnormal: ≥11 mm
Retropharyngeal nodes Abnormal: ≥5 mm
All other nodes Abnormal: ≥10 mm
Long-axis diameter for individual, nonclustered lymph nodes:
Jugulodigastric (level II) and submandibular (level I) nodes Abnormal: >15 mm
Retropharyngeal nodes Normal: 8 mm or less, abnormal: >8 mm
All other nodes Normal: 10 mm or less, abnormal: >10 mm
Short-axis diameter for a cluster or group of nodes in the drainage area of the primary tumor site[a] (for nodes other than retropharyngeal nodes):
Jugulodigastric (level II) nodes Abnormal: ≥9–10 mm
Other nodes Abnormal: ≥8–9 mm
Error rates and limitations:
Regardless of the size criterion used, the overall error rates for false-positive and false-negative diagnoses are in the range of ~15% and 20%, reflecting the limitations of the use of size criteria alone for determination of nodal metastasis.

[a]Nodal clustering or grouping is defined as the presence of three or more borderline lymph nodes in the first or second lymph node drainage region of a primary tumor site. When

present, the size threshold for metastatic lymphadenopathy for clustered nodes can be decreased by 1 to 2 mm, increasing sensitivity, without significantly affecting specificity.

Adapted from Forghani R, Yu E, Levental M, et al. Imaging evaluation of lymphadenopathy and patterns of lymph node spread in head and neck cancer. *Expert Rev Anticancer Ther*. 2015;15(2):207–224.

Table 5.6 Imaging Approach and Main Criteria Used for Determination of Metastatic Lymphadenopathy (the Criteria May Be Remembered Using the Acronym CRISPS)

Size (CRISPS) Different criteria can be used. Maximal short-axis diameter may be the most effective criterion (summarized in Table 5.3).
Nodal clustering or grouping (CRISPS) Presence of three or more borderline lymph nodes in the first or second lymph node drainage region of a primary tumor site
Internal architecture: Evaluation of nodal inhomogeneity or necrosis (CRISPS) When >3 mm in size, focal internal inhomogeneity can frequently be identified on CT and MRI and represents the most reliable imaging finding of nodal metastasis in the right clinical context (known or suspected head and neck cancer, absence of infectious symptoms, or suppurative lymphadenitis). Pitfalls/mimics: normal fatty hilum of the node, fatty hilar metaplasia, or an intranodal abscess.
Node morphology: Rounded Shape (CRISPS) Loss of normal elongated shape with rounded appearance of the node Longest axis (any plane)/shortest diameter ratio <2
Node contour or periphery (CRISPS) and extracapsular spread Thickened enhancing rim with infiltration of the adjacent fat planes or soft tissue structures in the absence of recent infection or treatment such as irradiation or surgical manipulation
Sentinel node (CRISPS) Awareness of the main primary and secondary drainage areas for an expected cancer site can heighten suspicion for the presence of metastases and can be used in conjunction with other features to increase confidence or suspicion for the presence of metastases
Clinical context Highest accuracy will be achieved when the clinical context and patient demographics are taken into account. An enlarged or inhomogenous lymph node in an otherwise healthy young patient is most likely to represent an inflammatory, reactive, or infected node, whereas the same node in a patient with known HNSCC is most likely to represent a metastatic lymph node.
Others Evaluate metabolic activity and uptake on PET when available; image-guided biopsy can be used for evaluation of borderline and indeterminate nodes.

Adapted from Forghani R, Yu E, Levental M, et al. Imaging evaluation of lymphadenopathy and patterns of lymph node spread in head and neck cancer. *Expert Rev Anticancer Ther*. 2015;15(2):207–224.

On imaging, node size is typically evaluated in the axial plane because this is most practical, and a convincing advantage for measurements in other planes has not been shown. Either the short-axis or the long-axis diameter may be used for evaluation of metastatic nodes, although in one large prospective study, the short-axis diameter was reported as the most effective size criterion.[52] The commonly accepted size criteria for evaluation of metastatic lymph nodes are summarized in Table 5.5. It is important to note that all the proposed size criteria apply to *homogenous, sharply delineated nodes*. Neither of the size criteria is perfect with overall estimated error rates of ~15% and 20%.[45–47]

The first lymph node or group of nodes draining a primary site are at the highest risk of harboring metastases and lower threshold for additional investigation or biopsy of indeterminate or borderline nodes in these areas.[46,53] When a cluster of borderline enlarged nodes, defined as three or more lymph nodes in the drainage area of the primary tumor site, is present, the short-axis size threshold can be decreased by 1 to 2 mm, increasing sensitivity without affecting specificity[45–47,52] (Table 5.5).

Tumor infiltration of a lymph node can result in intermixed areas of tumor, edema, necrosis, and residual normal node tissue. As a result, metastatic nodes can appear nonhomogenous (Fig. 5.20; Table 5.5). On imaging, this can result in areas of relatively low attenuation on CT or high signal on T2w and STIR images and is referred to as necrosis or internal inhomogeneity. If the focus of internal abnormality is >3 mm in size, it is frequently identifiable on CT (Fig. 5.20) and MRI and represents the most reliable imaging sign of nodal metastasis in the *appropriate clinical context*, that is, patients with suspected or biopsy-proven head and neck cancer.[45–47,52,54,55] The inhomogeneity may be central or peripheral in the subcapsular region. The differential diagnosis of internal nodal inhomogeneity that should not be mistaken for is the normal fatty hilum of the node or reactive fatty hilar metaplasia (Fig. 5.20) or an intranodal abscess/suppurative lymphadenitis.

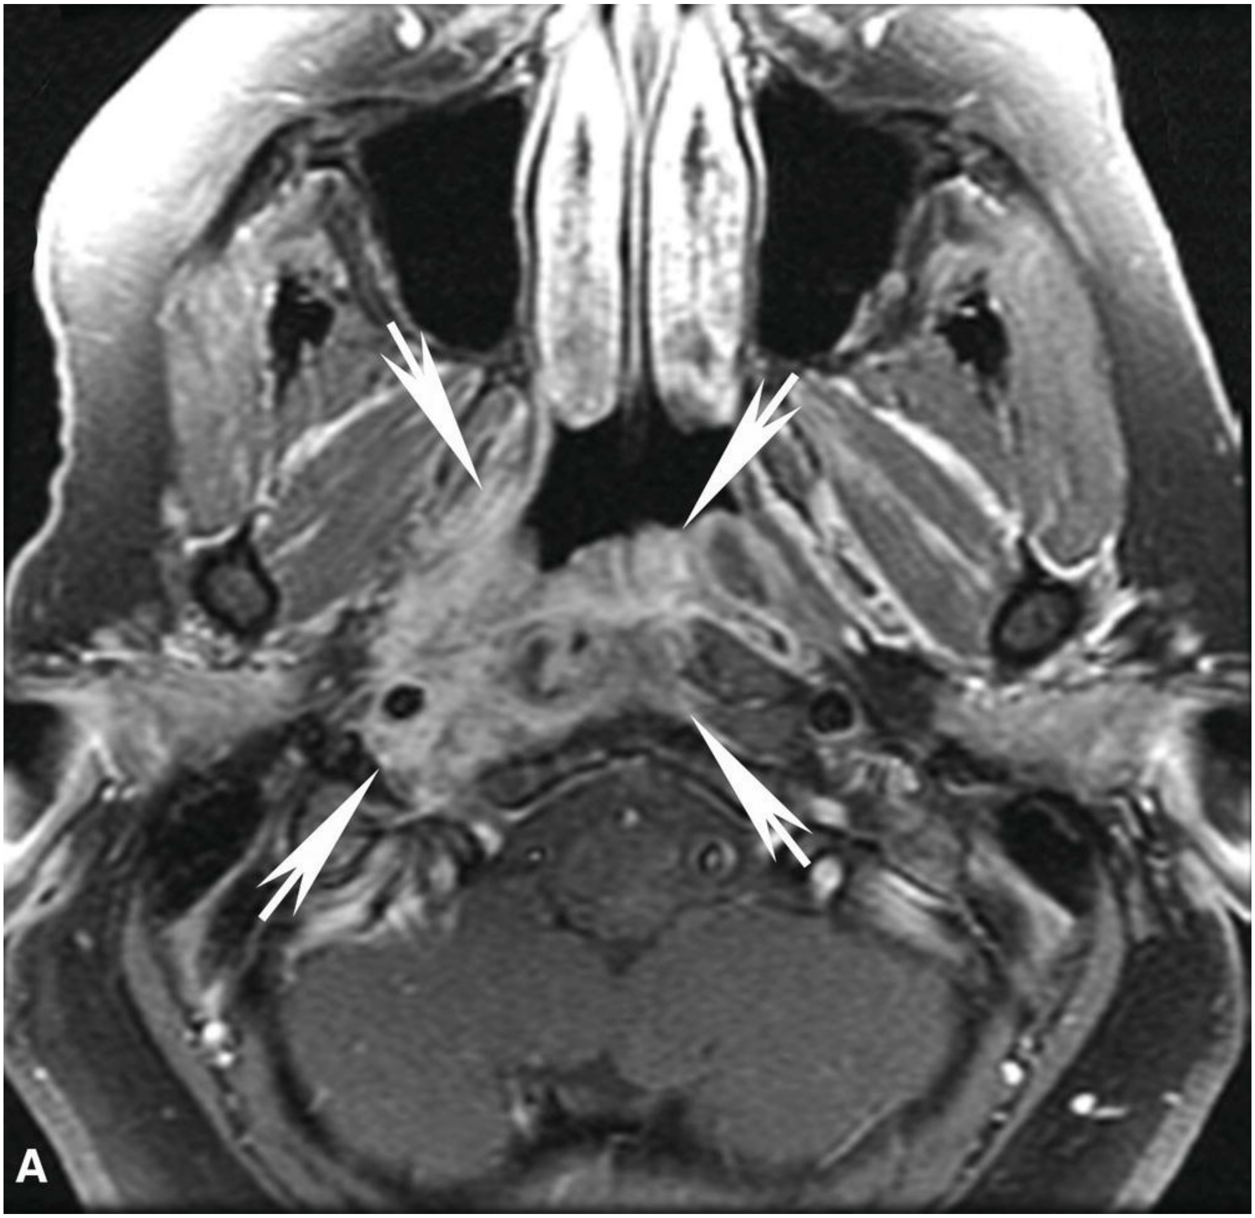
Other characteristics that can be used for evaluation of metastatic nodes are node shape and contour (or periphery). Normal nodes tend to be oblong elliptical or “lima bean”–shaped structures, whereas metastatic nodes tend to become rounded and spherical (Fig. 5.20). Unfortunately, depending on their location in the neck and the plane in which the node is assessed, this criterion may not be reliably applied to small lymph nodes. Normal nodes also typically have a smooth well-defined contour. Therefore, unless there has been treatment such as radiation therapy or neck surgery, contour irregularity is suggestive of pathology (Fig. 5.20). Transgression of tumor across the node capsule into the adjacent soft tissues is referred to as extracapsular, extranodal, or transcapsular spread of tumor (ECS). The presence of ECS is associated with an increased risk of tumor recurrence, distant metastases, and a decrease in patient survival.[56,57] On imaging, macroscopic ECS appears as infiltration of the adjacent fat planes or soft tissues, although this is not always present in histologically verified ECS, or may be present in the absence of ECS. Spread to adjacent anatomic structures should be identified, especially encasement of critical structures such as muscles or the carotid artery, which may indicate nonresectability.

Role of FDG-PET for the Evaluation of Nodal Metastases and N Stage

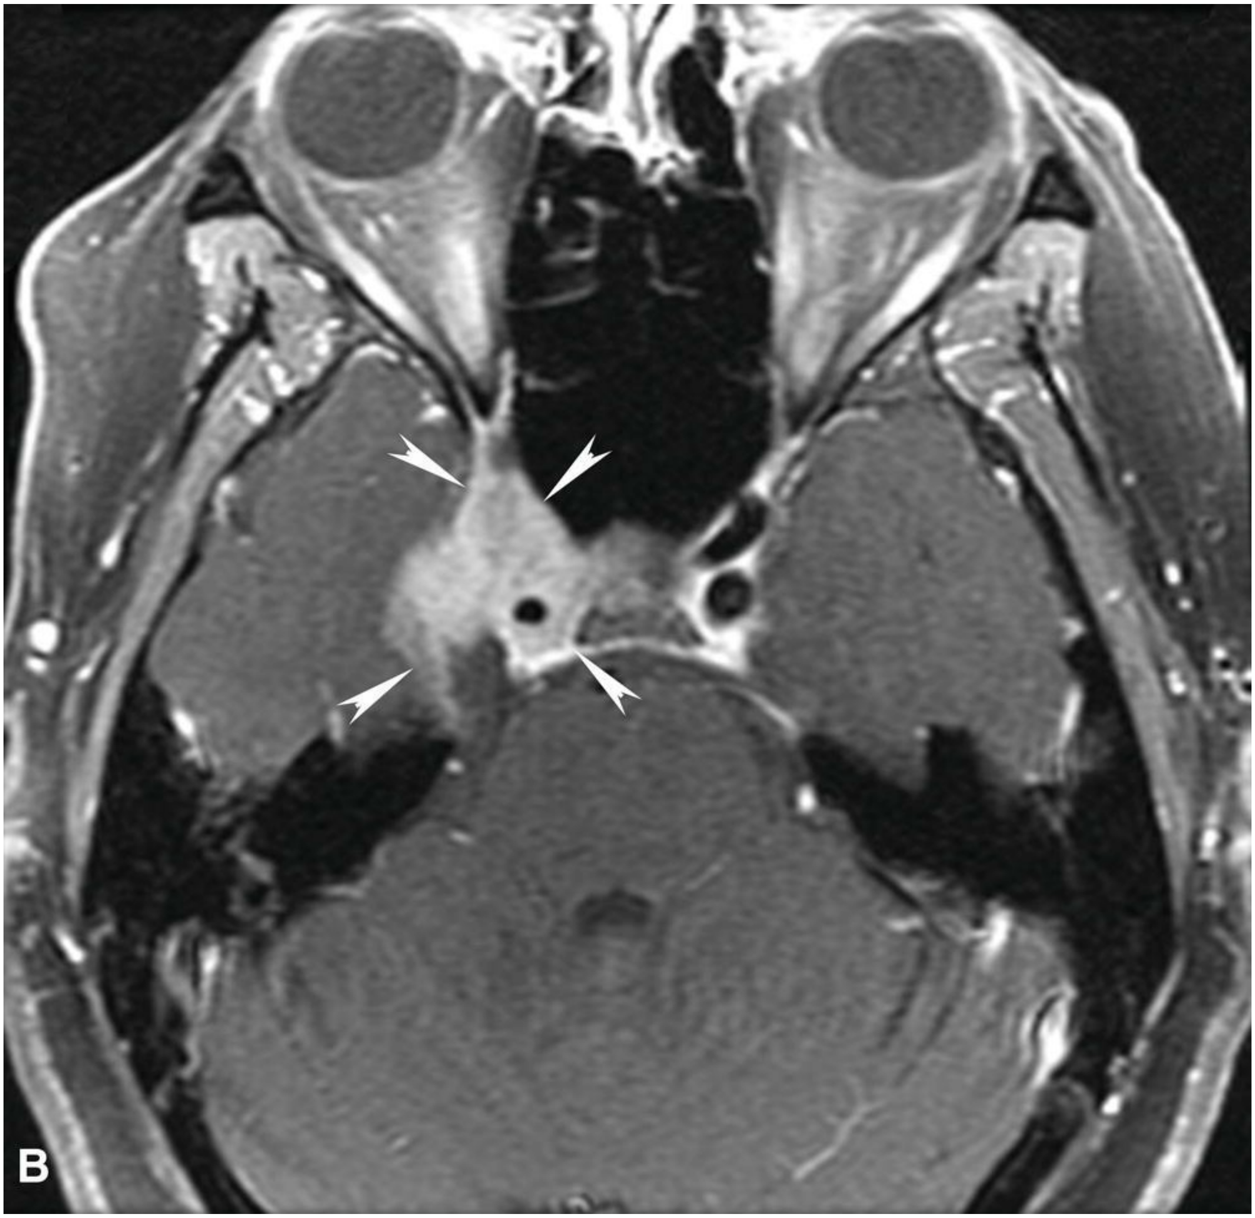
PET can detect metastases in small nodes that may otherwise appear normal on CT or MRI by demonstrating increased metabolic activity (Figs. 5.10 and 5.11). The addition of PET to conventional anatomic techniques such as CT and MRI increases sensitivity for detection of nodal metastases and can upstage the N stage by 15% to 20%.[13,14] In a recently published evidence-based guidelines, PET was recommended for nodal staging in patients with equivocal findings on conventional imaging.[58] Of course, one must be aware of pitfalls of PET, both false negatives such as in the evaluation of necrotic nodes (Fig. 5.10) and false positives, discussed earlier in this chapter. It is important to be aware that detection of metastases in small lymph nodes remains a challenge even with PET, particularly in lymph nodes measuring <7 mm. PET is not sufficiently sensitive to preclude an elective neck dissection in head and neck cancers with a high risk of occult metastases.[46]

Perineural Spread of Tumor

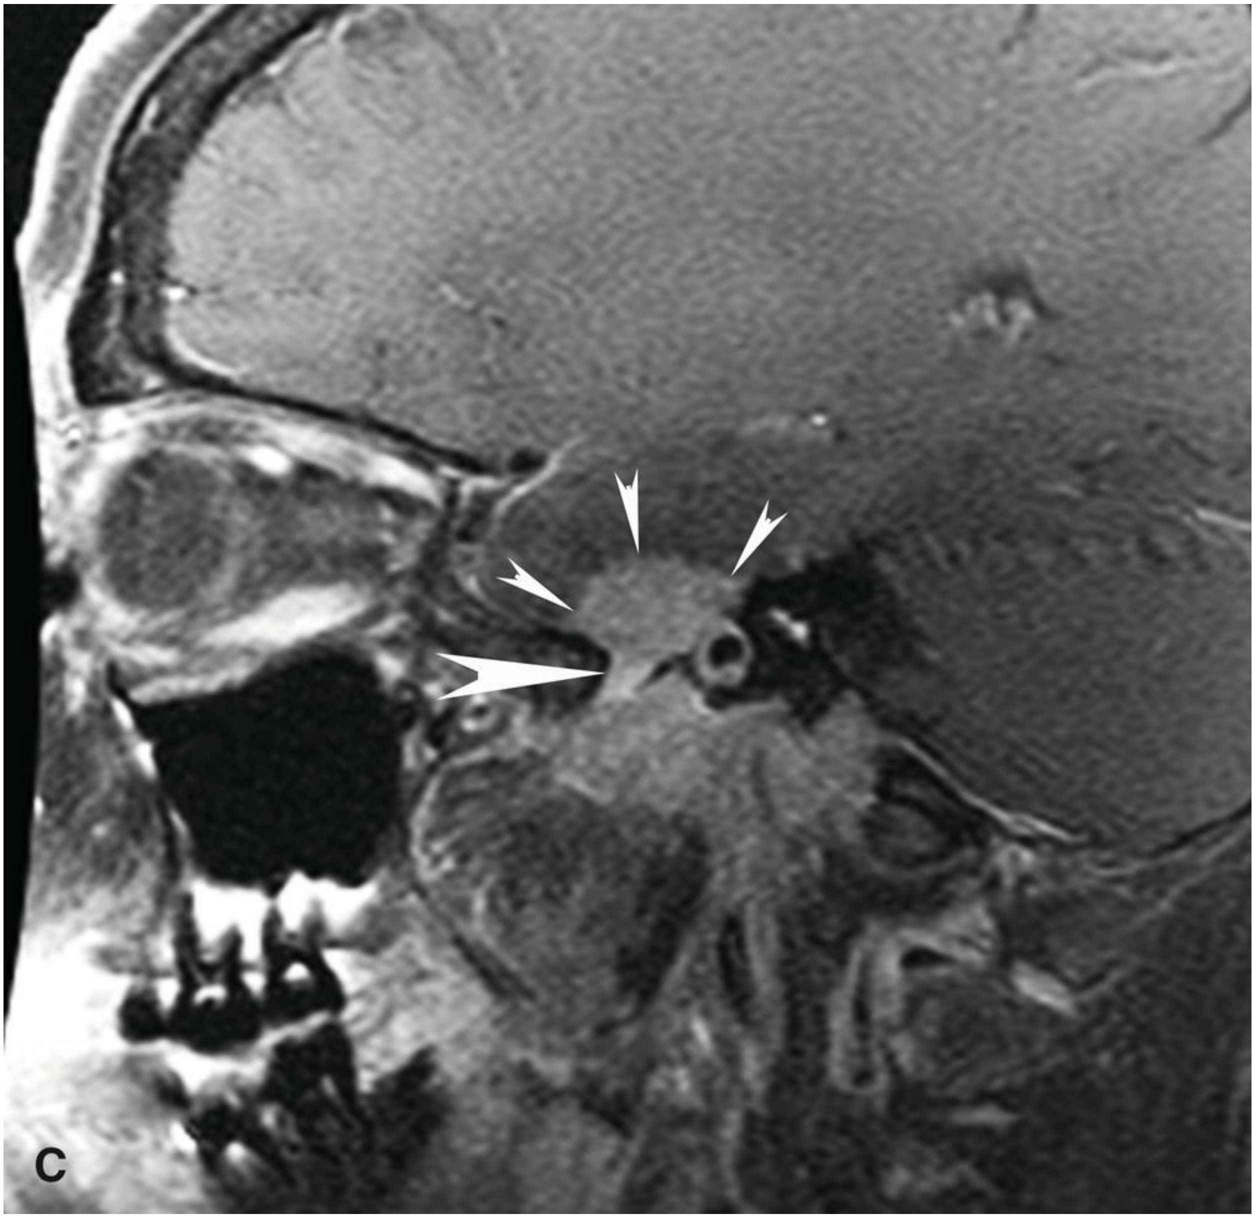
PNS of tumor is a well-recognized mode of tumor dissemination in head and neck cancer.[25,26] In PNS, tumor spreads from the primary site along the nerve and nerve sheath. PNS should be distinguished from perineural invasion (PNI), which refers to microscopic involvement of small nerves at the site of primary tumor on histology.[26,59,60] In PNS, tumor extends beyond the site primary tumor with large nerve involvement and can be thought of as a mode of metastasis.[26] Many head and neck tumors may have associated PNS including mucosal SCCs, salivary gland malignancies (in particular adenoid cystic carcinoma [Fig. 5.21]), and cutaneous malignancies such as SCC and desmoplastic melanoma. Other neoplasms that may present with PNS include NPC.[26] Adenoid cystic carcinoma has the greatest propensity for PNS, but given the much higher incidence of SCC, that tumor more commonly presents with PNS. PNS of tumor is typically retrograde, toward the central nervous system, but there can also be antegrade spread away from the CNS. Branches of the trigeminal and facial nerves are most commonly affected by PNS although other nerves may be affected as well depending on the primary tumor site. Because a significant percentage of patients with PNS may be asymptomatic initially, its detection requires heightened awareness and vigilance on the part of the radiologist in order to make a timely diagnosis.[25,26]



A



B

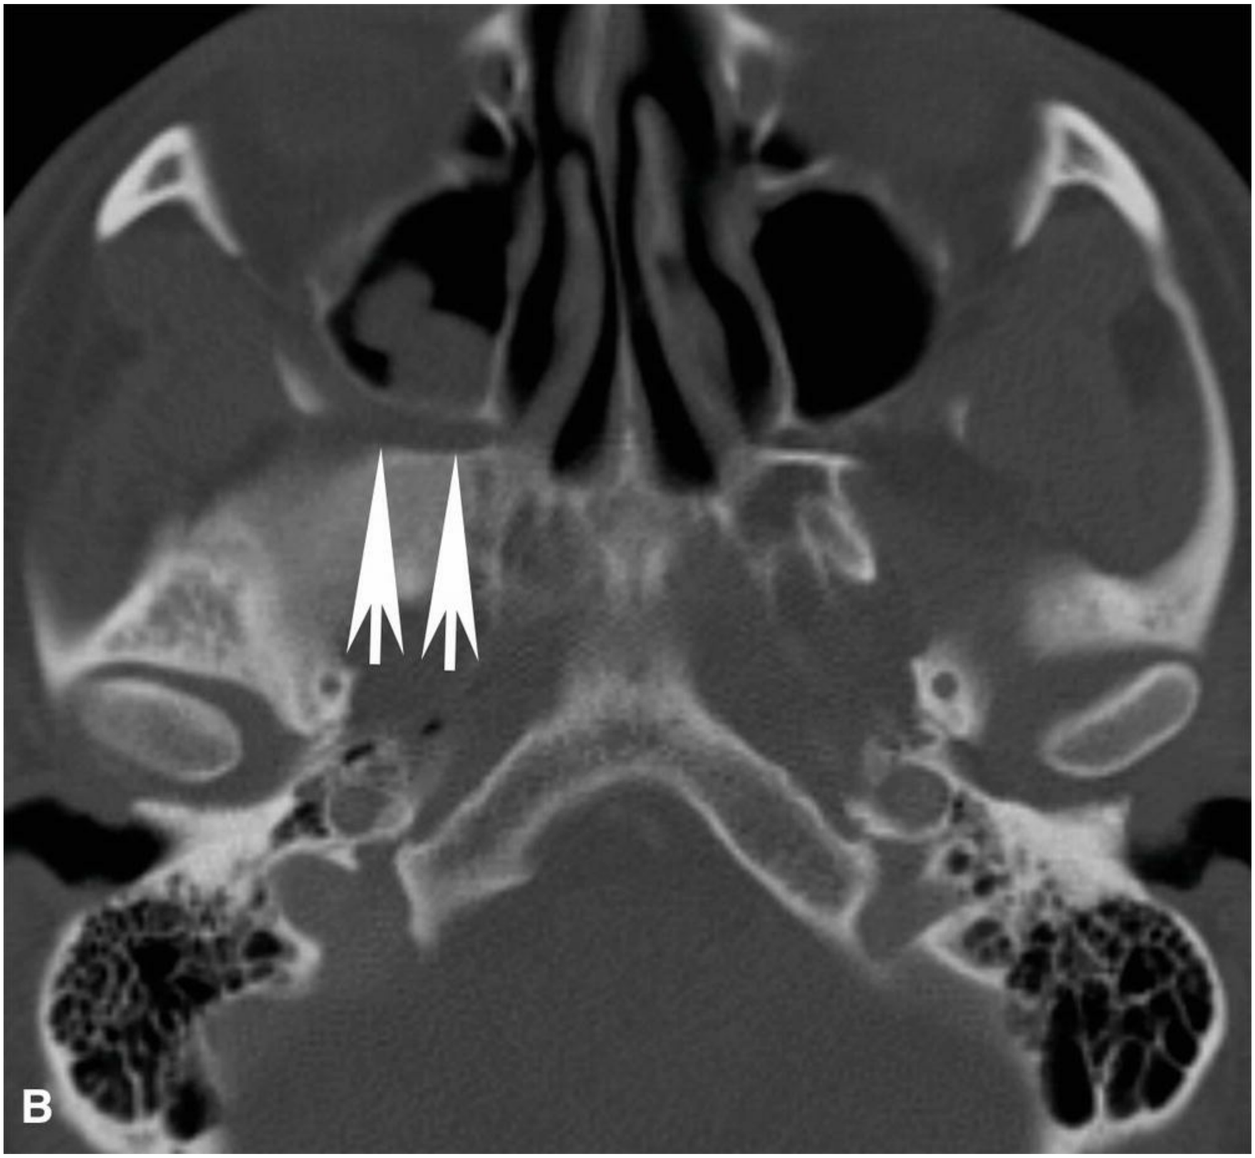


C

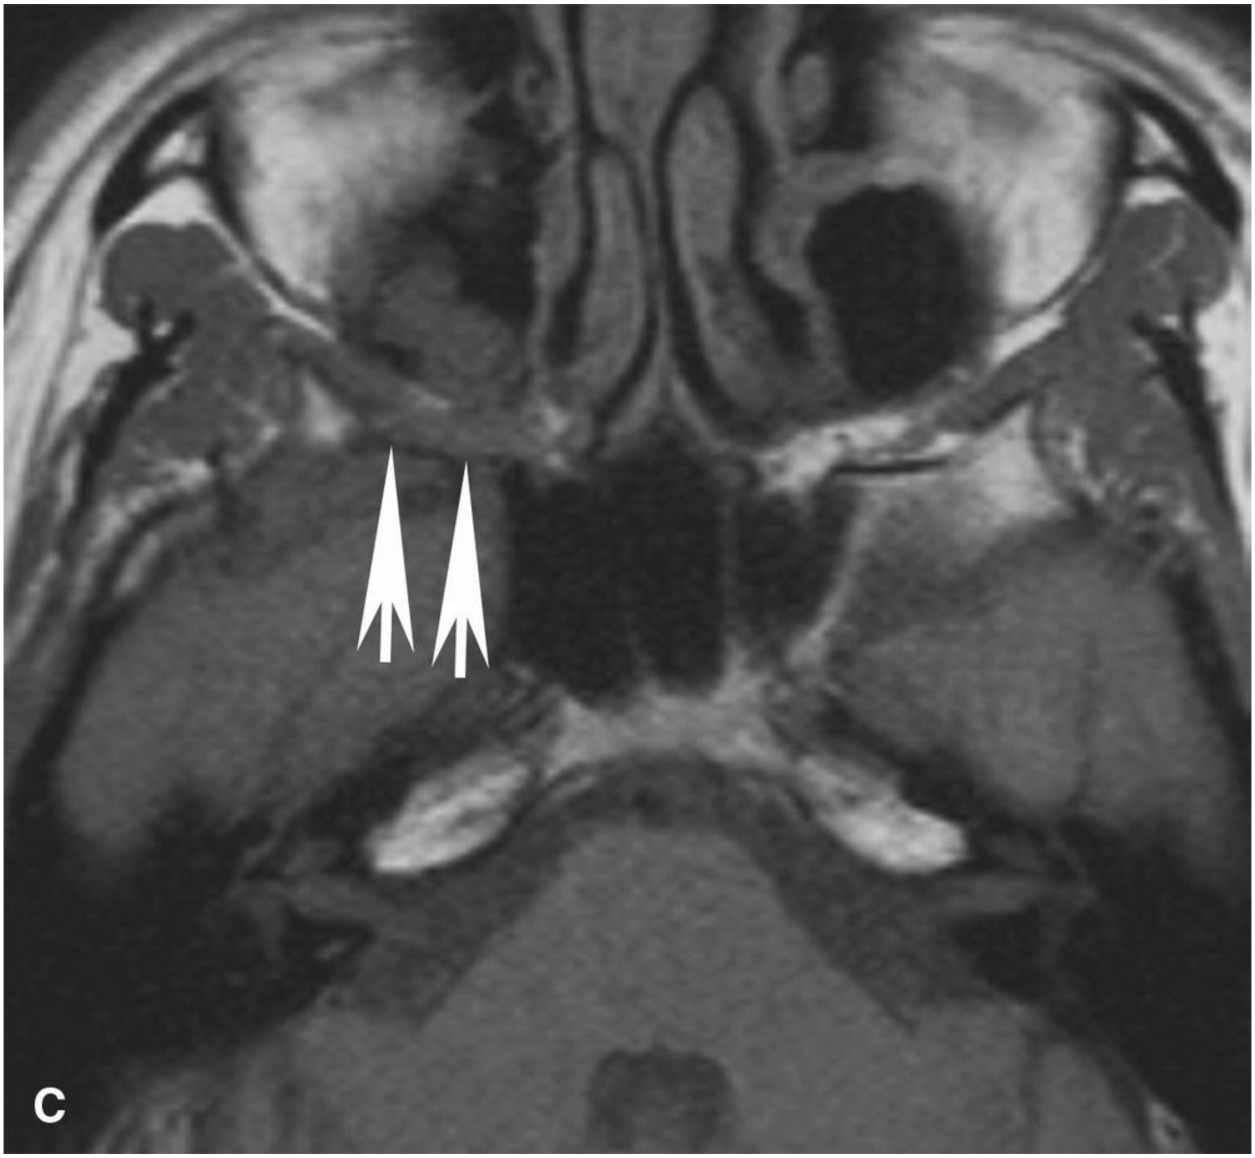
Figure 5.21. Adenoid cystic carcinoma of the nasopharynx with PNS of tumor and intracranial spread. Axial **(A, B)**, sagittal **(C)**, and coronal **(D)** contrast-enhanced fat-suppressed T1w MRI images are shown. There is an infiltrative nasopharyngeal tumor (**A**; *arrows*), the bulk of which is on the right side. There is PNS through the right foramen ovale (**C,D**; *large arrowhead*) with spread of tumor into the right middle cranial fossa and cavernous sinus (**B–D**; *small arrowheads*).

On CT, PNS can present as subtle infiltration of fat surrounding the nerve in different foramina or spaces such as the pterygopalatine fossa (PPF) (Fig. 5.22) or in the stylomastoid foramen. There can also be expansion and

remodeling of the foramina or surrounding bones (Fig. 5.22), or destruction of bone in late cases. However, PNS is much better seen on MRI[25,26] (Figs. 5.21 and 5.22). On T1w images, PNS will manifest as replacement and obliteration of normally bright fat in the PPF (Fig. 5.22) or fat surrounding the nerves within different foramina. On fat-suppressed contrast-enhanced images, enhancing tumor is clearly distinguishable from surrounding fat (Figs. 5.21 and 5.22). The involved nerve may appear expanded, but this is not an absolute requirement for diagnosis, and asymmetric enhancement of a nerve alone can suggest the presence of PNS in the absence of other explanation such as nonspecific neuritis or benign lesions of the nerve.



B



C

Figure 5.22. Perineural spread (PNS) of tumor. Axial contrast-enhanced CT scan displayed in soft tissue **(A)** and bone windows **(B)** as well as unenhanced T1w **(C)** and contrast-enhanced fat-suppressed T1w **(D)** MRI images are shown from a patient with adenoid cystic carcinoma of the right maxillary sinus (primary not shown). On the CT, there is asymmetry with obliteration of normal fat in the right pterygopalatine fossa (PPF; **A**; *arrows*) and mild asymmetry with expansion and remodeling of its bony margins (**B**; *arrows*). On MRI, there is loss of the normal expected fat signal intensity (*arrows* in **C**) and abnormal enhancement (*arrows* in **D**).

For evaluation of PNS, the MRI should be performed as a high-resolution exam with section thickness of no more than 3 mm through the skull base.[26]

Familiarity with detailed cranial nerve anatomy and patterns of spread is essential for optimal interpretation of these studies. Particular attention should be paid to key areas such as PPF, foramen ovale and rotundum, and the stylomastoid foramen. However, the spread pattern partly depends on the location of the primary tumor, requiring carefully directed assessment of neural pathways at risk. Attention should also be paid to indirect signs of PNS, such as denervation change (Fig. 5.8), as a clue to the presence of PNS.

SITE-SPECIFIC CONSIDERATIONS AND PATTERNS OF TUMOR SPREAD

Nasal Cavity and Paranasal Sinuses

Sinonasal malignancies are rare, constituting <5% of malignant head and neck neoplasms.[61–63] Malignancies involving the nasal cavity and paranasal sinuses are usually considered together, except for cancers of the nasal vestibule. SCC is the most common sinonasal cancer, followed by intestinal-type adenocarcinoma.[61,62] Other less common sinonasal cancers include adenoid cystic carcinoma, mucoepidermoid carcinoma, sinonasal undifferentiated carcinoma, melanoma, and olfactory neuroblastoma (Fig. 5.23). Rarely, other malignant neoplasms such as neuroendocrine carcinoma (Fig. 5.24), lymphomas (Fig. 5.25), sarcomas, and metastases from other primary sites, among other rare entities, may affect the paranasal sinuses.[62–64] In the paranasal sinuses, the maxillary sinus is most commonly affected. The ethmoids are less commonly affected, and the frontal and sphenoid sinuses are rarely affected.[61,62]

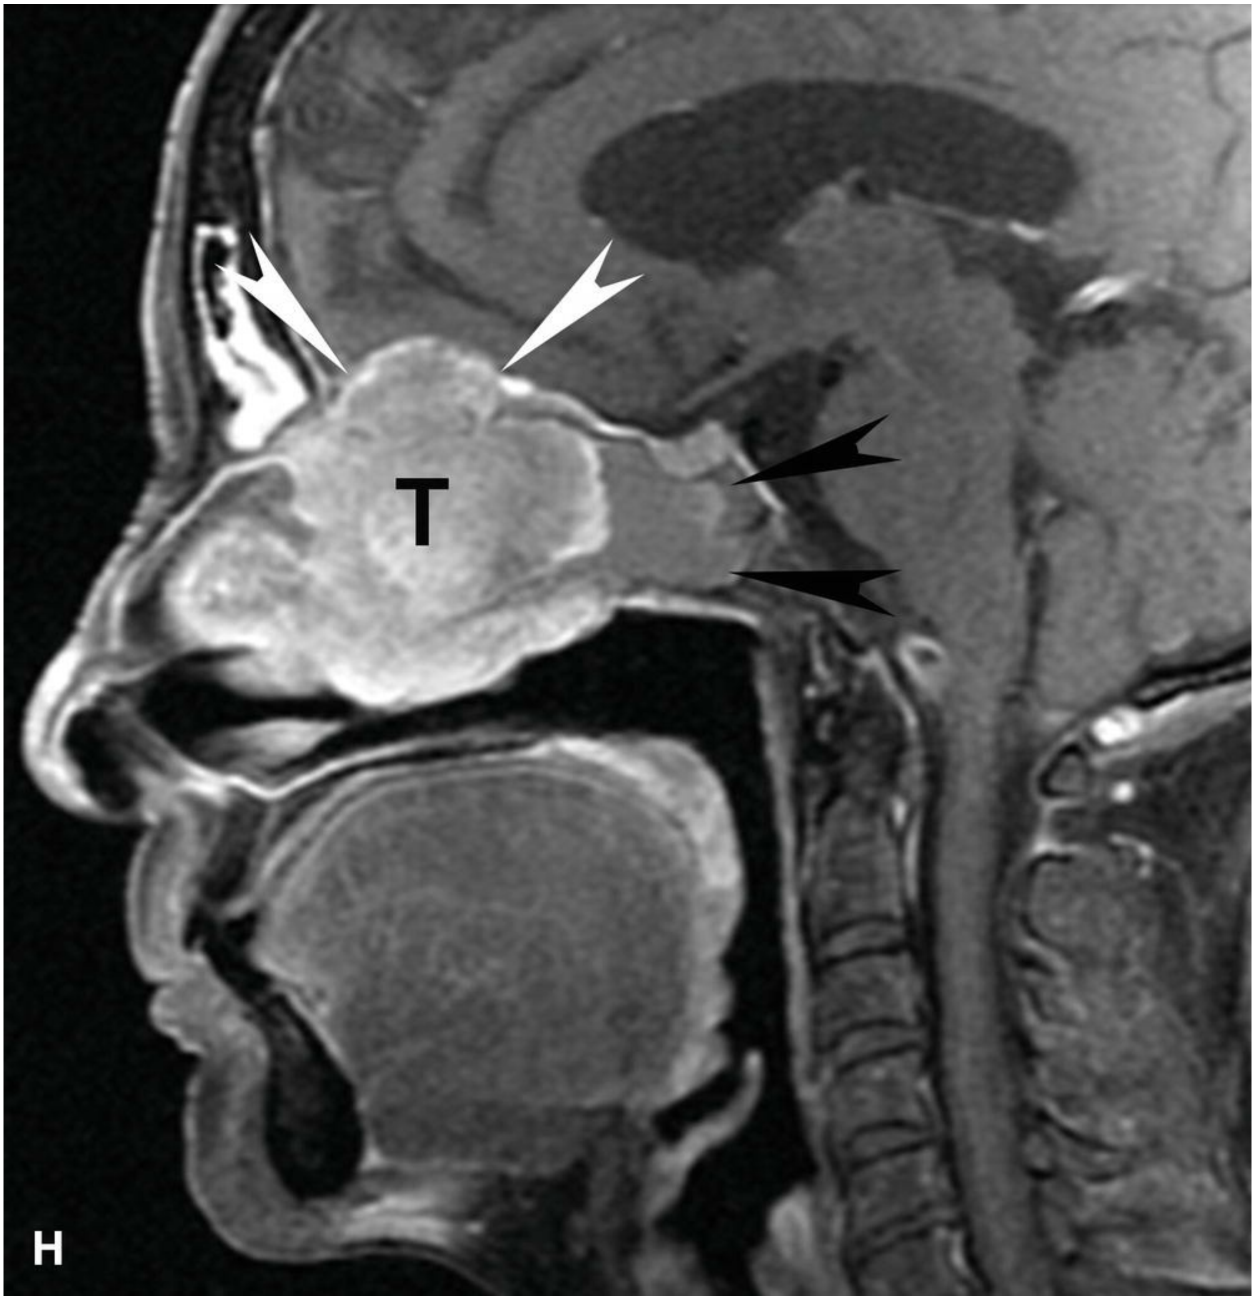

Figure 5.23. Olfactory neuroblastoma (ONB) with intracranial spread and facial node metastasis. Axial and coronal reformatted contrast-enhanced CT **(A–C)**, axial T2w **(D)**, T1w **(E)**, and contrast-enhanced T1FS **(F–H)** MRI images are shown. The tumor has a wide base with intracranial spread, which may be used to suggest ONB as a differential consideration, but the appearance and signal are otherwise nonspecific and biopsy is required for diagnosis (also compare to Figs. 5.24 and 5.25). In this case, the enhancing tumor (T) is clearly distinguishable from relatively low-density secretions in the maxillary sinuses (*black arrows* in **A and C**) and the signal of secretions

on MRI (*black arrowheads*). The *black arrowheads* point to secretions in some ethmoid air cells **(D–G)** and in the sphenoid sinus **(H)**. Note the variations in signal of the secretions adjacent to the mass, some with higher signal on T1w **(E)** suggestive of higher protein content. As expected, the secretions mostly have higher signal than tumor on T2w **(D)**. However, combined evaluation of all sequences clearly distinguishes tumor from the secretions, especially on the contrast-enhanced MRI images in most areas. The *white arrowheads* indicate intracranial extension of tumor. *White arrow* points to the right facial node metastasis **(B,G)**.

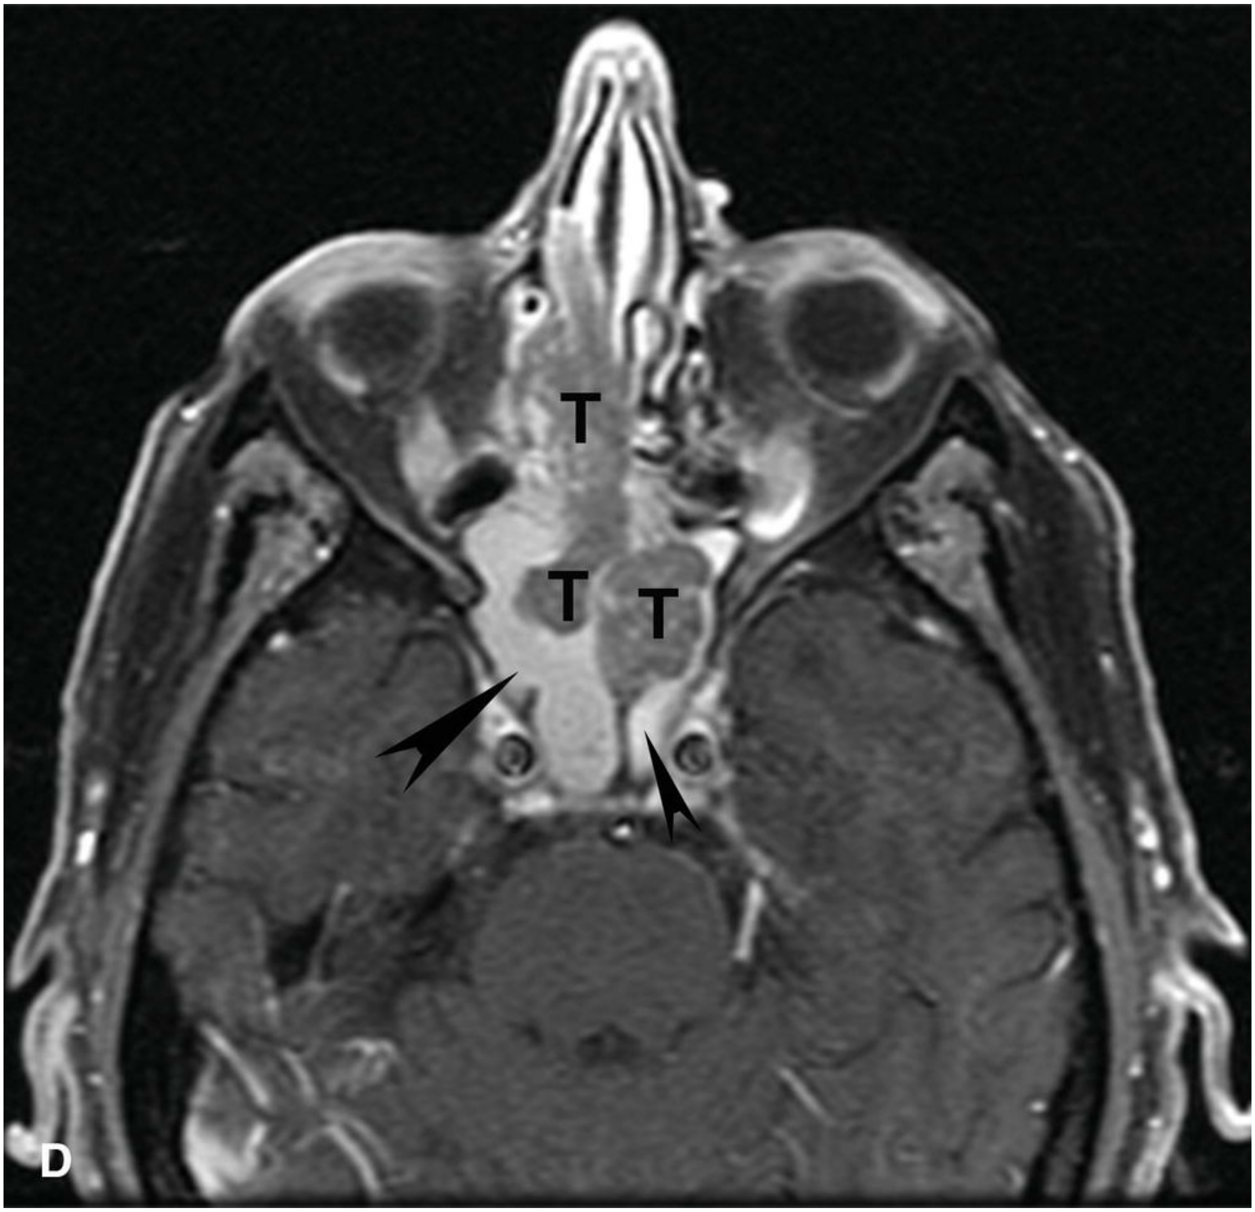

Figure 5.24. High-grade neuroendocrine sinonasal carcinoma: Differences in signal obstructive secretions. Axial contrast-enhanced CT **(A)** and axial T1w **(B)**, fat-suppressed T2w **(C)**, and contrast-enhanced fat-suppressed T1w **(D)** MRI images are shown from a 76-year-old male patient. On CT, parts of the tumor (T) have very similar density to the obstructive secretions and thus difficult to distinguish from tumor, especially in the left sphenoid sinus (*small arrowhead*). On MRI, on the other hand, the secretions are clearly distinguishable from tumor signal. Note that the higher density proteinaceous secretions in the left sphenoid sinus on CT also have lower signal on T2w and higher signal on T1w (*small arrowheads*) compared to the more watery secretions in the right sphenoid sinus (*large arrowhead*; see text for

explanations).

Figure 5.25. Anterior skull base diffuse large B-cell lymphoma. T1w **(A)**, T2w **(B)**, and contrast-enhanced fat-suppressed T1w **(C, D)** MRI images are shown from a 37-year-old male patient. The large heterogeneously enhancing tumor (T) involves the anterior skull base with a large intracranial component, extends into the orbit with involvement of the orbital apex (*white arrowheads*), invades the right temporalis muscle (*white arrows*), and has a small component extending into the ethmoids. Note the cerebral edema at the site of compression on the T2w images (**B**, *black arrowheads*).

The main role of imaging in evaluation of sinonasal tumors is to accurately determine the lesion stage in order to guide therapy and surgical planning. Occasionally, imaging can help narrow the differential for sinonasal tumors, but preoperative differentiation of different histologic subtypes of tumors is often not possible (Figs. 5.23 to 5.25), perhaps with the exception of melanotic melanomas, which may appear hyperintense to gray

matter on unenhanced T1w images.[63] Regardless, a biopsy is required for a histopathologic diagnosis.

Sinonasal cancers typically spread by direct and perineural extension[63] and frequently present with a relatively advanced stage (Fig. 5.23). Because of their proximity to multiple critical structures, it is important to carefully evaluate extension outside the sinonasal region[65] (Figs. 5.23 and 5.25). Specific evaluation needs to be made for invasion of the orbits or intracranial compartment, including specific assessment of orbital apex involvement. Invasion of clivus/skull base changes the stage and should be noted.

As mentioned, sinonasal tumors can also spread by perineural extension. The major nerves supplying the sinonasal region are the first two divisions of the trigeminal nerve. The second branch (maxillary division) of the trigeminal nerve is most likely to be involved. The PPF represents the site of convergence of multiple neural pathways and must be specifically evaluated on every scan. Spread of tumor to the PPF can provide a route for further spread into the orbit, intracranial compartment, infratemporal fossa, skull base, and even the oral cavity.[65]

Lymph node metastases from sinonasal cancers are relatively uncommon[63] (Fig. 5.23). However, when present, they usually indicate tumor spread outside of the sinonasal cavity and portend a poor prognosis. Nodal metastases are most commonly seen with tumors of the maxillary antrum. The lateral retropharyngeal nodes represent the primary nodal drainage area for these tumors. However, the lymphatic drainage is inconstant and variable, and as result, the upper internal jugular and level IB nodes are the most common sites harboring nodal metastases.[63] The site of metastasis partly depends on the location of the tumor.

CT and MRI are complementary for evaluation of sinonasal tumors. CT is excellent for evaluating bone detail and demonstrates the tumor–air interface very well (Figs. 5.23 and 5.24). CT also provides the necessary landmarks for sinonasal and skull base surgery. Inflammatory changes and secretions within the sinus, such as secondary to outflow obstruction from tumor, on the other hand, can sometimes have similar attenuation to tumor (Fig. 5.24). Secretions with low protein content have a low density and typically can be distinguished from intermediate to high soft tissue density of tumor (Fig. 5.23). However, higher density secretions and/or lower density

tumors may be indistinguishable on CT (Fig. 5.24). After administration of contrast, most tumors enhance whereas secretions do not have solid enhancement (Figs. 5.23 and 5.24).

Whereas CT is excellent for demonstrating bone detail, MRI is generally considered superior for determination of overall extent of tumor (Figs. 5.23 to 5.25). MRI is especially superior to CT for detection of the extent of tumor spread outside the paranasal sinuses, such as in the intracranial compartment, for evaluation of PNS, and for distinction of tumor from inflammatory and postobstructive changes and secretions (Figs. 5.23 to 5.25). Like on CT, the appearance of secretions on MRI depends on their protein content. Watery, low protein content secretions have fluid signal that is hypointense on T1w and hyperintense on T2w[65] (Figs. 5.23 and 5.24). Particularly with chronic obstruction, protein concentration of secretions tends to increase (Fig. 5.24). Typically, this results in increased signal on T1 (Fig. 5.24). The signal of secretions initially remains high on T2, but starting at ~25% protein content, the signal starts to drop on T2w images as well (Fig. 5.24). With very high protein content, typically >28%, the signal of secretions will decrease on both T1 and T2w images. If the protein content is high enough, the secretions can occasionally present as a signal void on both sequences and mimic a normal aerated sinus on MRI.[65] Regardless of signal variations, secretions are almost always distinguishable from soft tissue signal and solid enhancement of tumor. The normal linear mucosal enhancement should not be mistaken for tumor (Fig. 5.23). MRI is more sensitive for detection of bone marrow infiltration. Multiplanar assessment, and particularly coronal images, are essential for the evaluation of the roof of the ethmoid, cribriform plate, orbital roofs, floor of anterior cranial fossa, and palate and should be performed both on CT and MRI.[65]

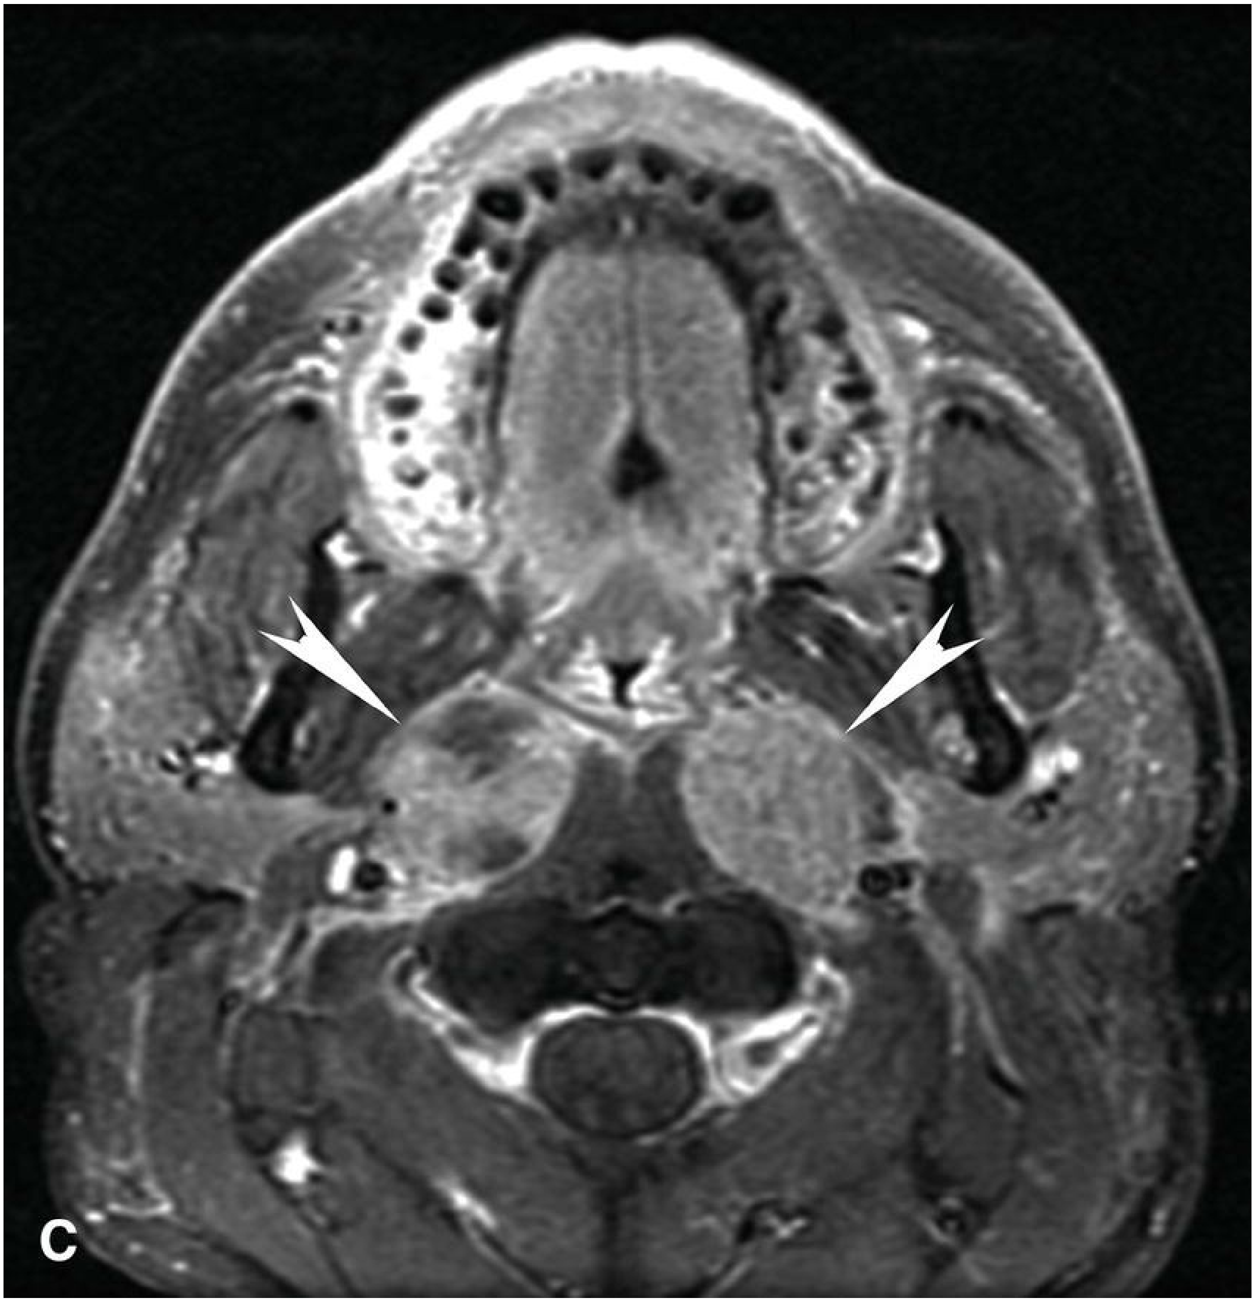
Nasopharynx

NPC is a distinct disease from SCC. NPC has the highest incidence in Southeast Asia but is less common in the West and among Caucasians[66] and, according to the WHO classification, has 3 histologic subtypes. In general, NPC is a locally aggressive neoplasm with a high propensity for nodal spread (Figs. 5.26 and 5.27). Uncommonly, other tumor types may arise in the nasopharynx (Fig. 5.21). Although NPC may arise at any site in the nasopharynx, it frequently arises in the region of the fossa of Rosenmüller[67]

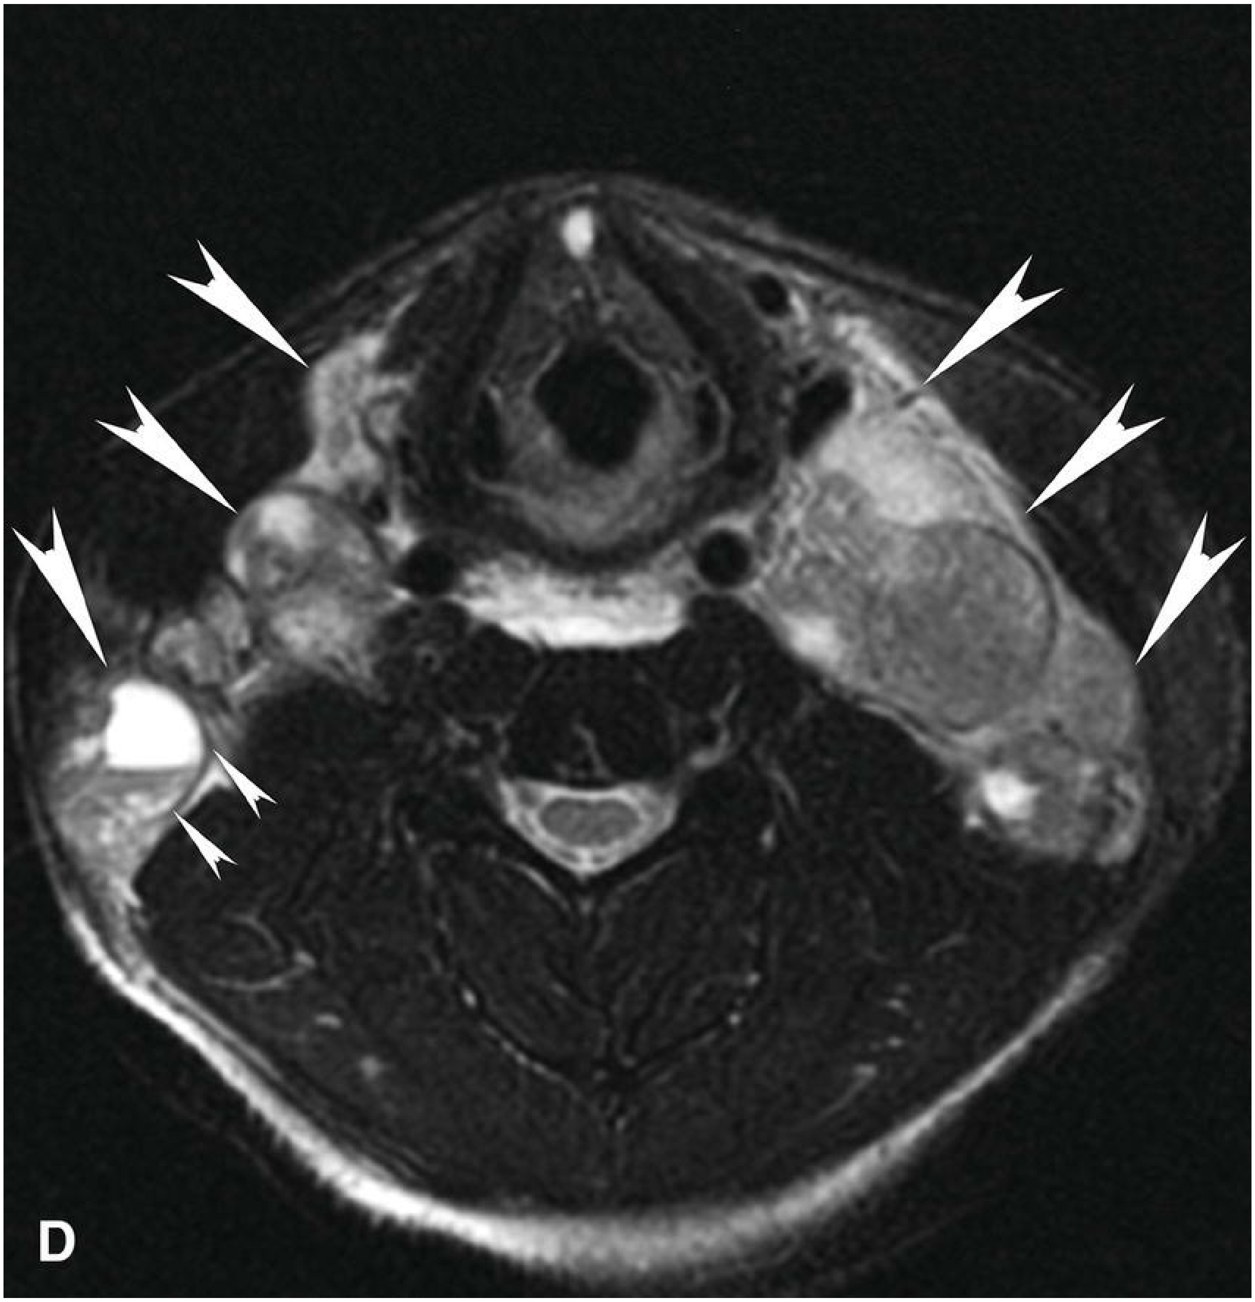
(Fig. 5.27). The nasopharyngeal mucosa is surrounded by a muscular and fascial sling constituted by the superior constrictor muscles and the buccopharyngeal fascia, derived from the middle layer of deep cervical fascia.[66] There is also the pharyngobasilar fascia (PBF), a tough aponeurosis extending from the superior constrictor muscles to the skull base. However, there are defects in the PBF on either side at the site of passage of the eustachian tube and levator veli palatini muscle, referred to as the sinus of Morgagni. The PBF can be seen on T2w images as thin low intensity line extending posteriorly from the medial pterygoid plates and lining the lateral and posterior nasopharyngeal walls.[66] NPC may spread submucosally or transgress adjacent fascial boundaries or defect and invade adjacent spaces such as the masticator and retropharyngeal spaces.[67,68] Invasion of the skull base may occur directly adjacent to the tumor site or tumor may spread via foramen lacerum and the neural foramina along the floor of the middle cranial fossa.[67] Extension along the course of the Eustachian tube potentially provides access to the middle ear, but this is very rare. Extension into adjacent spaces, including the parapharyngeal space, skull base, paranasal sinuses, intracranial compartment, masticator space, or beyond needs to be documented when present for proper staging. PNS of tumor primarily occurs after tumor has invaded into the PPF, or foramen ovale, and may thus facilitate intracranial spread and is a T4 designator.[67]

A

B



C



D

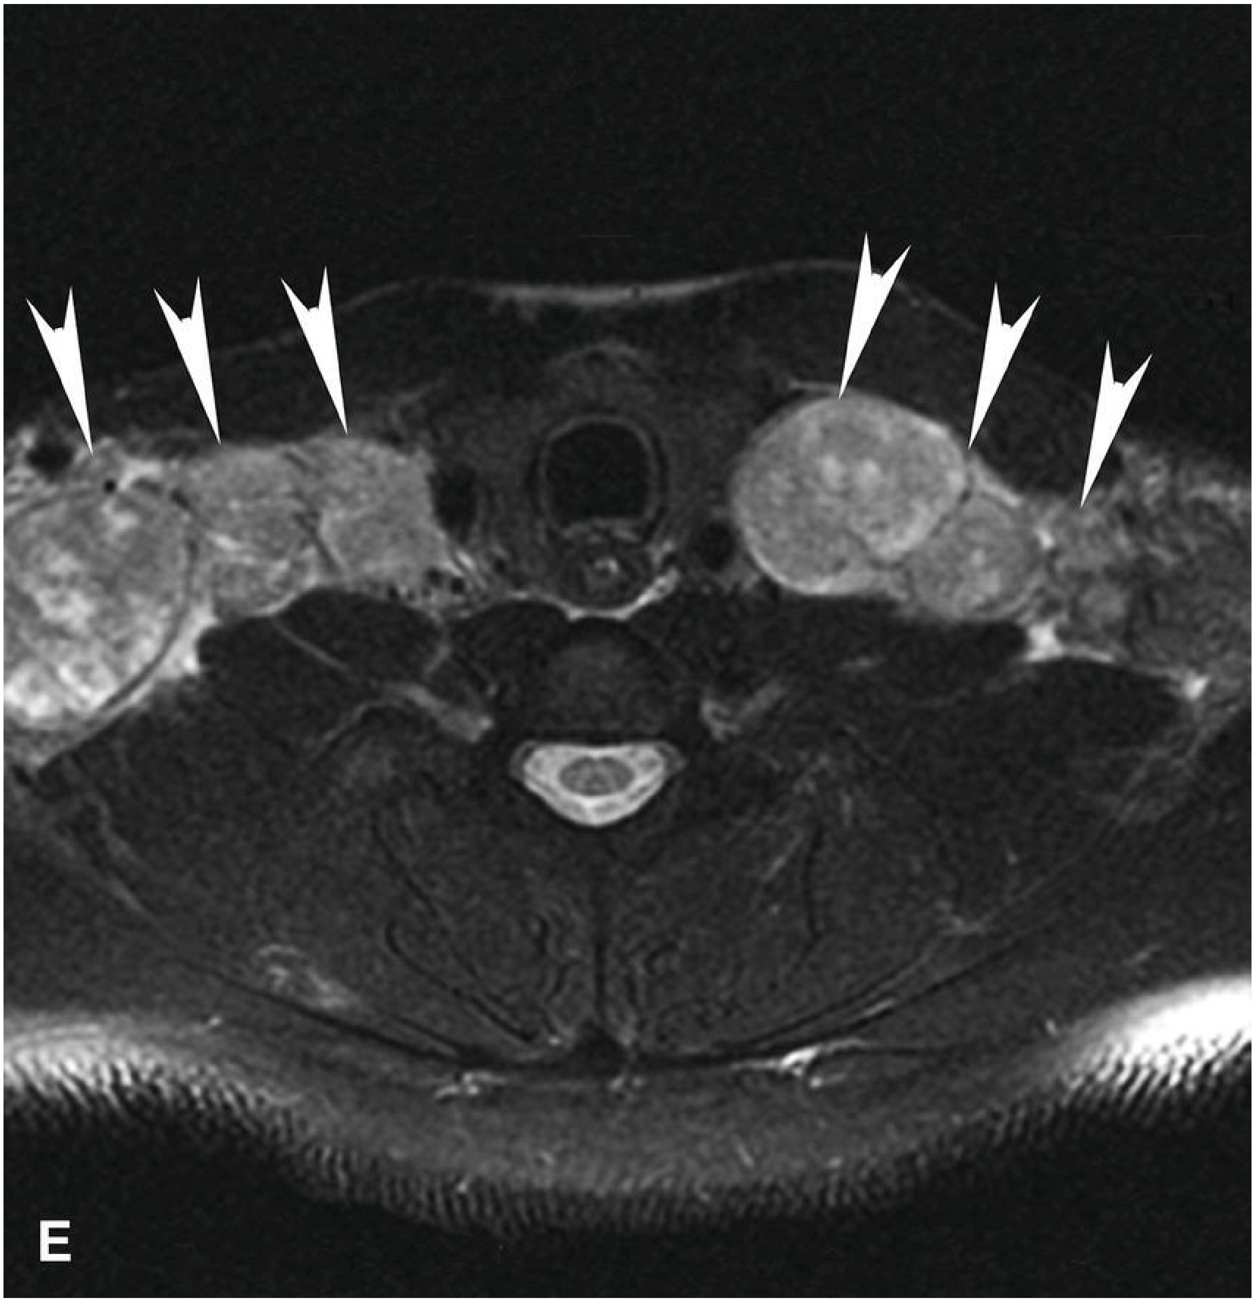


Figure 5.26. Nasopharyngeal carcinoma (NPC). Axial T2FS **(A, B, D, E)** and axial contrast-enhanced fat-suppressed T1w **(C)** MRI images are shown from a 39-year-old man presenting with NPC. The primary mass (**A**; *arrows*) is relatively noninvasive, T2 stage. However, there is massive bilateral cervical lymphadenopathy (**B–E**; *large arrowheads*) including the lateral retropharyngeal nodes **(B, C)**, level II (not shown), level III **(D)**, level IV **(E)**, and level V **(E)**. This is a good example highlighting the propensity of this tumor for nodal spread, presenting with N3 stage. Note the fluid level in the right level VA node (**D**; *small double arrowheads*), a rare presentation of

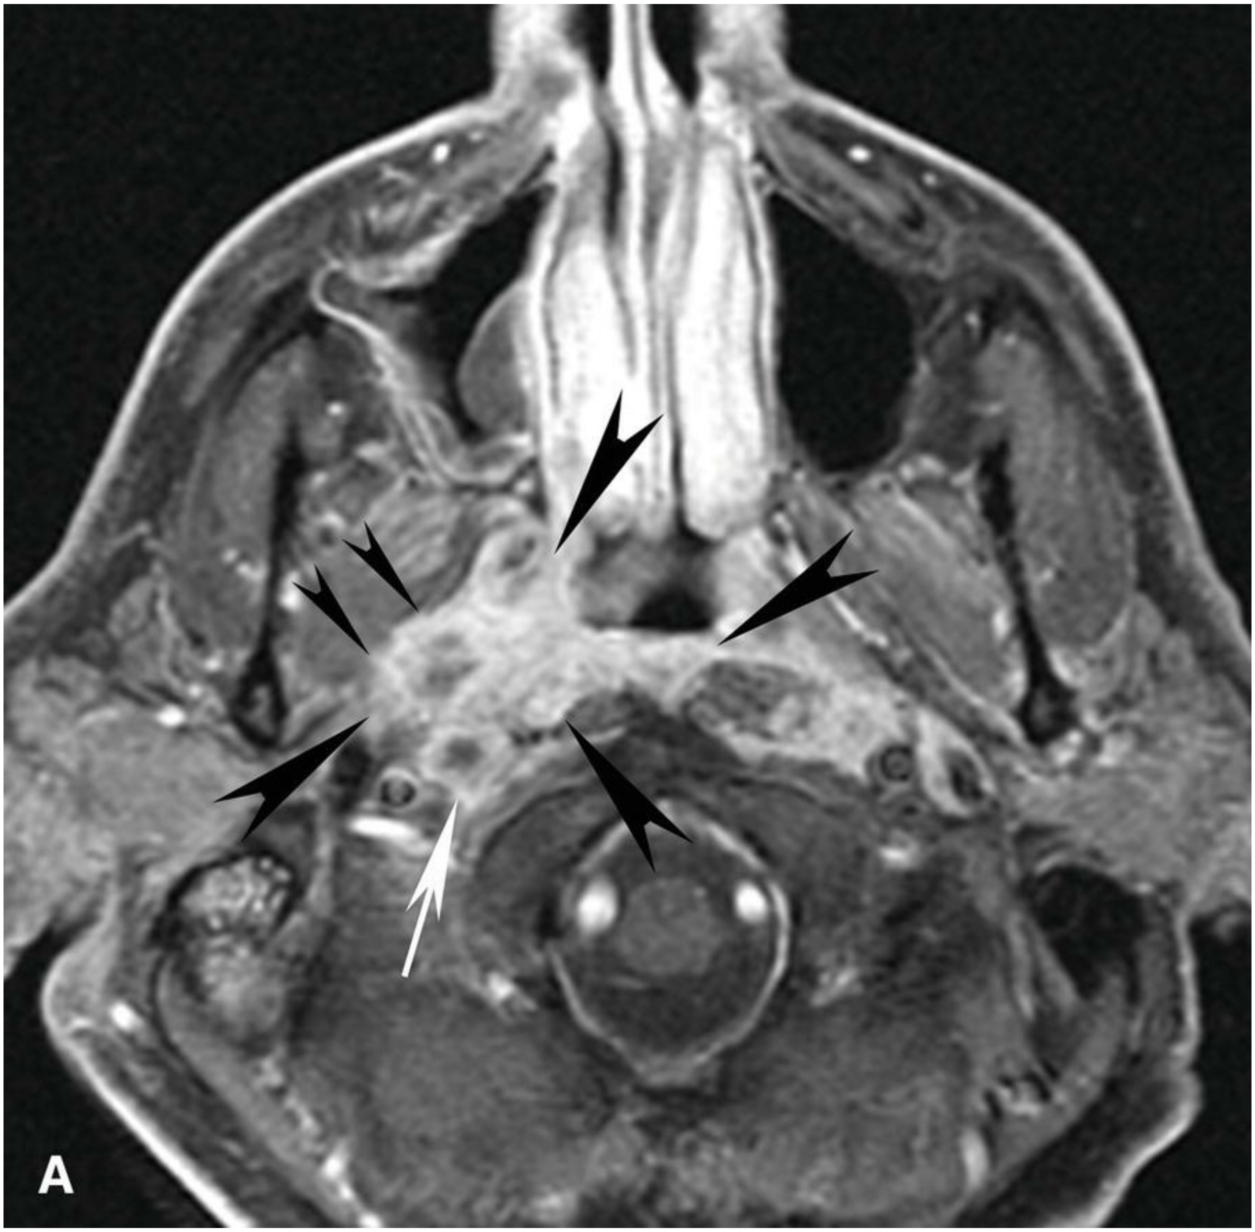
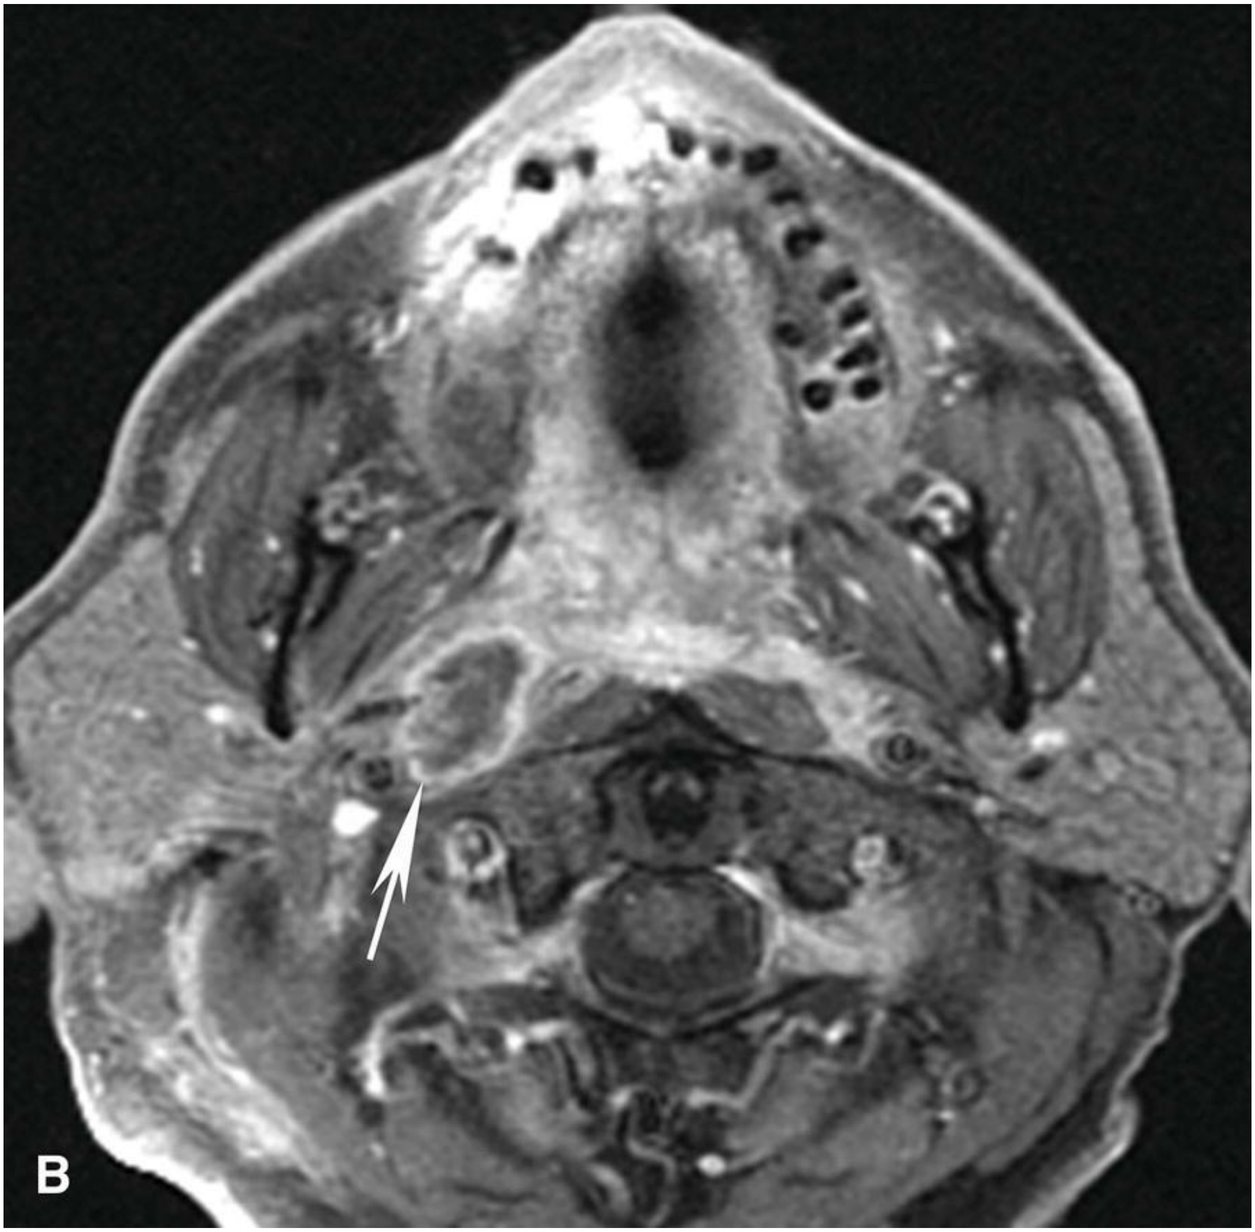
necrosis. There are also typical inhomogeneous/necrotic nodes elsewhere, including the retropharyngeal nodes (*arrowheads*, **B, C**).





B

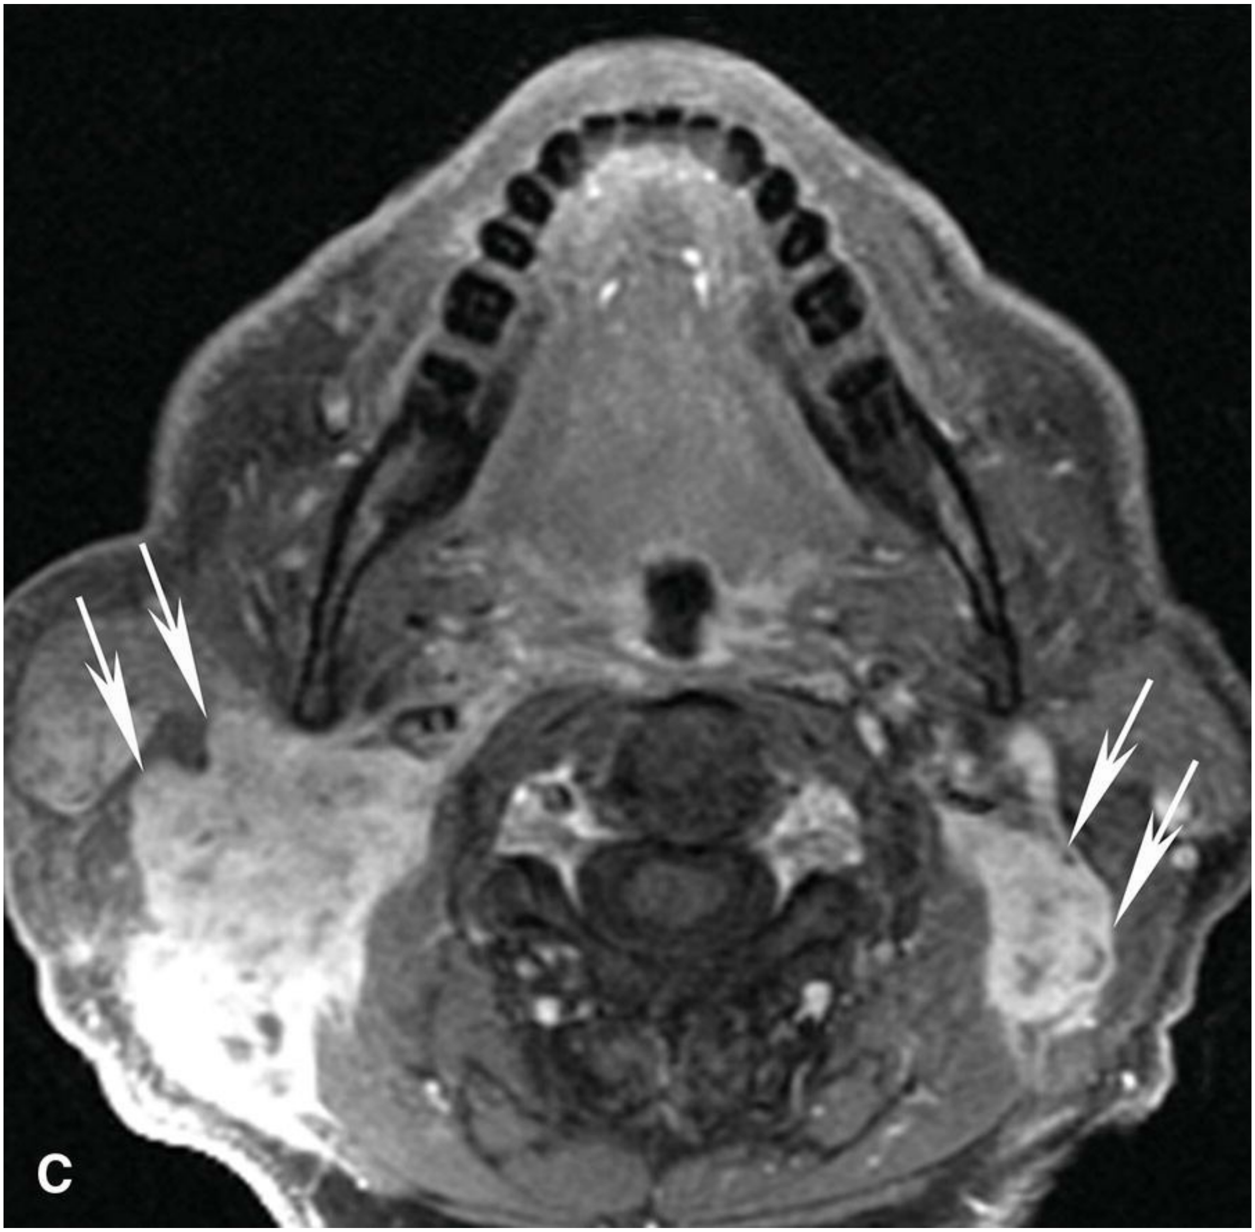


Figure 5.27. Nasopharyngeal carcinoma (NPC). **A–C:**Axial contrast-enhanced T1FS MRI images are shown from a 73-year-old man presenting with NPC (**A**; *large black arrowheads*). The lesion is centered in the region of the right fossa of Rosenmüller, the most common site of origin of NPC. There is submucosal spread of tumor along with invasion of the right longus muscles. In addition, there is a small area of focal spread across the right parapharyngeal space into the right masticator space (*small black arrowheads*). There is extensive lymphadenopathy including a necrotic right lateral retropharyngeal node (**A, B**; *white arrow*) and bilateral conglomerate level II adenopathy (**C**; *double white arrows*).

The appearance of NPC, particularly when small, is nonspecific on imaging and can overlap with normal adenoid tissues. Laterality and presence of excess tissue in the region of fossa of Rosenmüller should heighten suspicion for presence of tumor and trigger endoscopic evaluation, particularly in a patient presenting with middle ear effusion or other clinical signs suggesting possible NPC. Although both CT and MRI play a role in evaluation of NPC, MRI has been demonstrated to be superior for initial T stage determination of biopsy-proven NPC.[1–6] On MRI, NPC usually is typically isointense relative to muscle signal on T1w images and relatively hypointense on T2w images (although still hyperintense with respect to muscle). After contrast administration, there is moderate to intense enhancement of the tumor (Fig. 5.27).

When evaluating the nasopharynx, especial attention needs to be made to any asymmetry in tissues and obliteration of fat planes. Similar to other sites, when evaluating for bone invasion, attention needs to be paid to tumor signal within the bone to try and distinguish marrow edema. In addition to axial images, coronal and sagittal images can be very useful for evaluation of roof of nasopharynx and bone invasion. Evaluation of cavernous sinuses, intracranial compartment, and PNS is best done with MRI. In the AJCC classification, the N staging of NPC is different from other head and neck cancers. NPC has high propensity for nodal spread, and there are frequently nodal metastases at the time of presentation, in 60% to 90% of cases[66] (Figs. 5.26 and 5.27). The most common sites of nodal spread from NPC are to levels II, III, IV, and V, the lateral retropharyngeal nodes, and the posterior auricular nodes.[46,69]

Oral Cavity

Cancers of the oral cavity are considered separately from those of the oropharynx because malignancies such as SCC of the oral cavity tend to differ from those arising in the oropharynx in presentation, routes of spread, and clinical management. A large and varied collection of benign and malignant tumors may arise in the oral cavity, but among the malignancies, >90% are SCC.[70] The oral cavity has multiple anatomic subsites that include the lip (mucosal part), buccal mucosa, floor of mouth (FOM), oral tongue, retromolar trigone (RMT; or retromolar gingiva), hard palate, and alveolar ridge. The alveolar ridge may be further divided into upper and lower

alveolar ridge, referring to the mucosa overlying the alveolar process of the maxilla and mandible, respectively. Two of the most common oral cavity cancers are those arising in the oral tongue (Figs. 5.3 and 5.6) and FOM (Fig. 5.28). The nodal spread patterns of SCCs of the oral cavity partly depend on the specific subsite, but overall, the most common nodal groups involved are levels I, II, and III.

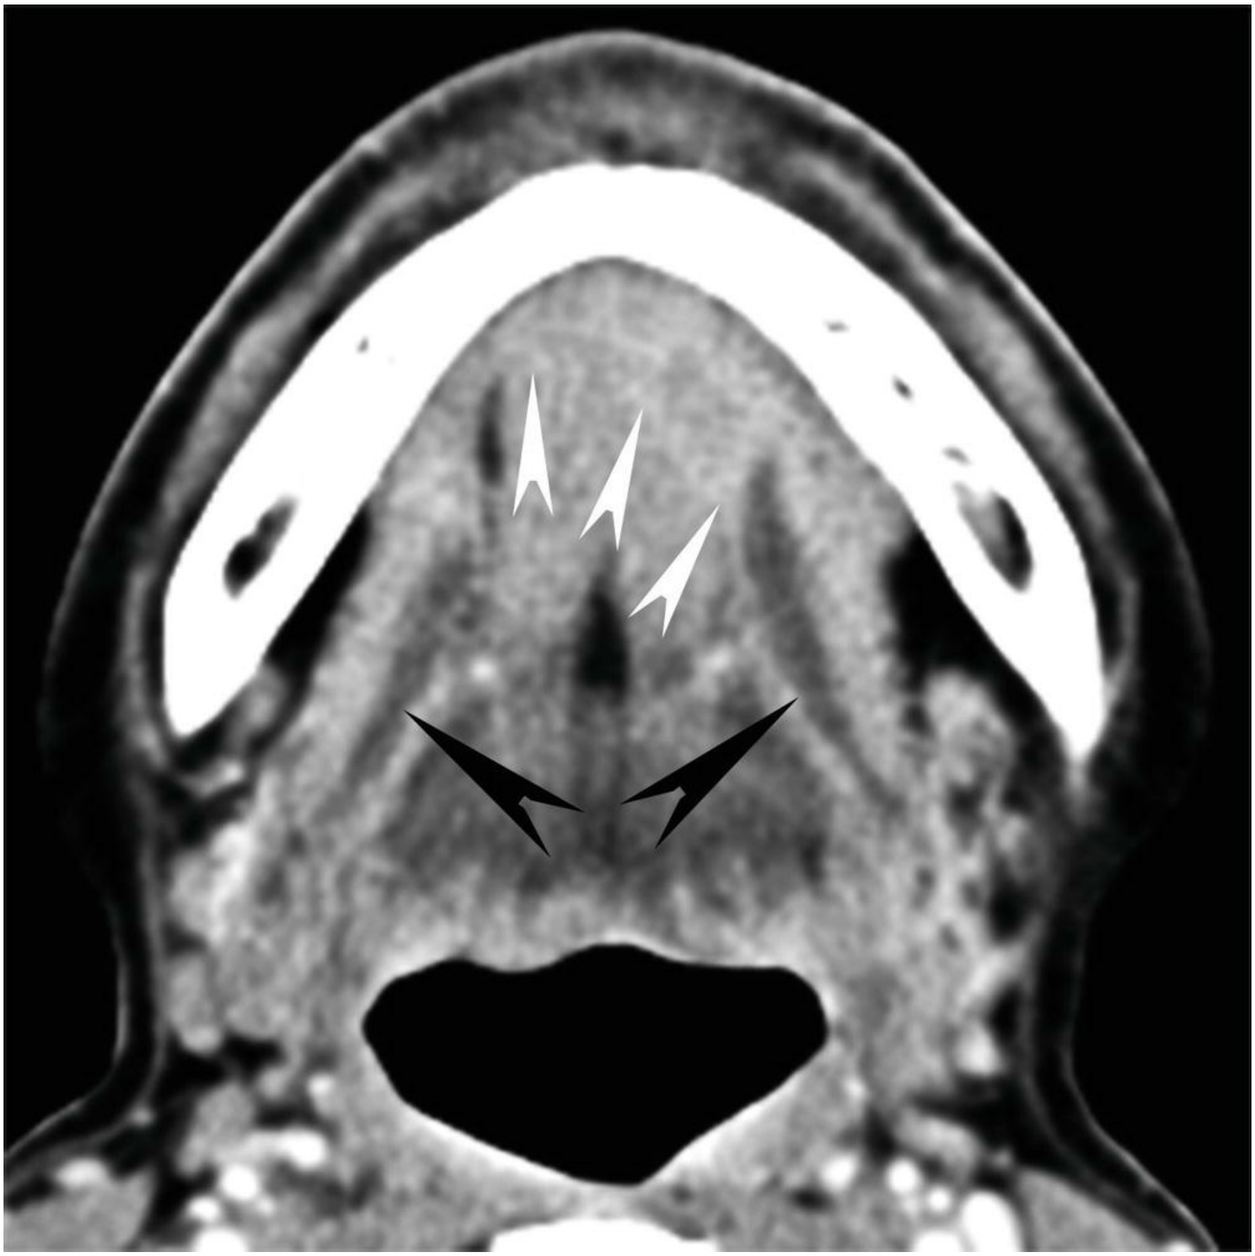

Figure 5.28. Floor of mouth (FOM) SCC. Axial contrast-enhanced CT demonstrates a very subtle lesion in the anterior left FOM (*small white arrowheads*), crossing to the contralateral sublingual space (SLS). The tumor

can barely be distinguished from adjacent normal soft tissues. One clue is the asymmetry in the left SLS. A more obvious clue is the presence of bilateral Wharton duct obstruction (*large black arrowheads*) by the tumor.

The CT and MRI appearance of oral cavity SCC is similar to other sites and was described earlier. MRI has been reported to have a slight advantage for evaluation of tumors, especially determination of T stage, tends to be less prone to dental artifact, and may improve visualization of the lesion at some subsites such as the hard palate (Fig. 5.5) and FOM.[37,71–74] Frequently, CT is still used as the first-line modality for evaluation of oral cavity cancer, and an MRI can be obtained to complement the evaluation for specific indications. These include evaluation of equivocal lesions or lesions obscured by dental artifact, hard palate lesions because these can be understaged on CT, complementary evaluation of bone to assess for marrow invasion, and for evaluation of PNS. As discussed earlier, the technologists should be trained to automatically perform a second acquisition covering the oral cavity and oropharynx at a different angle whenever they identify dental work on the scout view used for acquisition planning. This will increase the yield of the scan and can uncover pathology that would otherwise be obscured by dental artifact. For lesions affecting the oral tongue, obtaining an additional acquisition with the tongue out can also be helpful and may reveal an otherwise obscured lesion out of region of severe dental artifact.

Oral tongue SCC occurs on the lateral and ventral (undersurface) aspect of the tongue, in its middle and posterior thirds[70] (Fig. 5.6). These tumors may spread medially into the tongue musculature (Figs. 5.3 and 5.6) or spread along the extrinsic muscles toward their sites of attachment outside the tongue such as mandible, hyoid bone, or styloid process. Tumors may also spread to the FOM, and posteriorly located tumors may spread to the base of the tongue (BOT) (Fig. 5.3). When advanced, these tumors may invade the mandible and this will be discussed in greater detail later. Sometimes, tumors may also spread superficially along the palatoglossus arch/anterior tonsillar pillar to the palate superiorly and posteriorly to the peritonsillar tissues. In evaluating these tumors, it is important to identify any extension across the midline into the contralateral tongue because this can significantly impact prognosis and management.[70,75] Invasion of neurovascular bundle and depth of invasion of tumor are also important to assess. Tumor thickness is an

independent prognostic factor for oral tongue cancers and should be reported. It is noteworthy that the fat content of the normal tongue can vary among individuals, and this can affect visibility of the lesion (Fig. 5.6).

SCCs of the FOM frequently arise near the anterior midline of the FOM (Fig. 5.28). The muscles of the FOM form a relative barrier to tumor spread, and therefore, these tumors tend to spread either horizontally or superiorly. Because of the proximity to the mandible, these tumors can directly invade the mandible. FOM tumors can also invade the neurovascular bundle and intrinsic tongue muscles. Because the sublingual spaces communicate anteriorly, this provides a route for contralateral extension as well (Fig. 5.28). FOM lesions can be subtle on CT due to isodensity with adjacent uninvolved tissue. Careful attention should be paid to obliteration of fat planes and asymmetry of the sublingual spaces (Fig. 5.28). Indirect signs, such as Wharton duct dilation secondary to obstruction of their ostia, can be helpful and be the only clue to the presence of tumor (Fig. 5.28). Associated obstructive and inflammatory changes of the submandibular gland should not be confused with invasion by tumor; salivary obstruction may also be a source of false-positive palpation of submandibular adenopathy.

Although uncommon, SCC of the RMT is an important subgroup of oral cavity tumors.[70,76,77] The RMT is at the junction of the oral cavity, oropharynx, and nasopharynx. As a result, tumors arising in the RMT can have complex patterns of spread with invasion of adjacent spaces[70,78–80](Fig. 5.18). In addition, RMT tumors have a propensity for early bone invasion with reported mandibular invasion in 12% to 53% of cases.[78–81]

Other less common subsites for SCC of the oral cavity include the buccal mucosa (Figs. 5.2, 5.4, and 5.14), gingiva, and hard palate. On imaging, it may be difficult or impossible to distinguish buccal from gingival tumors or gingival tumors arising on the lingual side of the mandible from those originating in the FOM. When evaluating buccal lesions or gingival lesions extending into the vestibule, obtaining an additional acquisition with “puffed cheeks” can be helpful for tumor visualization (Fig. 5.4). Because many of these tumors are close to the bone, there is a propensity for early bone invasion. In addition, cancers arising in the mucosa of the posterior hard palate may spread along the palatine branches of the maxillary nerve, through the palatine foramina to the PPF, with the potential for further retrograde PNS through foramen rotundum.

Determination of mandibular invasion is essential for proper staging of oral cavity tumors. Involvement of the mandible must be carefully evaluated, because it upstages the staging to T4. Sites of abutment of tumor against bone represent the most likely sites of bone invasion. With regard to surgical management, both the presence and extent of bone invasion, that is, superficial cortical invasion versus marrow invasion, are important and both CT and MRI may be warranted for optimal assessment.[70]

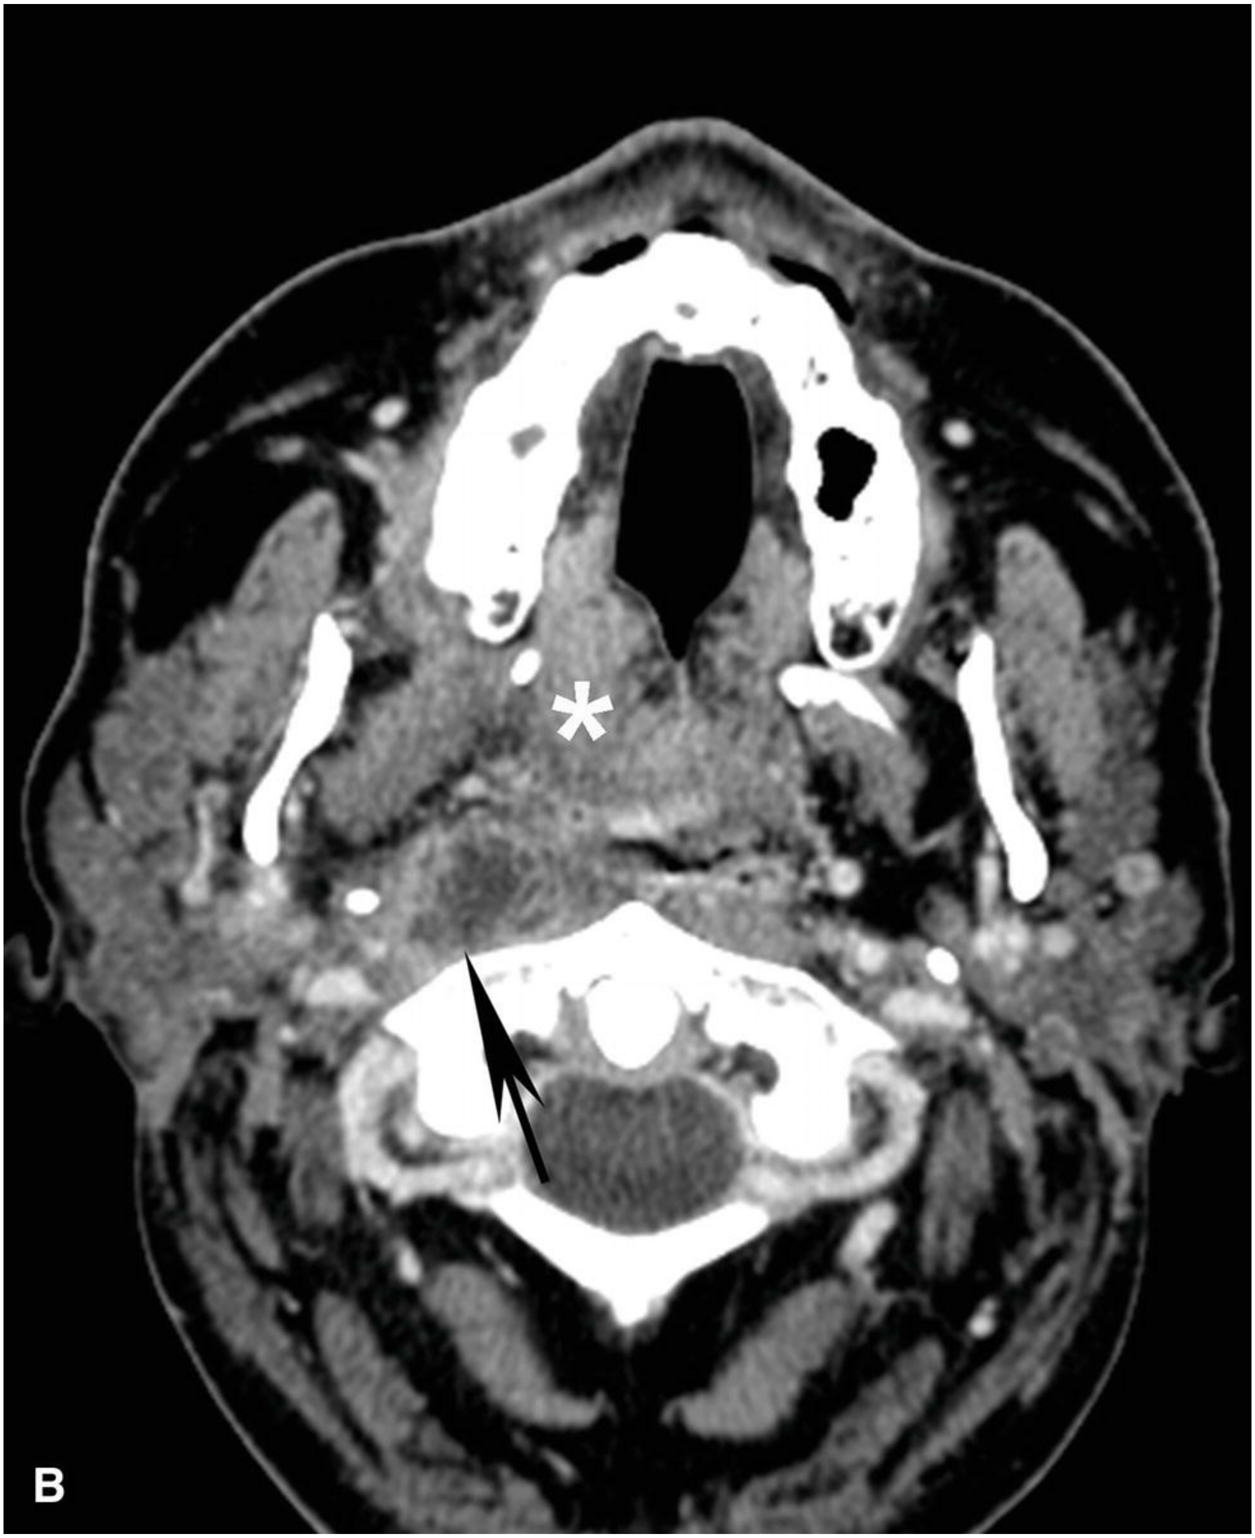
Oropharynx

The subsites in the oropharynx (OP) are the BOT, anterior and posterior tonsillar pillars and palatine tonsils, the soft palate, the glossotonsillar sulci, and the posterior and lateral oropharyngeal walls.[24,82] SCC accounts for 95% of neoplasms arising in the OP.[82]

SCC of the OP (SCCOP) has a dichotomous pathobiology that includes a classic subset that is associated with tobacco and alcohol use (Figs. 5.29 and 5.30) and a second subset that is associated with human papillomavirus (HPV) infection (Fig. 5.31). The HPV-positive SCCOP is responsible for the paradoxical increase in the age-adjusted incidence of OP carcinomas and represents a unique demographic, molecular, and clinical entity.[82–88] Typically, HPV-positive SCCOP patients present at a younger age, may lack or have limited exposure to classic environmental risk factors such as tobacco or alcohol use, and tend to have a more favorable prognosis.[88–93] Among HPV-positive SCCOPs, over 90% arise in the BOT or tonsils, or intervening glossopharyngeal sulcus (Fig. 5.31).

Figure 5.29. HPV-negative posterior oropharyngeal wall SCC. Axial contrast-enhanced CT from a 74-year-old male demonstrates an enhancing mass with submucosal extension to the lateral oropharyngeal wall on the right (*black arrowheads*). (V, Vallecula.)

PPS
T
A



B

C

Figure 5.30. Advanced HPV-negative oropharyngeal (OP) SCC. Axial contrast-enhanced CT images are shown from a 41-year-old man. **A:** There is very large OP mass (T) involving the tonsil but also the right soft palate (*large white arrowhead*). There is submucosal spread along the right

parapharyngeal space (PPS) with invasion of pterygoid muscles, indicating a T4 stage. The tumor abuts the right internal carotid (*small black arrow*) and invades the right parotid gland (*large white arrow*). More anteriorly, the lesion spreads to the base of the tongue (*double white arrowheads*). There is also extension into the region of right retromolar trigone (*small white single arrowhead*). **B:** At a level superior to **(A)**, there is asymmetric appearance of the right soft palate secondary to tumor spread (*white asterisk*). Note the irregular necrotic right retropharyngeal node (*black arrow*). **C:** Section obtained at a level below **(A)** demonstrates submucosal spread of tumor (*black asterisks*) with involvement of the base of tongue and glossotonsillar sulcus. There is a large necrotic right level II node abutting the tumor (*white arrowhead*). **D:** Axial section caudal to **(C)** demonstrates a component of the tumor invading the intrinsic and extrinsic muscles of the oral tongue (*white arrows*). There is also possible invasion of the right submandibular gland (SMG).

A

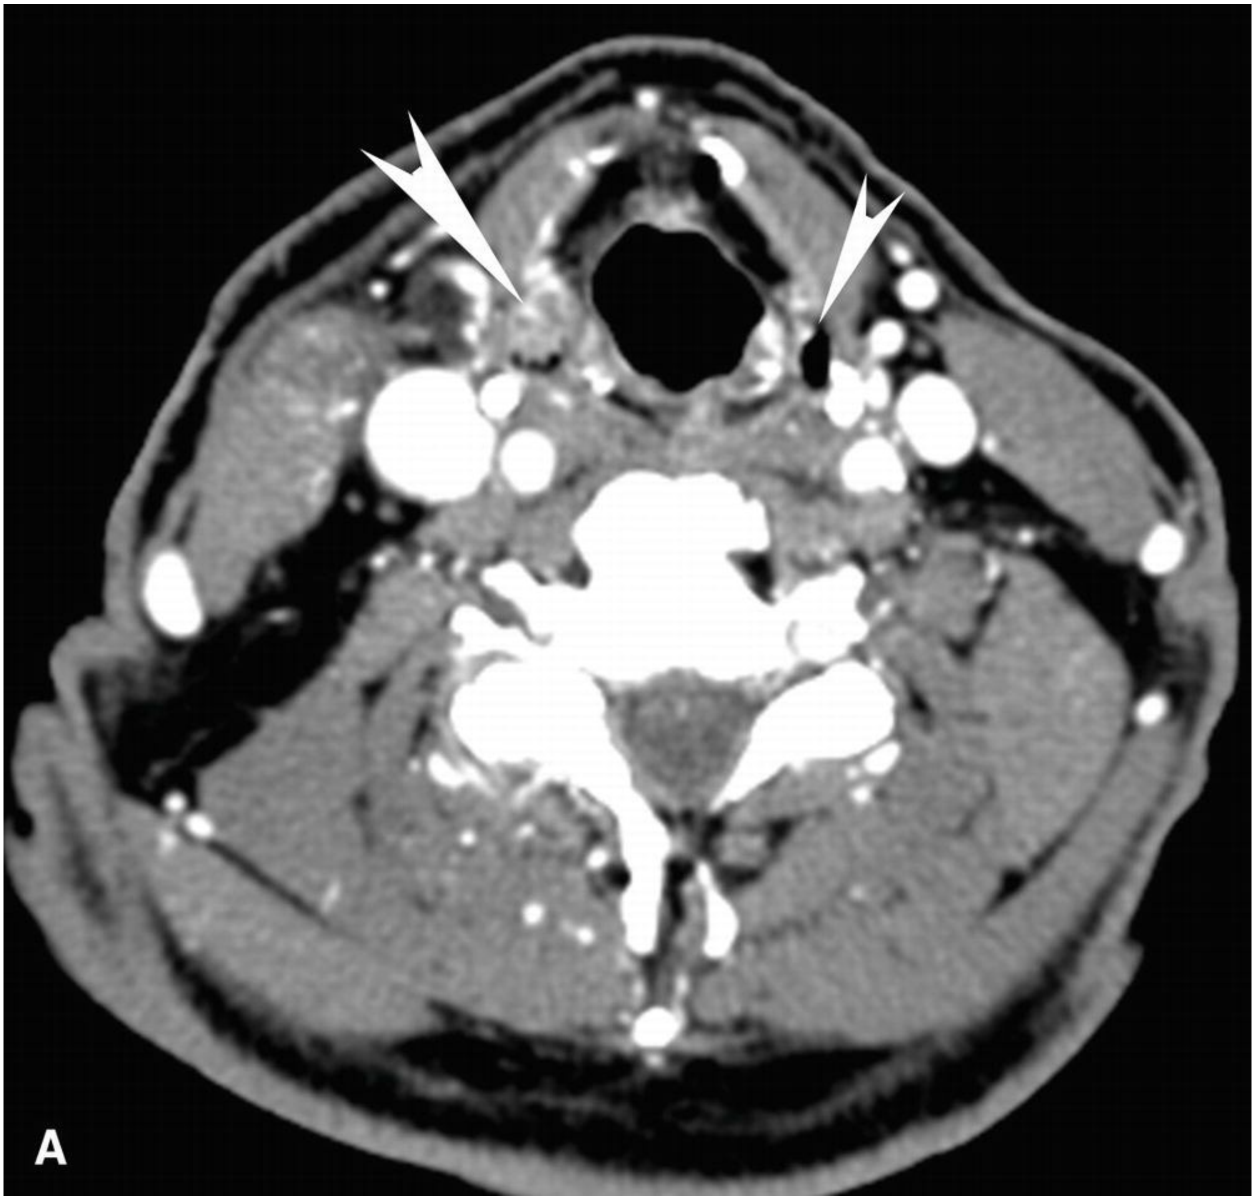
Figure 5.31. HPV-positive oropharyngeal (OP) SCC. Axial contrast-enhanced CT images are shown from a 59-year-old man. **A:** There is a mass in the right tonsil (*arrowheads*). The density of the mass is similar to the adjacent soft tissues, and it is difficult to appreciate its margins clearly, but the asymmetric enlargement is readily visible. **B:** Typical cystic level II node (*arrow*) associated with HPV-positive OP SCC.

Spread of tumor from the OP can occur to multiple adjacent spaces, either along adjacent mucosal surfaces or submucosally (Figs. 5.29 to 5.31). Tumors arising in the BOT may infiltrate the tongue musculature anteriorly (Fig. 5.30) or spread inferiorly into the epiglottis. Obliteration of the fat in the pre-epiglottis is a sensitive sign of tumor infiltration. Tonsillar region cancers can extend into the tongue anteriorly or superiorly into the nasopharynx (the latter upstages to T4). Because the size of the tonsils can vary, detection of tumor can sometimes be challenging. Any area of asymmetry needs to be carefully examined for changes in architecture or enhancement, and biopsy may be required in equivocal cases (Fig. 5.31). In general, tumor spread to the oral cavity, larynx (but not the lingual surface of the epiglottis), masticator space, nasopharynx, and skull base all upstage the disease and should be accurately determined. Encasement of the carotid artery is also important and must be carefully evaluated.

Consistent with their distinct pathobiology, HPV-positive and HPV-negative SCCOPs tend to have different imaging characteristics. There is a much higher incidence of cystic nodal metastases in HPV-positive compared to HPV-negative SCCOPs[88,94] (Fig. 5.31). HPV-positive SCCOPs are also less likely to invade adjacent muscle than HPV-negative tumors.[88] One study has also described a statistically insignificant trend for HPV-positive tumors having greater enhancement, appearing more exophytic, and having well-defined borders compared to HPV-negative tumors.[88]

Hypopharynx

The imaging approach to hypopharyngeal cancers is similar to the larynx, discussed in more detail in the next section. The first-line imaging modality for evaluation of hypopharyngeal cancers (Figs. 5.32 to 5.34) is CT in most centers.



A

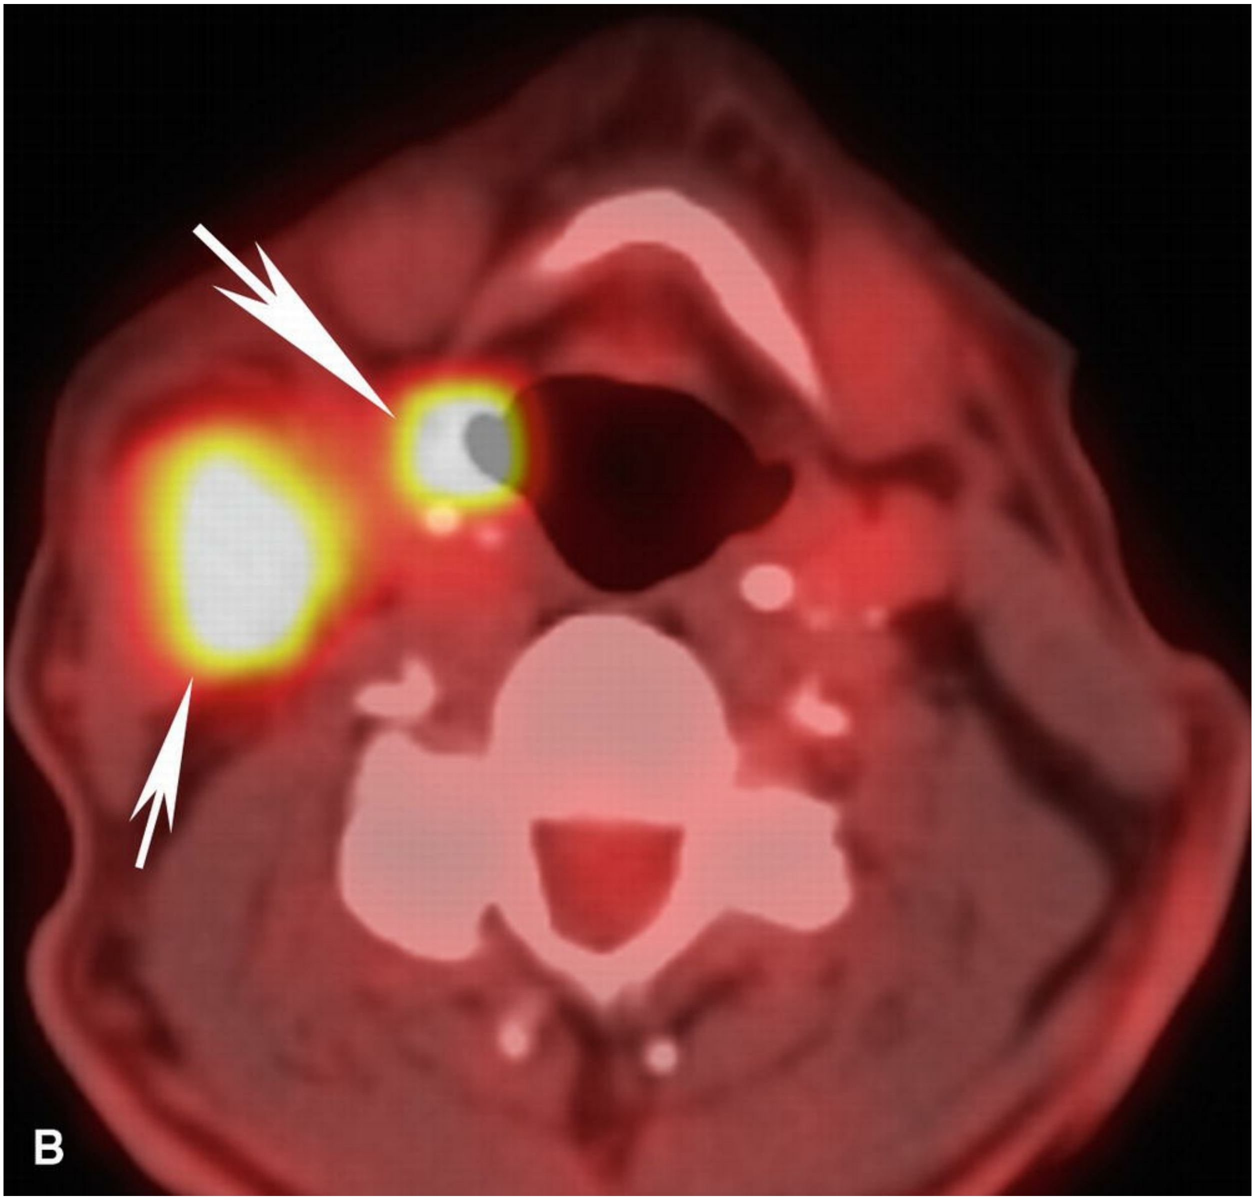


Figure 5.32. SCC of the hypopharynx. **A:** Axial contrast-enhanced CT from an 80-year-old man demonstrates a small right pyriform sinus SCC (*large arrowhead*). The lesion is subtle but visible on CT. Note the asymmetry when compared to the normal contralateral, aerated left pyriform sinus (*small arrowhead*). **B:** The lesion is well seen on PET (*large white arrow*). The PET scan (at slightly higher level) also demonstrates abnormal uptake within a large pathologic right level II to III nodal metastasis (*small arrow*).

Figure 5.33. SCC of the hypopharynx. Axial contrast-enhanced CT from a 77-year-old man demonstrates a heterogeneously enhancing hypopharyngeal mass (*black arrowheads*). The mass is centered in the hypopharynx, posterior to the arytenoid cartilages, distinguishing it from a primary arising in the larynx.

A

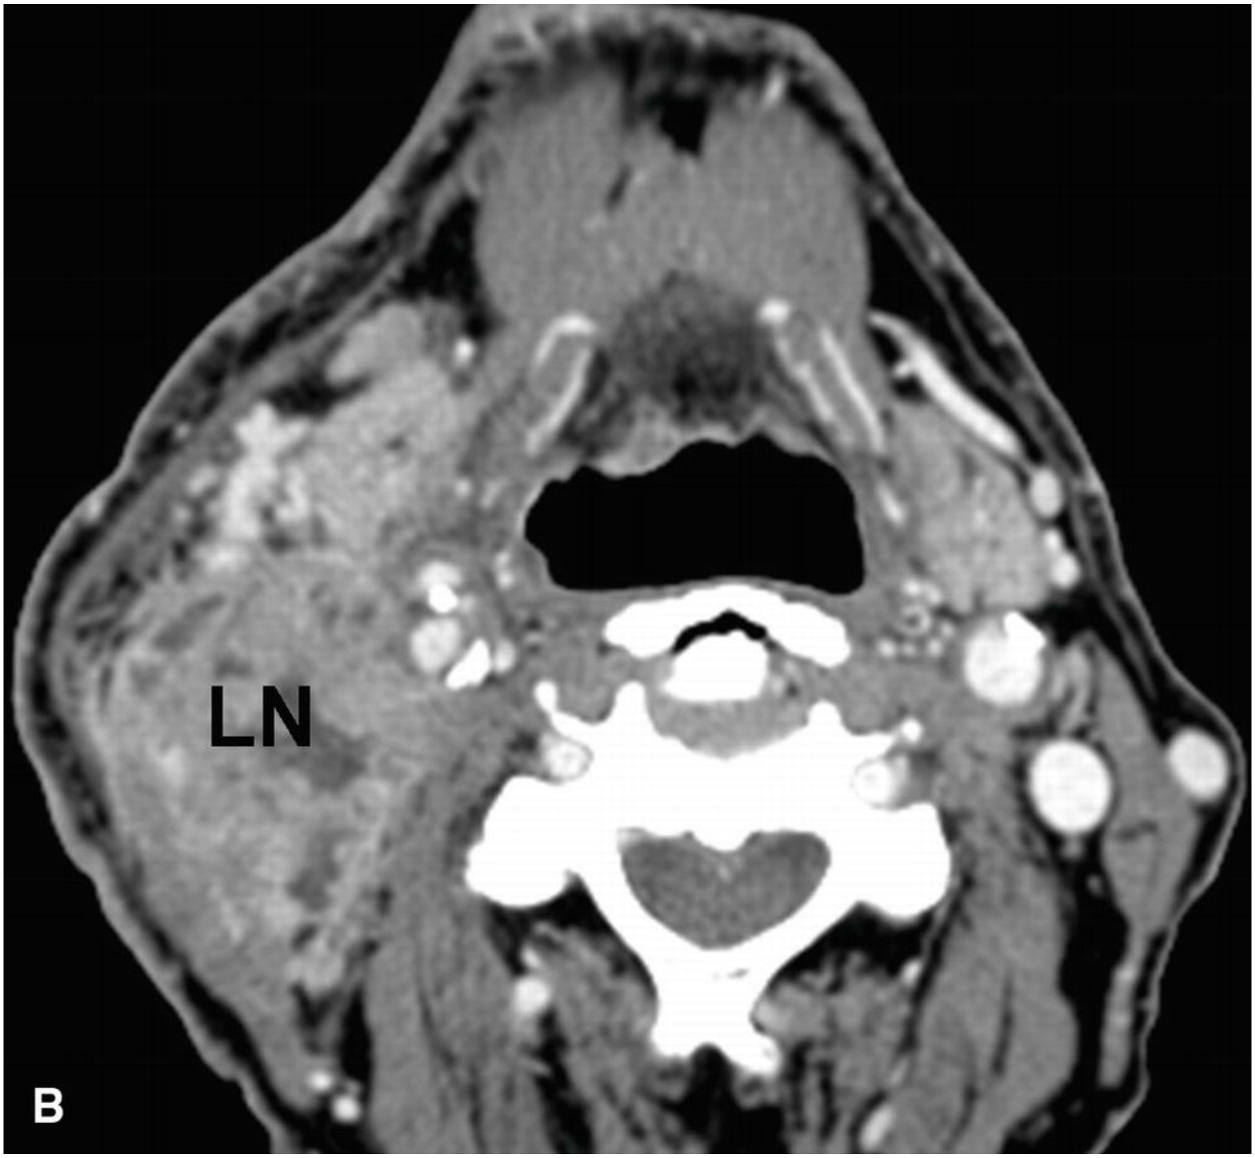

Figure 5.34. SCC of the hypopharynx. **A:** Axial contrast-enhanced CT image from an 88-year-old man demonstrates a lesion arising in the right pyriform sinus (*asterisk*), extending through the thyroarytenoid gap (*black arrowheads*), with invasion of the right paraglottic space (*arrow*) in the larynx. **B:** Image higher up in the neck demonstrates massive partly necrotic right level II lymphadenopathy (LN) with very irregular margins suggesting extracapsular spread of tumor.

Because of the intimate relation with the larynx, hypopharyngeal cancers can spread to the larynx (Fig. 5.34) and vice versa. Determination of their extent and involvement of specific laryngeal structures, including the thyroid cartilage, is essential for proper staging of these tumors. There are multiple

potential pathways of spread of hypopharyngeal carcinomas to adjacent structures. For tumors arising in the pyriform sinus, those arising on its medial wall may extend caudally to the arytenoid cartilage and cricoarytenoid joint.[95] Tumors arising on the lateral wall of the pyriform sinus may spread anteriorly to involve the laryngeal paraglottic fat and the posterior thyroid cartilage by spreading through the thyroarytenoid gap (Fig. 5.34). This is the area where the posterior paraglottic fat meets the pyriform sinus, extending between the two cartilages, and is readily seen on CT and MRI. This area should be carefully evaluated for spread of tumor and resultant obliteration of the normal fat in that area.

In addition to spread to the larynx, hypopharyngeal cancers can spread superiorly, inferiorly, or posteriorly, and this needs to be carefully evaluated and documented. Lateral extension of these tumors could result in the tumors coming in contact with the carotid artery. Invasion of cricoid or thyroid cartilage, even when focal or partial, upstages a tumor to a T4a stage.[95,96] Furthermore, because of the rich lymphatic drainage of the hypopharynx, tumors arising in this area commonly present with nodal metastases. For SCCs of the hypopharynx, the main node groups involved by nodal spread are level II, III, IV, and VB nodes.

Larynx

CT is the first-line modality for evaluation of laryngeal tumors. MRI can also be used to evaluate the larynx, but obtaining high-quality images may be challenging because of inability of patients to remain motionless for prolonged periods of time. Therefore, MRI is usually performed as a complementary exam to the CT scan, for example, for evaluation of cartilage invasion as discussed below. Ideally, this should be performed with a surface coil as a targeted high-resolution acquisition.

When evaluating the location of a laryngeal tumor on axial images, the supraglottic location of a tumor can be reliably determined by identification of fat in the paraglottic space (Fig. 5.35). This is the space between the laryngeal mucosa and the inner lamina of the thyroid cartilage, and in the supraglottic region, the paraglottic space is made up of fat at the level of the false cords (Fig. 5.35). On the other hand, at the level of the true vocal cords, the thyroarytenoid muscle occupies most of the paraglottic region, and there should not be paraglottic fat visible. This serves as a landmark for the level of

true vocal cords on axial images, as does the vocal process of the arytenoid cartilage (Fig. 5.36).

*
B

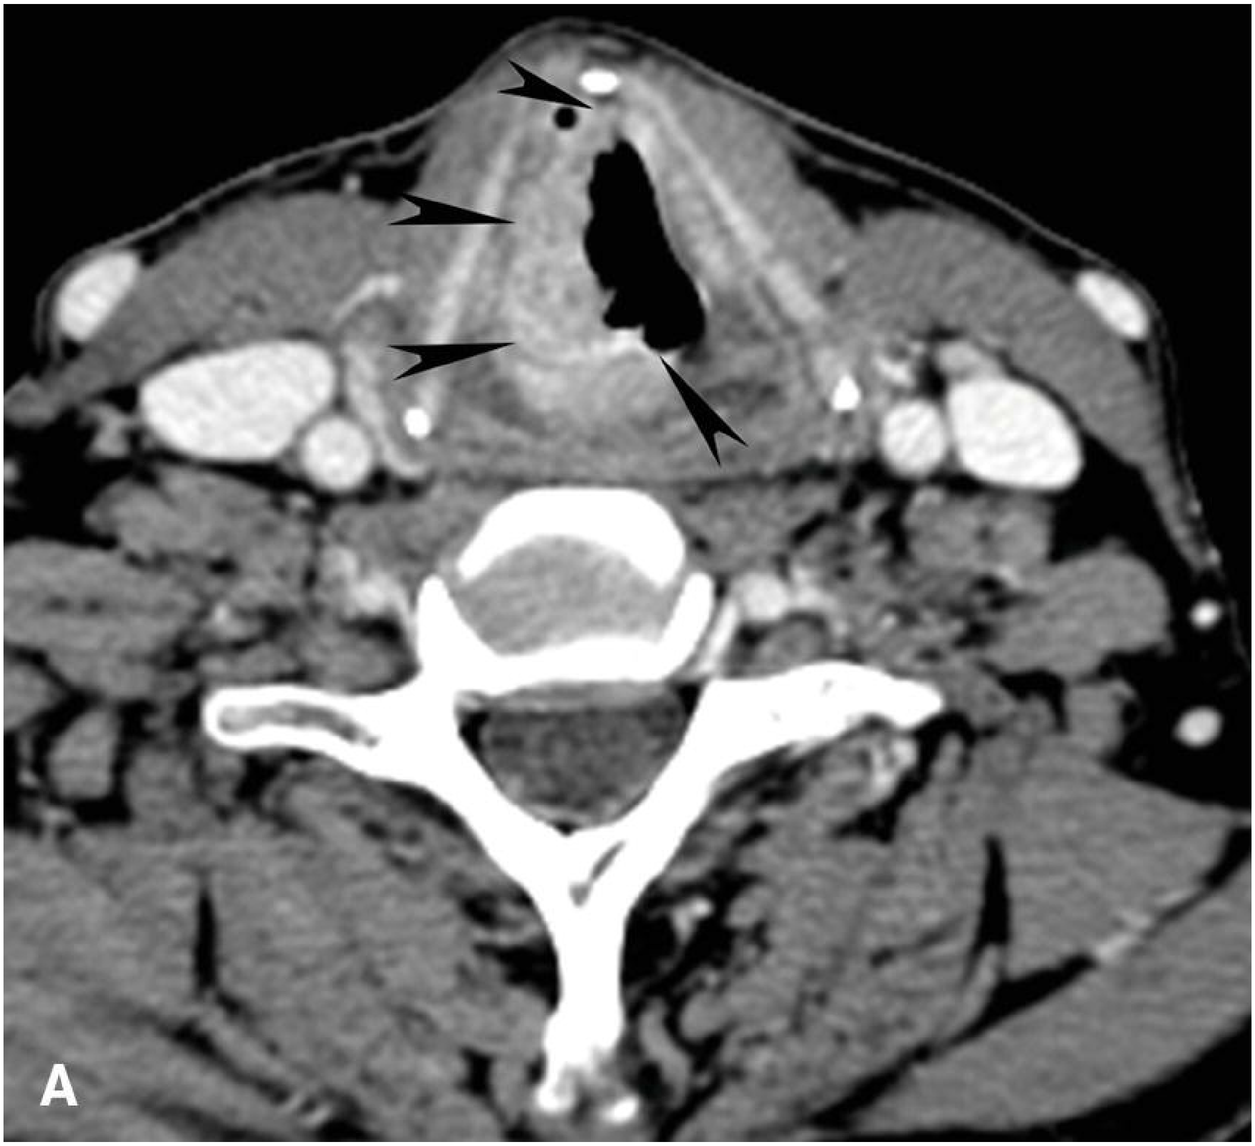
Figure 5.35. SCC of the larynx. Axial CT images are shown from an 81-year-old woman with a transglottic SCC at the anterior commissure. **A:** Image obtained at the level of the false cords demonstrates a small fluid-filled, obstructive internal laryngocele (*black arrowhead*). When encountered, this finding always mandates careful scrutiny in order to identify a potential obstructive cancer. Note the presence of paraglottic fat at this level (e.g., contralateral normal paraglottic fat marked by *white arrowhead*). This is a reliable indicator of supraglottic location on axial images. **B, C:** Images obtained more caudally demonstrate a tumor involving the midline anterior commissure and extending bilaterally (*asterisk*). Note

variable ossification of the thyroid cartilage with component of nonossified thyroid cartilage (*small black arrowheads*).

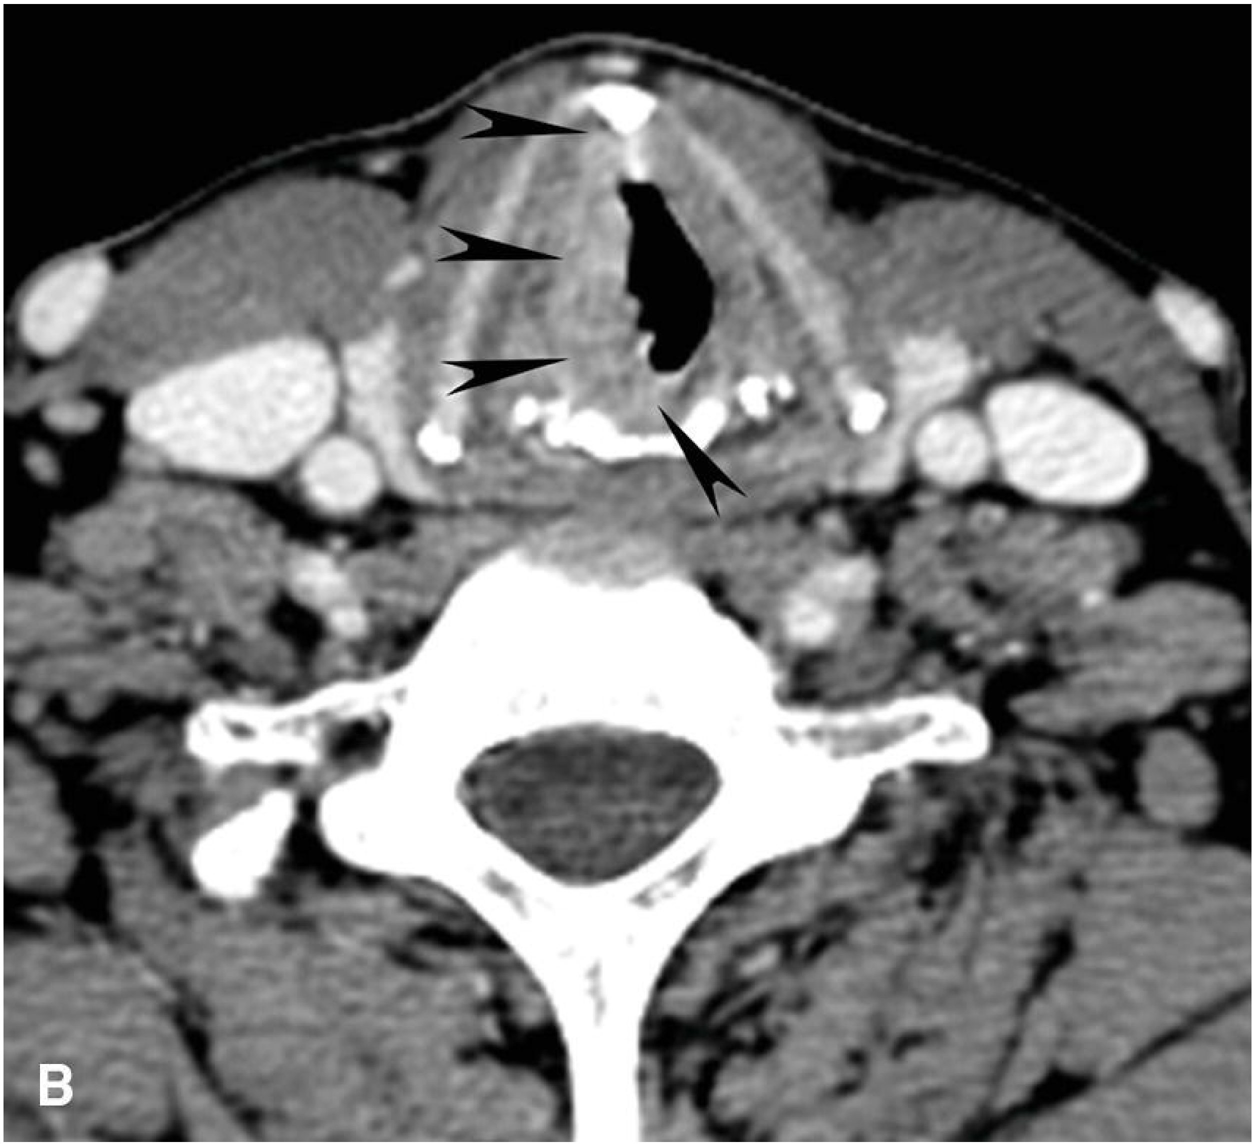
Figure 5.36. SCC of the larynx. Axial CT image from a 57-year-old woman

with a glottic and subglottic laryngeal cancer. There is tumor (*asterisk*) involving the left true cord with associated asymmetry of that cord. Note the absence of significant paraglottic fat on the normal contralateral side (*black arrow*), a landmark for the level of true cords on axial images.

As in other parts of head and neck, identification of asymmetry and infiltration of fat is important for determination of tumor invasion. In the supraglottic larynx, one should assess for obliteration of paraglottic fat. If a section can be found below the site of tumor invasion where the paraglottic fat is not obliterated, then the lesion can be confidently considered as a supraglottic tumor. However, if a tumor extends to the true cord, evaluation is more challenging. For these lesions, involvement is suggested by comparing the width of suspected cord to the contralateral side and evaluating for asymmetry (Figs. 5.36 and 5.37), although this evaluation is less reliable, particularly for small tumors. Evaluation of subglottic extension of tumor can also be challenging. In this area, the only sign of tumor may be subtle irregularity and enhancement of the mucosal surface of the lumen with mild associated luminal distortion (Figs. 5.37). Evaluation in other planes such as the coronal or sagittal plane can also be helpful for assessment of these lesions. Similar to other sites in the head and neck, superficial mucosal lesions are best assessed clinically.



A



B

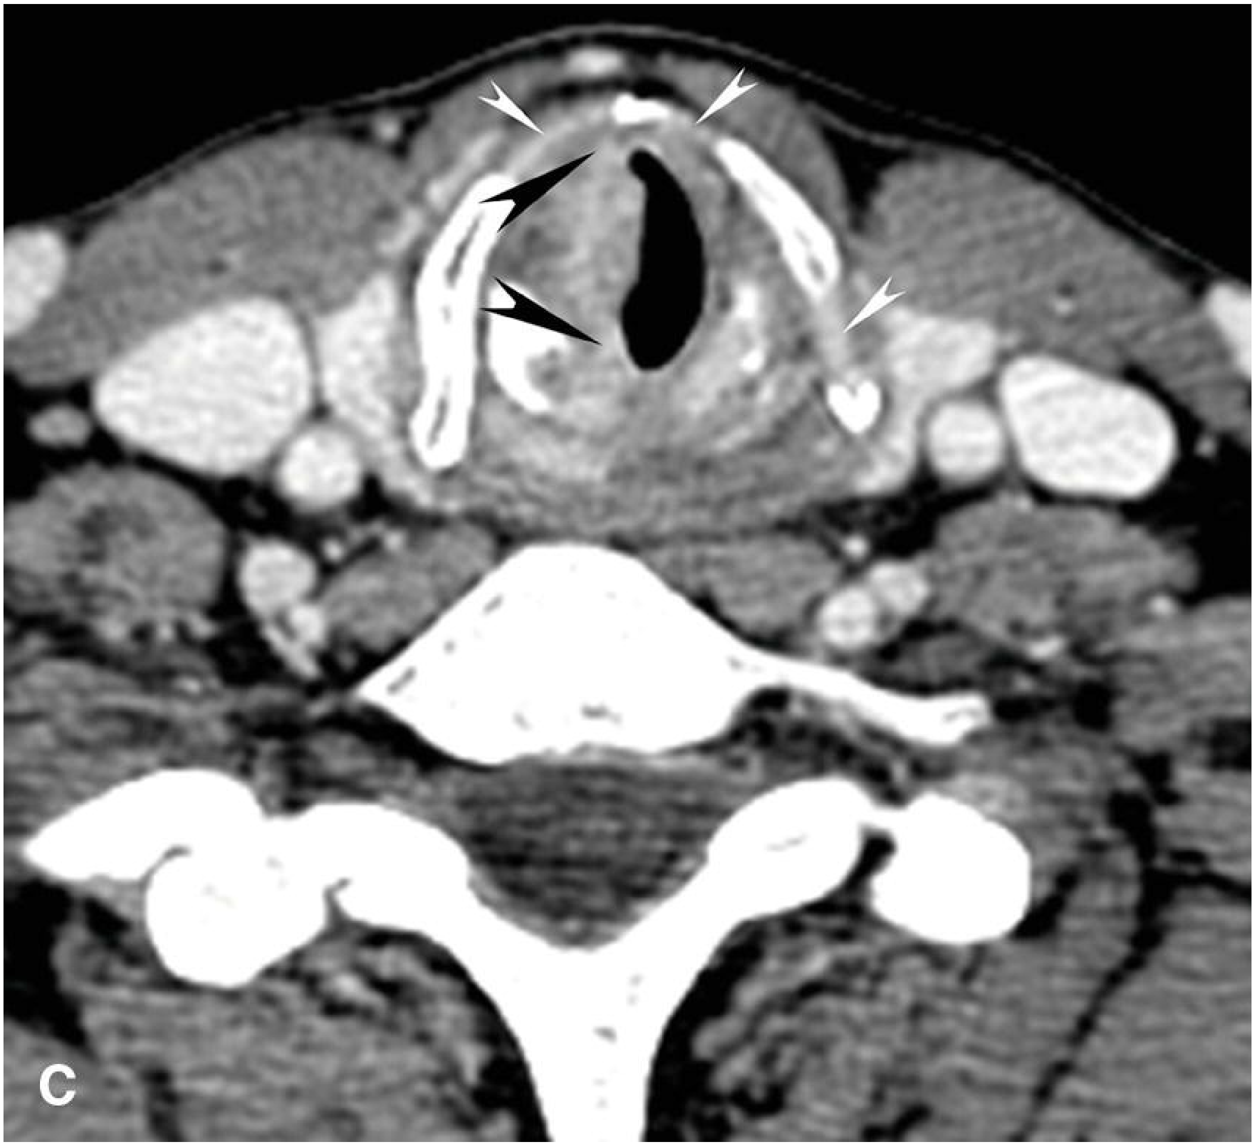


Figure 5.37. SCC of the larynx. Axial CT images (**A**, upper glottic level; **B**, lower glottic level; **C**, immediate subglottic level) from a 48-year-old male smoker demonstrate a right transglottic laryngeal cancer (*black arrowheads*). The lesion extends to the anterior commissure and also crosses the midline posteriorly. Note incomplete ossification of the thyroid cartilage with interspersed areas of ossification and nonossification, especially in **(C)** (*small white arrowheads*).

Determination of the presence or absence of laryngeal cartilage invasion is an important part of staging of laryngeal and hypopharyngeal tumors. For laryngeal cancer, tumors involving only the inner cortex of the thyroid cartilage are classified as T3 stage, but those with through and through

invasion, that is, involvement of both the inner and outer cortex, are staged as a T4 lesion.[96,97] This is unlike hypopharyngeal tumors, where even localized cartilage invasion leads to a T4a designation. It should be noted that extralaryngeal spread, with or without cartilage invasion, will also lead to a T4a designation.[96]

CT can generally identify gross cartilage invasion reliably, but determination of early and partial cartilage invasion can be challenging.[98,99] One of the challenges in evaluation of cartilage invasion is the variable appearance and ossification of thyroid cartilage.[96,100–102] The main criteria used for evaluation of thyroid cartilage invasion are sclerosis, erosion (minor areas of osteolysis), lysis (major areas of osteolysis), and extralaryngeal spread of tumor.[99] Sclerosis is a sensitive sign but is very nonspecific and unreliable because it can be seen in normal cartilage in older patients. Erosion, lysis, and extralaryngeal spread are less sensitive but much more specific and reliable signs of cartilage invasion. One must be cautious in stating that there is involvement of cartilage on the basis of a defect in the calcification of a cartilage alone because the variability in calcification makes this finding unreliable (Figs. 5.37). The most definite sign is demonstration of tumor beyond the external surface of the cartilage. MRI can also be used to evaluate cartilage invasion but with variable success and may overestimate cartilage invasion because of reactive changes and edema that may lead to a false-positive diagnosis of cartilage invasion.[96,101,103–105] Similar to evaluation of bone invasion, it is important to compare the signal changes in the cartilage to adjacent tumor. If similar, tumor invasion should be suspected.

POSTTREATMENT IMAGING IN HEAD AND NECK CANCER

Overview

The modern management of head and neck cancer involves multidisciplinary efforts, often including oncologic surgery, plastic and reconstructive surgery, radiation therapy, and chemotherapy. Complicated and variable approaches to surgical resection, local tissue reconstruction, neck dissection, radiation

therapy, and concurrent versus neoadjuvant chemotherapy regimens can complicate imaging findings during and after treatment.[106] The goal of imaging in the posttreatment stage is in large part to identify evidence of viable residual disease and/or recurrence. However, differentiating posttreatment changes from residual or recurrent tumor can be challenging due to altered anatomy, radiation changes, and postsurgical scarring. Furthermore, radiation therapy may induce tissue changes including edema, inflammation, and fibrosis that can make assessment challenging.

The main imaging modality used in the evaluation of the posttreatment neck is CT, with MRI, PET/CT, and US offering additional, complementary information. US and CT are readily available, enable rapid image acquisition, and are helpful in the acute setting for clinical diagnosis. MRI provides superior soft tissue contrast. Diffusion-weighted MR imaging can be a useful tool to differentiate tumor recurrence from normal posttreatment changes but can be technically challenging to optimize and can be limited in its spatial resolution. Combined imaging with PET and CT (PET/CT) offers a highly sensitive technique for detection recurrence of head and neck cancer in the posttreatment setting. PET/CT performed <10 to 12 weeks after completion of radiation therapy has a high false-positive rate because of the presence of postirradiation inflammation, edema, or distortion. However, PET/CT performed after 12 weeks has a very high negative predictive value.[107,108] In this section, we will review key posttreatment imaging appearances including tumor recurrence, postsurgical complications, mucosal necrosis, osseous complications, radiation-induced brain necrosis, and radiation-induced neoplasm.

Treatment Methods and Expected Posttreatment Imaging Findings

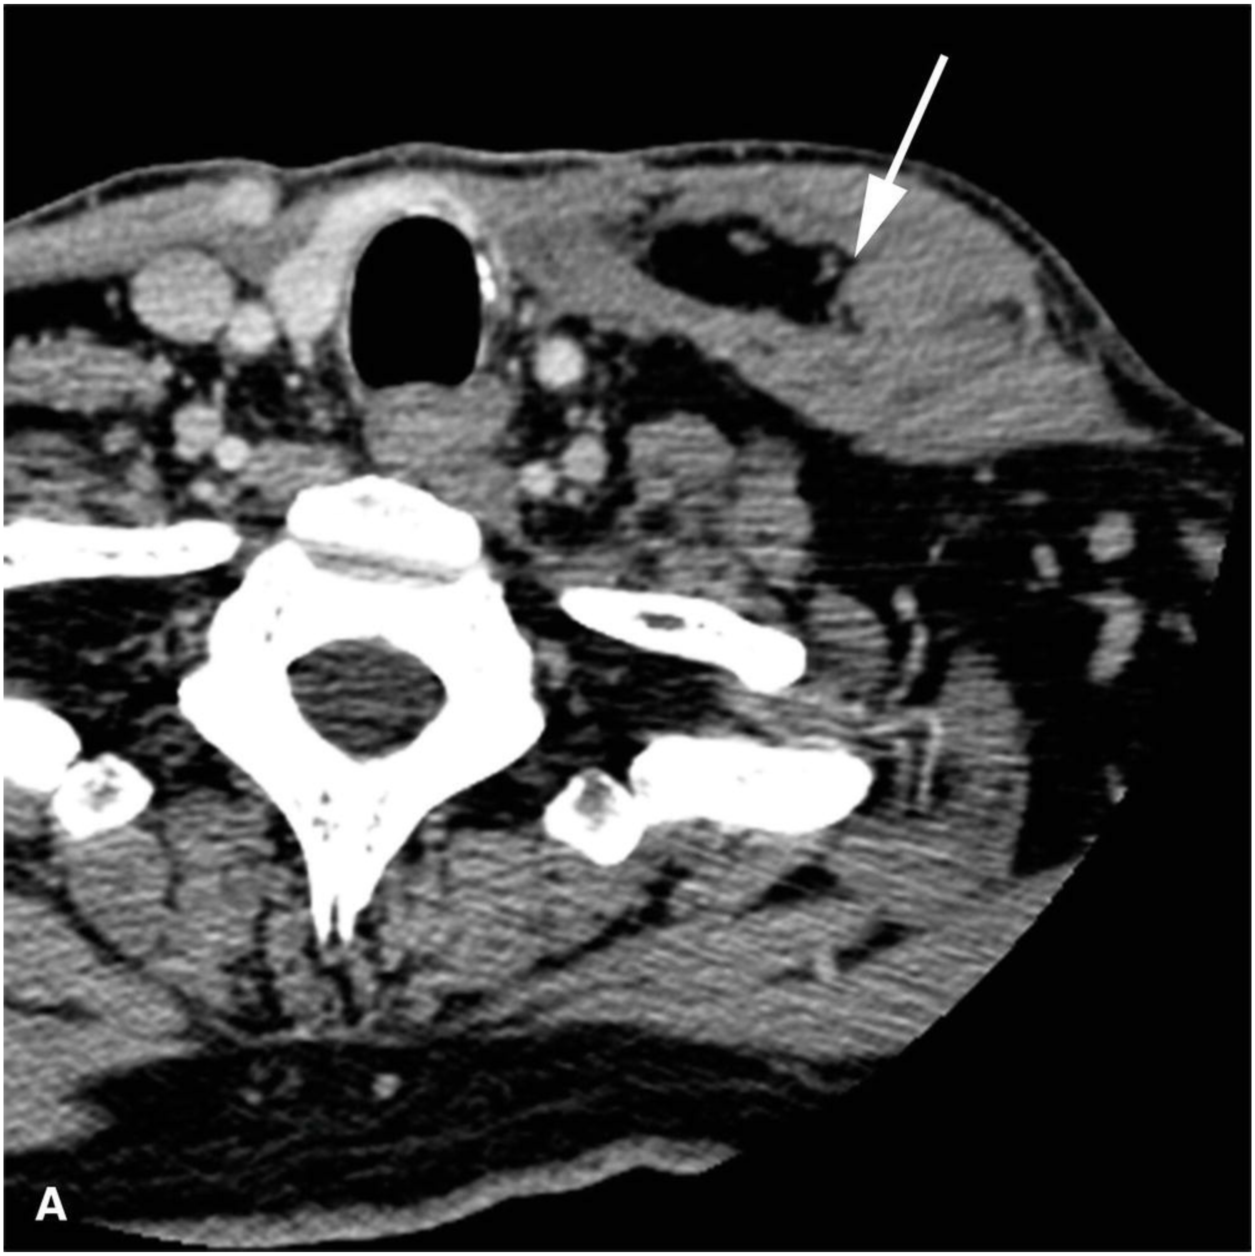
The management of early-stage head and neck cancer typically consists of single-modality treatment with either radiation therapy or surgery. Multimodality treatment consisting of a combination of curative surgery followed by adjuvant radiation therapy, with or without chemotherapy, is typically employed for locally advanced head and neck cancer (stage III or IV) without distant metastases. Oral cavity and sinonasal carcinomas are typically treated with surgery followed by adjuvant radiation therapy, with or without chemotherapy, depending on the histopathologic findings and nodal

stage. Primary treatment with chemoradiation is used for locally advanced head and neck cancer, particularly for nasopharyngeal, oropharyngeal, hypopharyngeal, and laryngeal carcinomas.

Surgery With or Without Reconstruction

Curative resection requires a wide local excision with negative margins. The physiologic and anatomic complexity of the neck requires complex reconstructive techniques to close the defect and maximize posttreatment function. With regard to imaging, it is critical to compare the postoperative study with a recent, same-modality preoperative scan. Depiction of the postoperative appearance of the countless possibilities of postresection head and neck surgery is beyond the scope of this chapter, but some examples are presented below.

There are two main types of flap reconstruction, free and pedicled, for repair of a surgical defect. Free flap reconstructive technique (free tissue transfer) involves the transfer of distant tissue that is vascularized by local vessels, with anastomosis to the tissue defect by using microvascular techniques (Fig. 5.38). Pedicled or rotational flap reconstruction involves elevation and rotation of nearby donor tissue, usually muscle or mucosa, to cover a defect, with preservation of the original arterial and venous structures.



A

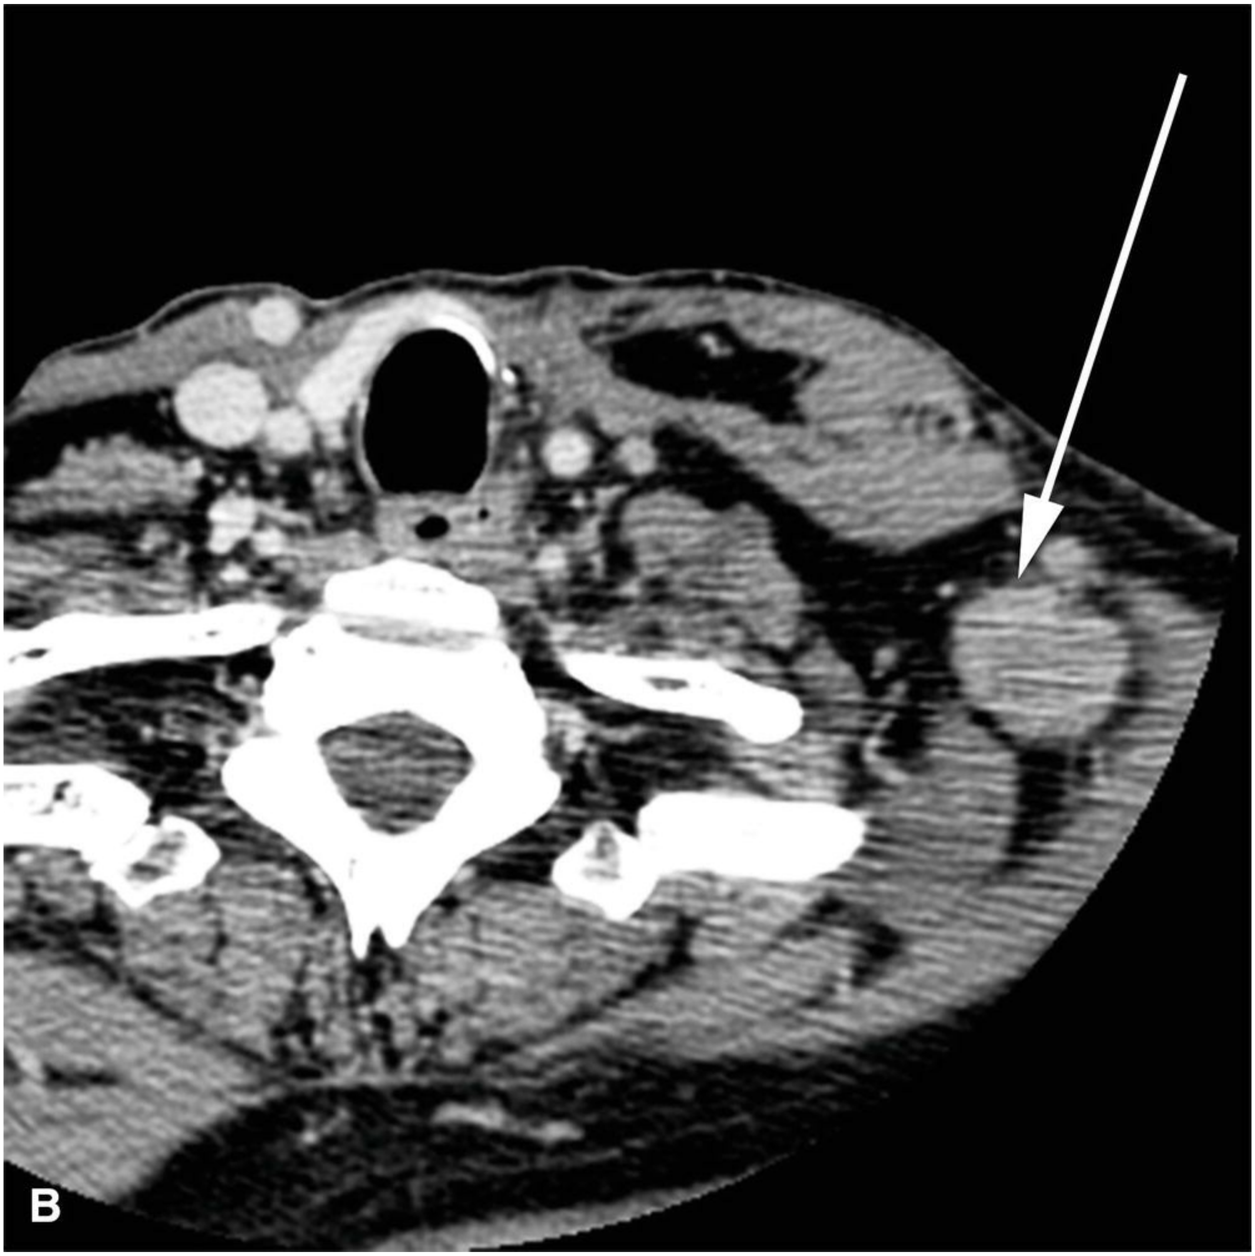


Figure 5.38. A 57-year-old man with recurrent squamous cell carcinoma to the left neck was treated with a left neck dissection, brachytherapy, and flap reconstruction. Five months after the surgery, a second recurrence was identified adjacent to the operative bed. **A:** Postoperative baseline CT of the neck with contrast shows expected findings of a pedicled flap (*arrow*). **B:** Subsequent, a CT of the neck with contrast reveals a recurrent mass is evident posterolateral to the flap (*arrow*).

Myocutaneous flaps are initially depicted as a mass with soft tissue attenuation and variably enhancing soft tissue intensity on MRI, representing

muscle. Fatty flap components suppress or become dark with fat suppression techniques and do not enhance. These flaps will gradually show denervation atrophy, which causes volume loss and fatty replacement of the muscle. Sharp boundaries exist between the flap and the adjacent normal structures, which is an important sign indicating benignity. It is therefore important to assess the superior and inferior margins of the flap, where local recurrence most commonly occurs. The muscular components of myocutaneous flaps show a wide spectrum of enhancement on MRI after contrast material administration, ranging from almost no contrast enhancement to diffuse intense enhancement. These enhancement characteristics do not predict failure of the flap and should not be misconstrued as tumor recurrence. The presence of striations in the muscular component of a graft is expected and generally indicates a healthy flap, helping to avoid misdiagnosis if the muscle enhances.[109] Normal flaps do not enhance on CT.

Neck Dissection

Radical neck dissection, modified radical neck dissection, and selective neck dissection are the three major types of neck dissection. Radical neck dissection involves the removal en bloc of all of the ipsilateral lymph nodes (levels I to V), the sternocleidomastoid muscle, internal jugular vein, submandibular gland, and spinal accessory nerve. Extended radical neck dissection is the same as radical neck dissection but includes the removal of additional nodes (levels VI and VII) and/or nonlymphatic structures such as the internal carotid artery, hypoglossal nerve, and vagus nerve. Indications for radical neck dissection are extensive cervical involvement or lymph nodes with gross extracapsular spread and invasion into the adjacent tissues.

Modified radical neck dissection is the same as radical neck dissection but preserves the sternocleidomastoid muscle, internal jugular vein, submandibular gland, and/or spinal accessory nerve. Modified radical neck dissection is indicated in patients with less spread and invasion. Modified radical neck dissection has some advantages; for example, preservation of the spinal accessory nerve prevents the development of adhesive capsulitis (frozen shoulder) and modified radical neck dissection causes less cosmetic deformity than radical neck dissection.

There are four subtypes of selective neck dissection. These are the supraomohyoid type (levels I to III), the lateral type (levels II to IV), the

posterolateral type (levels II to V), and the anterior compartment type (levels VI and VII). Selective neck dissection preserves the functional and cosmetically relevant structures (see Fig. 5.38 for depiction of a posterolateral type; other types are shown in figures below).

Radical and modified radical neck dissections typically have obvious and expected imaging findings of absence of the resected tissue and lymph nodes. Selective neck dissections may have more subtle findings, especially when limited to one or two stations. There is typically formation of fibrosis or scar surrounding the carotid sheath, which is evident as increased density on CT and low to intermediate signal intensity on T1- and T2-weighted MR images. Neck dissection obliterates normal fat planes, which makes identifying nodal recurrence more challenging.

Radiation Therapy

External beam radiation therapy (EBRT) is the main type of radiation therapy used for the treatment of cancer of the head and neck. EBRT includes three-dimensional conformal radiation therapy, intensity-modulated radiation therapy, and stereotactic radiosurgery. EBRT uses photon, electron beam, or proton beam radiation delivered from a source external to the patient. Definitive doses of radiation with EBRT for head and neck cancer consist of 66 to 70 Gy delivered daily during a period of ~7 weeks. Intensity-modulated radiation therapy has become the preferred technique for administering photon external beam radiation as it allows sparing of at-risk organs, including the parotid glands, pharyngeal constrictor muscles, and orbits.

Radiation therapy reactions are divided into early and late changes based on 90 days from treatment. Early reactions are reversible in most cases. Late complications may take months to years to emerge and are often irreversible. The early complications of radiation therapy are seen frequently, particularly oral mucositis and skin desquamation, and completely resolve within a few weeks after completion of radiation therapy. Late complications include xerostomia, dysphagia, accelerated dental caries, soft tissue necrosis, osteoradionecrosis, radiation-induced vascular complications, and radiation-induced neoplasms. The severity and duration of radiation reactions may be exacerbated by multiple factors including the smoking and alcohol consumption habits.

Imaging findings of early radiation reactions are thickening of the skin and platysma, stranding of the subcutaneous fat, edema and fluid in the retropharyngeal space, increased enhancement of the major salivary glands, thickening and increased enhancement of the pharyngeal walls, and thickening of the laryngeal structures (Fig. 5.39). Late reactions to radiation therapy include atrophy of the salivary glands and thickening of the pharyngeal constrictor muscle, platysma, and skin.

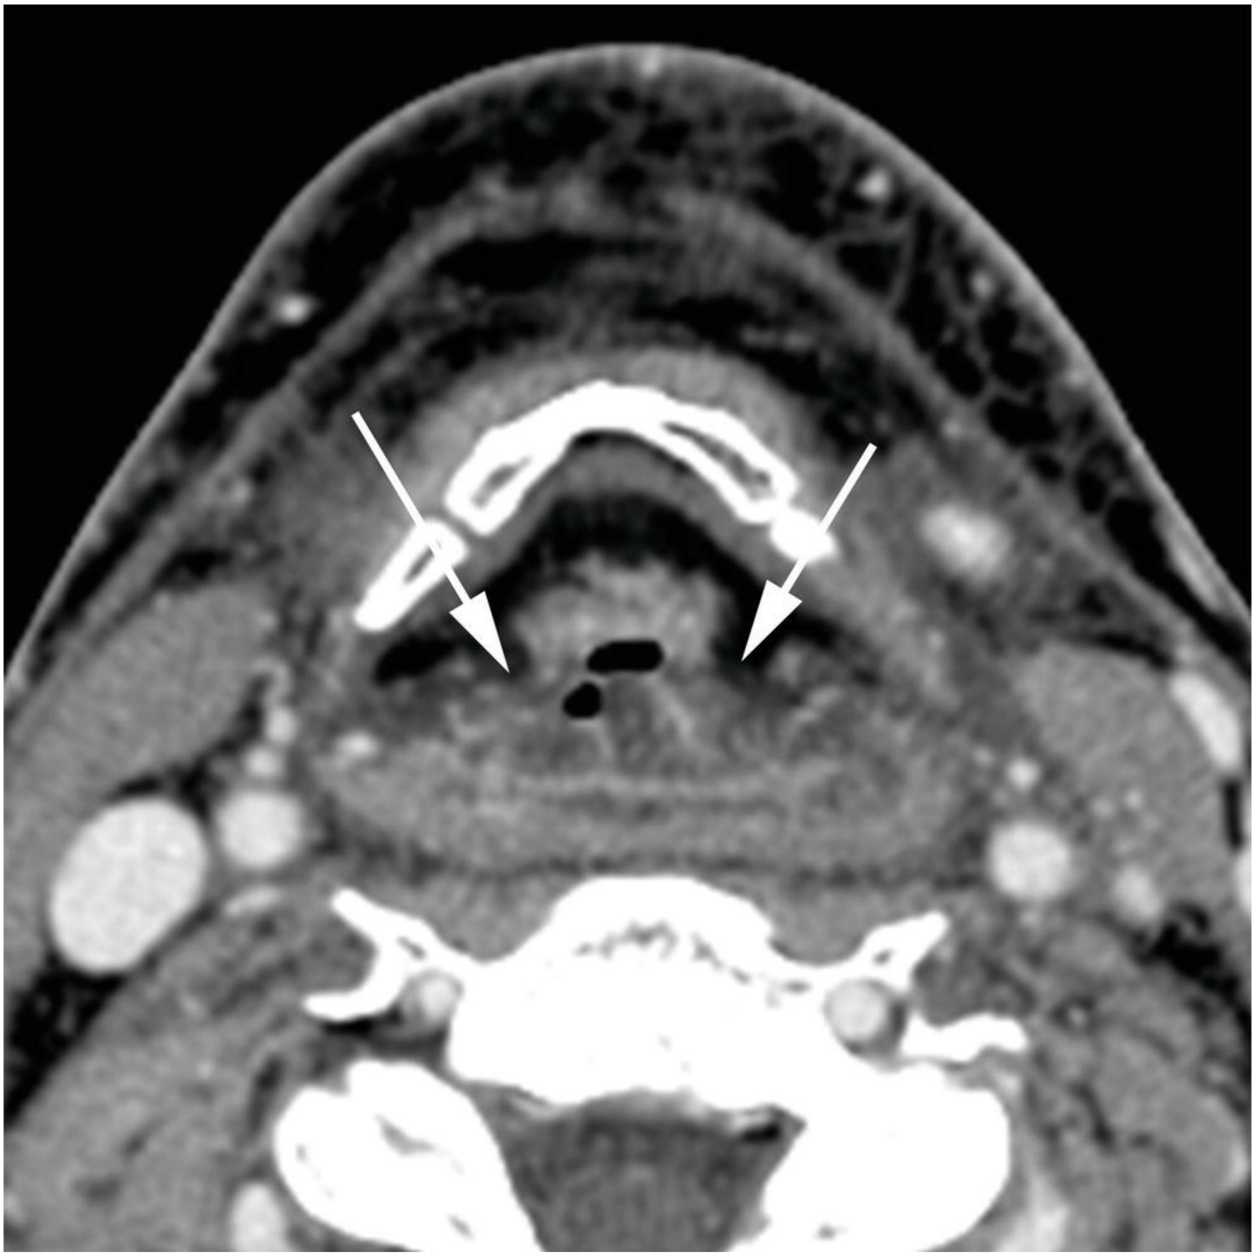

Figure 5.39. A 60-year-old male with T2 N2C squamous cell carcinoma of the left base of the tongue who was treated with chemoradiation including a

radiation boost. CT of the neck with contrast reveals significant supraglottic edema (*arrows*) and near complete airway obliteration.

Posttreatment Imaging Appearance of Tumor Recurrence and Various Complications

Tumor Recurrence

Tumor recurrence deep to flap reconstructions is often not evident visually or palpable. The most common locations for tumor recurrence are in the operative bed and at the margins of the surgical site (Fig. 5.40). Tumors are most likely to recur within the first 2 years after treatment and may recur within weeks after surgery. On imaging, tumor recurrence can manifest as a slightly expansile lesion in the operative bed or as progressive thickening of soft tissues deep to the flap (Fig. 5.38). CT typically demonstrates recurrence as an infiltrating slightly hyperattenuating mass with enhancement, with or without bone destruction. Tumor recurrence typically enhances greater than skeletal muscle (Fig. 5.41). Therefore, if a suspected mass has lower attenuation than that of muscle on CT, it is unlikely to be a malignancy and often is related to edema. MR imaging demonstrates tumor recurrence as an infiltrative mass with intermediate T1-weighted signal intensity, intermediate to high T2-weighted signal intensity, and enhancement.

A

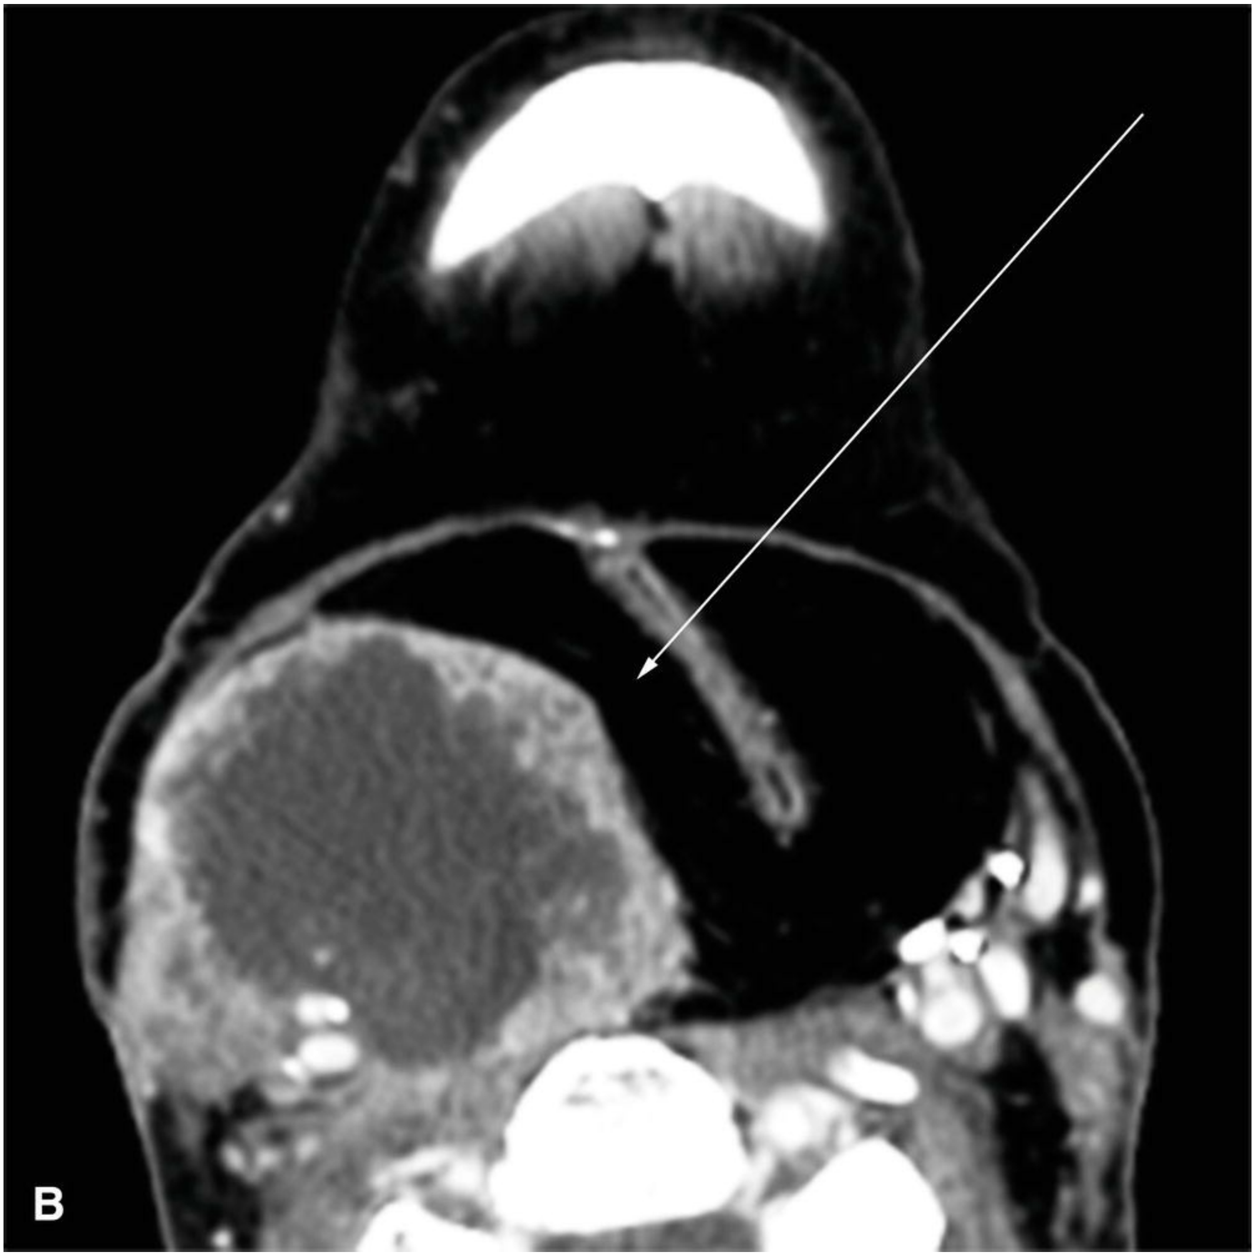

Figure 5.40. A 56-year-old woman who required total laryngopharyngectomy and free flap reconstruction for recurrent laryngeal carcinoma. This sequence demonstrates evolution of massive recurrence. **A:** CT of the neck with contrast displayed a small enhancing nodule that developed along the right carotid artery (*arrow*). **B:** A subsequent CT of the neck with contrast clearly revealed to be a site of dramatic recurrent cancer (*arrow*).

A

Figure 5.41. A 50-year-old man with T1 N2B squamous cell carcinoma of the right tonsil treated with induction chemotherapy and concurrent chemoradiation. Axial postcontrast CT imaging obtained 2 **(A)** and 12 **(B)** months following completion of therapy reveals the development of an area of mucosal ulceration (*short arr*ow in **B**), which had previously been normal (*arrow* in **A**). Thick marginal enhancement surrounding the mucosal defect (*long arrow* in **B**) was regarded as concerning and proved to be tumor recurrence.

Cervical lymph node metastases occur in well-defined patterns, and an

understanding and familiarity with these patterns is helpful for making an early diagnosis. Oral cavity carcinomas frequently metastasize to level I, II, and III nodes. Oropharynx and supraglottic laryngeal cancers metastasize to level II, III, and IV nodes. Nasopharynx, hypopharynx, and BOT carcinomas frequently metastasize to level II, III, IV, and V nodes. Thyroid cancer typically spreads to level III, IV, and VI nodes. Bilateral lymph node metastases are more frequently seen with nasopharyngeal, oropharyngeal, BOT, and supraglottic laryngeal carcinomas.

The detection of lymph node recurrence and metastases is more difficult following neck dissection and radiation therapy because of the obliteration of fat planes. Lymph node recurrence and metastases can be identified based on relative hyperenhancement and expansive features (Fig. 5.42). Similar to its use for the primary tumor site, diffusion-weighted MR imaging can be useful in the characterization of enlarged posttreatment lymph nodes that manifest as low signal intensity on apparent diffusion coefficient (ADC) maps.[110]

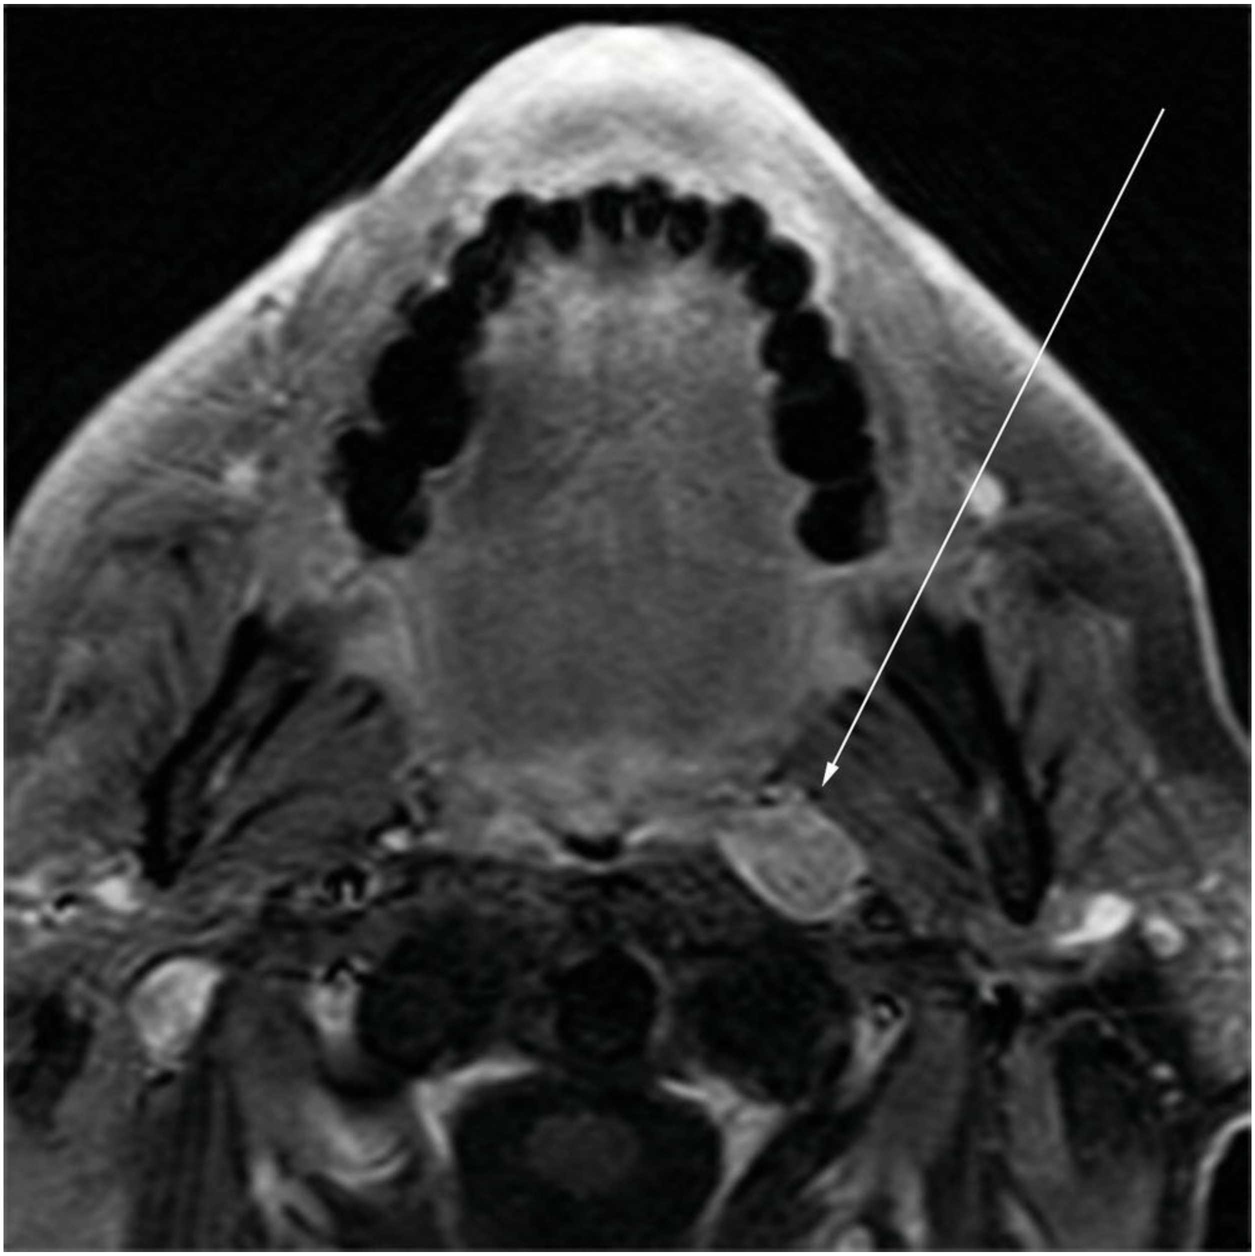

Figure 5.42. A 55-year-old man status postsurgery and radiation for olfactory neuroblastoma. Axial T1-weighted postcontrast image reveals an enhancing retropharyngeal nodal metastasis (*arrow*) 3 years after therapy.

Perineural tumor spread is a unique form of tumor recurrence, and has the same appearance as when it occurs prior to therapy. Perineural tumor spread in the head and neck is most commonly seen with cutaneous and mucosal SCC, followed by adenoid cystic carcinoma and other less common malignancies. The imaging findings of perineural tumor spread are nerve enlargement with enhancement, foraminal enlargement, obliteration of fat

planes, and replacement of the skull base foramina with soft tissue (Fig. 5.43). Perineural tumor spread is more readily identifiable at MR imaging, given the greater soft tissue contrast, but can be seen at CT. Close correlation with prior images and clinical symptoms can help distinguish perineural tumor spread from treatment-related changes. Follow-up imaging may be required in equivocal cases.[26,111]

B

C

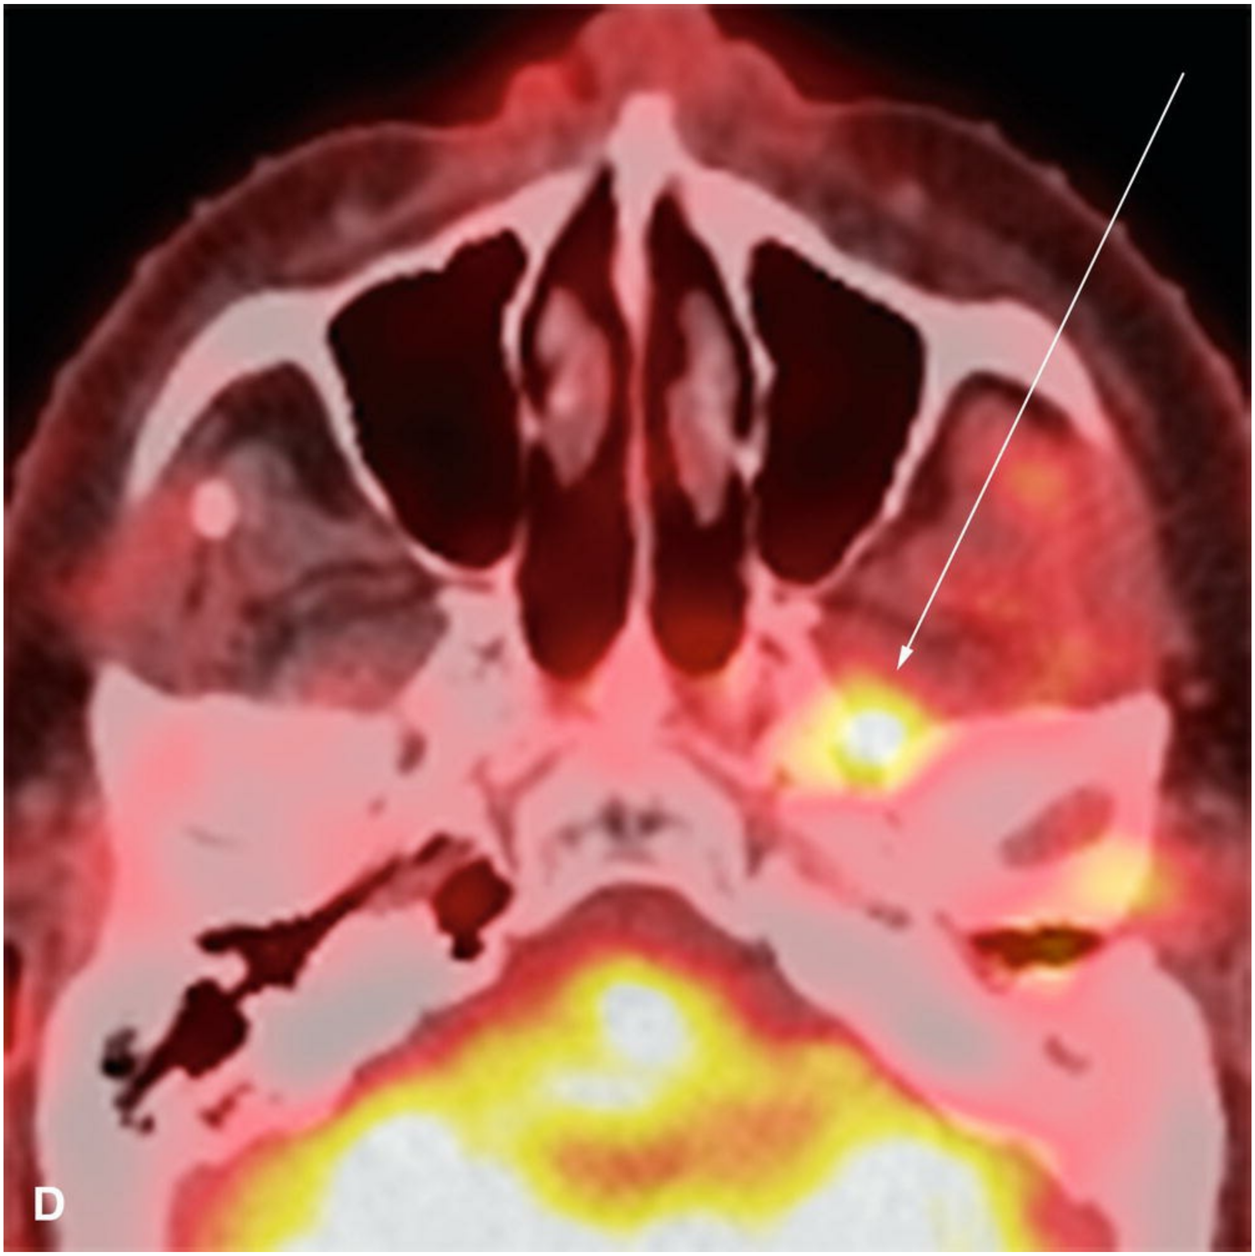

Figure 5.43. A 58-year-old man with previously treated left preauricular squamous cell carcinoma recurrent along the auriculotemporal branch of the mandibular nerve. Contrast-enhanced axial CT images, soft tissue windows **(A, B)**, bone algorithm **(C)**, reveal abnormal enhancement (*arrows*) within **(B)** and most notably beneath **(A)** the left foramen ovale and subtle foraminal enlargement (*arrow* in **C**) indicating perineural tumor spread. FDG-PET/CT **(D)** shows hypermetabolism associated with these changes of perineural disease recurrence (*arrow*).

Complications after Surgery

Surgical complications tend to occur early and include wound infection, abscess, fistula, flap necrosis, hematoma, chylous fistula, and serous retention (Fig. 5.44). Multiple risk factors have been reported, including preoperative radiation therapy, preoperative chemoradiation therapy, prior tracheotomy, long duration of surgery, type of flap, age, primary tumor stage, medical complications, malnutrition, anemia, tobacco use, and a history of habitual alcohol consumption.

B
*

C

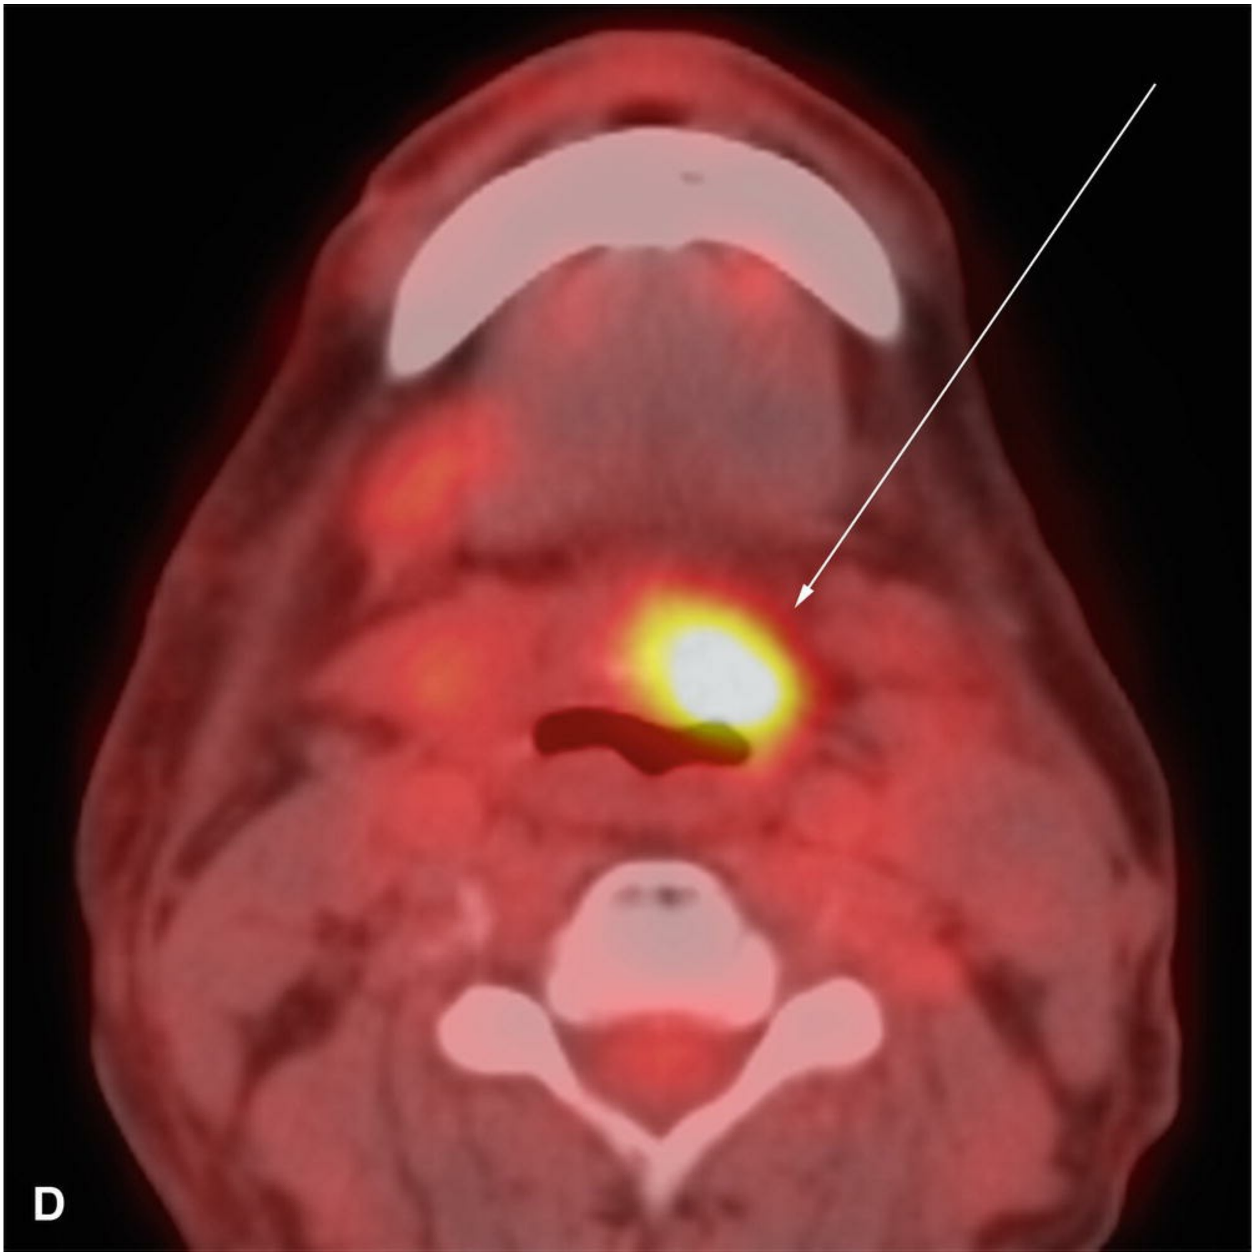

Figure 5.44. A 58-year-old man treated with induction chemotherapy, total laryngectomy, bilateral neck dissection, and postoperative radiation therapy for a T4a N2C M0 squamous cell carcinoma of the larynx. A posttreatment CT of the neck with contrast in axial **(A)** and sagittal **(B)** reveals a mucosal dehiscence (*asterisk*) along the neopharynx. There was also abnormal enhancement **(C)** and hypermetabolism on FDG-PET/CT **(D)** along the base of the tongue (*arrow*). Biopsy of this site confirmed recurrent squamous cell carcinoma.

After surgery, a fluid collection is sometimes seen, and serous retention

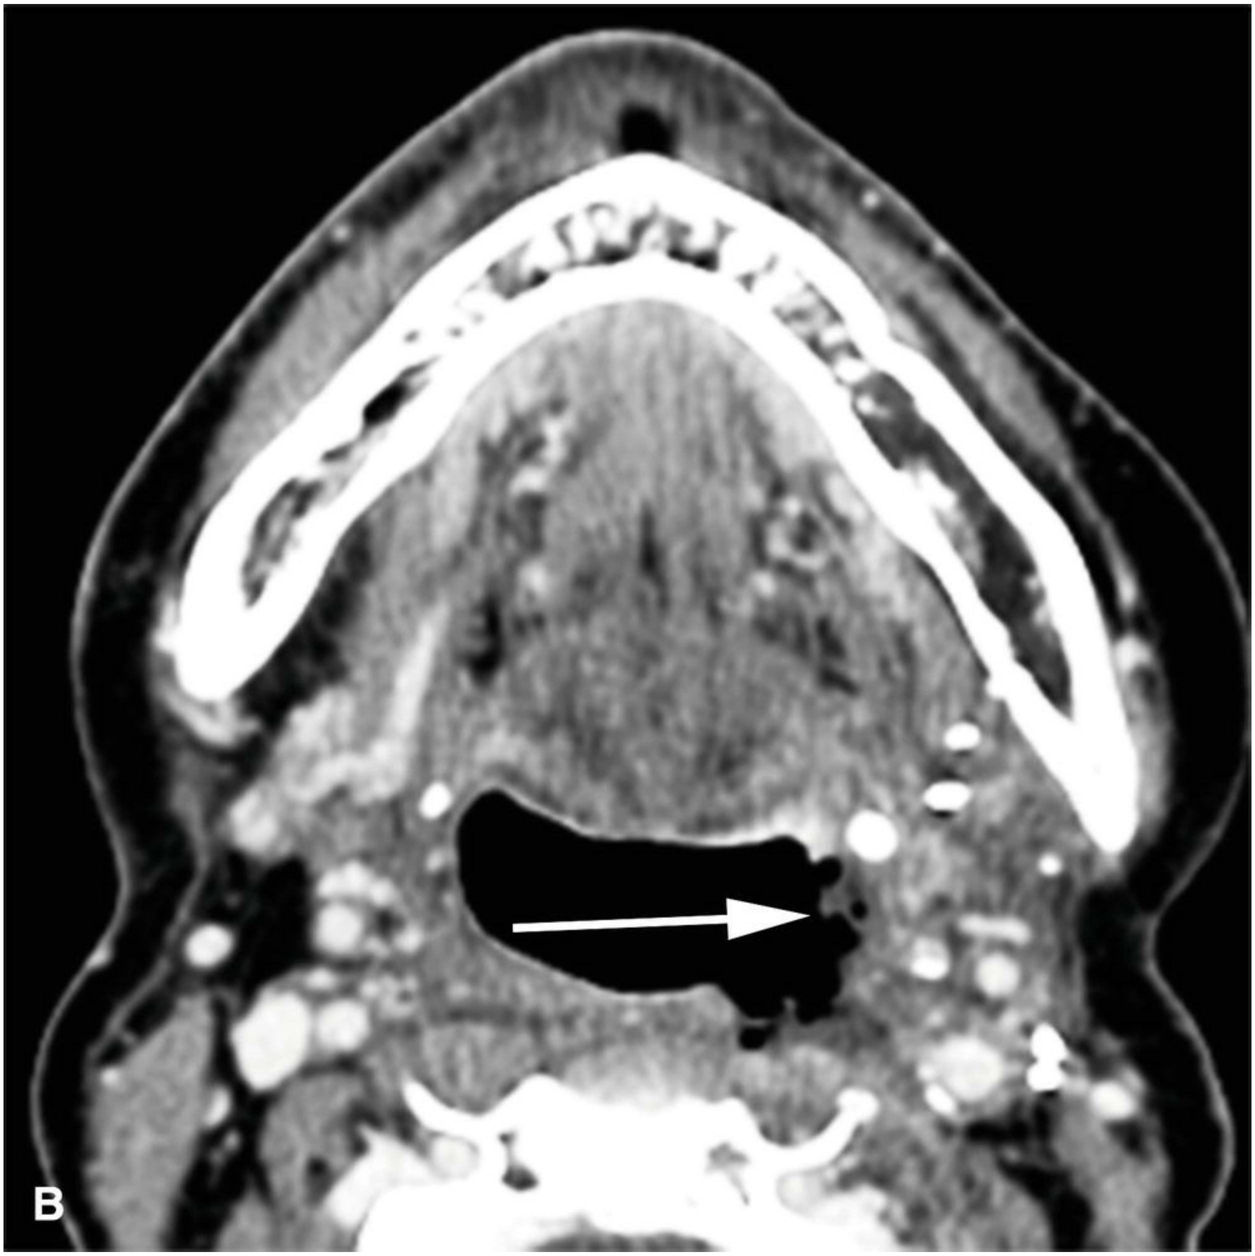
may often resolve spontaneously, requiring no further treatment. Chylous fistula occurs in 1% to 2% of patients after neck dissection, especially when level IV nodes are dissected. Chylous fistula is often located in the lower left portion of the neck, so this characteristic location helps raise the suspicion of this complication. It is important to distinguish a benign fluid collection from an abscess or tumor recurrence. Early surgical complications such as serous retention, abscess, hematoma, and chylous fistula often show imaging findings similar to those of a fluid collection, with peripheral enhancement at CT and MR imaging. Clinical symptoms, such as fever, pain, and swelling, and laboratory parameters, such as a leukocytosis and elevated C-reactive protein level, can be used in distinguishing an abscess from other types of fluid collections.

Mucosal Necrosis

Mucosal necrosis is an uncommon but important late toxic effect of head and neck radiation therapy that may cause substantial pain and interferes with the patient's ability to chew and swallow. The risk for mucosal necrosis is greatest during the first 6 to 12 months after radiation therapy. In more than 95% of cases, soft tissue necrosis heals spontaneously, but healing may take 6 months or more or require hyperbaric oxygen therapy. Mucosal necrosis is a separate entity from acute mucositis; the latter results from an acute loss of functional cells and temporary lack of replacement from the pools of rapidly proliferating cells. If the reaction is severe, subsequent fibrosis occurs and leads to impairment of microvascular and lymphatic flow. This impairment produces hypoxic, hypocellular, and hypovascular tissue that is unable to maintain normal tissue turnover, resulting in mucosal necrosis and ulceration.

On CT and MR imaging, mucosal necrosis shows a lack of mucosal enhancement with breech of the mucosa and air dissecting submucosally with or without ulceration (Fig. 5.41). Pockets of gas identified adjacent to the lesion should raise concern for necrosis. Gas is more readily identifiable on CT compared with MR imaging. If the ulceration is associated with adjacent enhancement, the differentiation between radiation necrosis and recurrent tumor becomes difficult (Fig. 5.41). FDG-PET imaging often reveals hypermetabolism associated with areas of ulceration, which should not be mistaken as an absolute sign of recurrence (Figs. 5.45 and 5.52). Tumor recurrence and mucosal necrosis typically occur within 2 years after therapy,

so the time of the onset is less useful in distinguishing between radiation-induced injury and tumor recurrence. Mucosal complications are more easily diagnosed with the findings from clinical examination than with imaging but are not always clinically clear, and correlation with findings from clinical examination and close interval follow-up are necessary.[112,113]



B

C

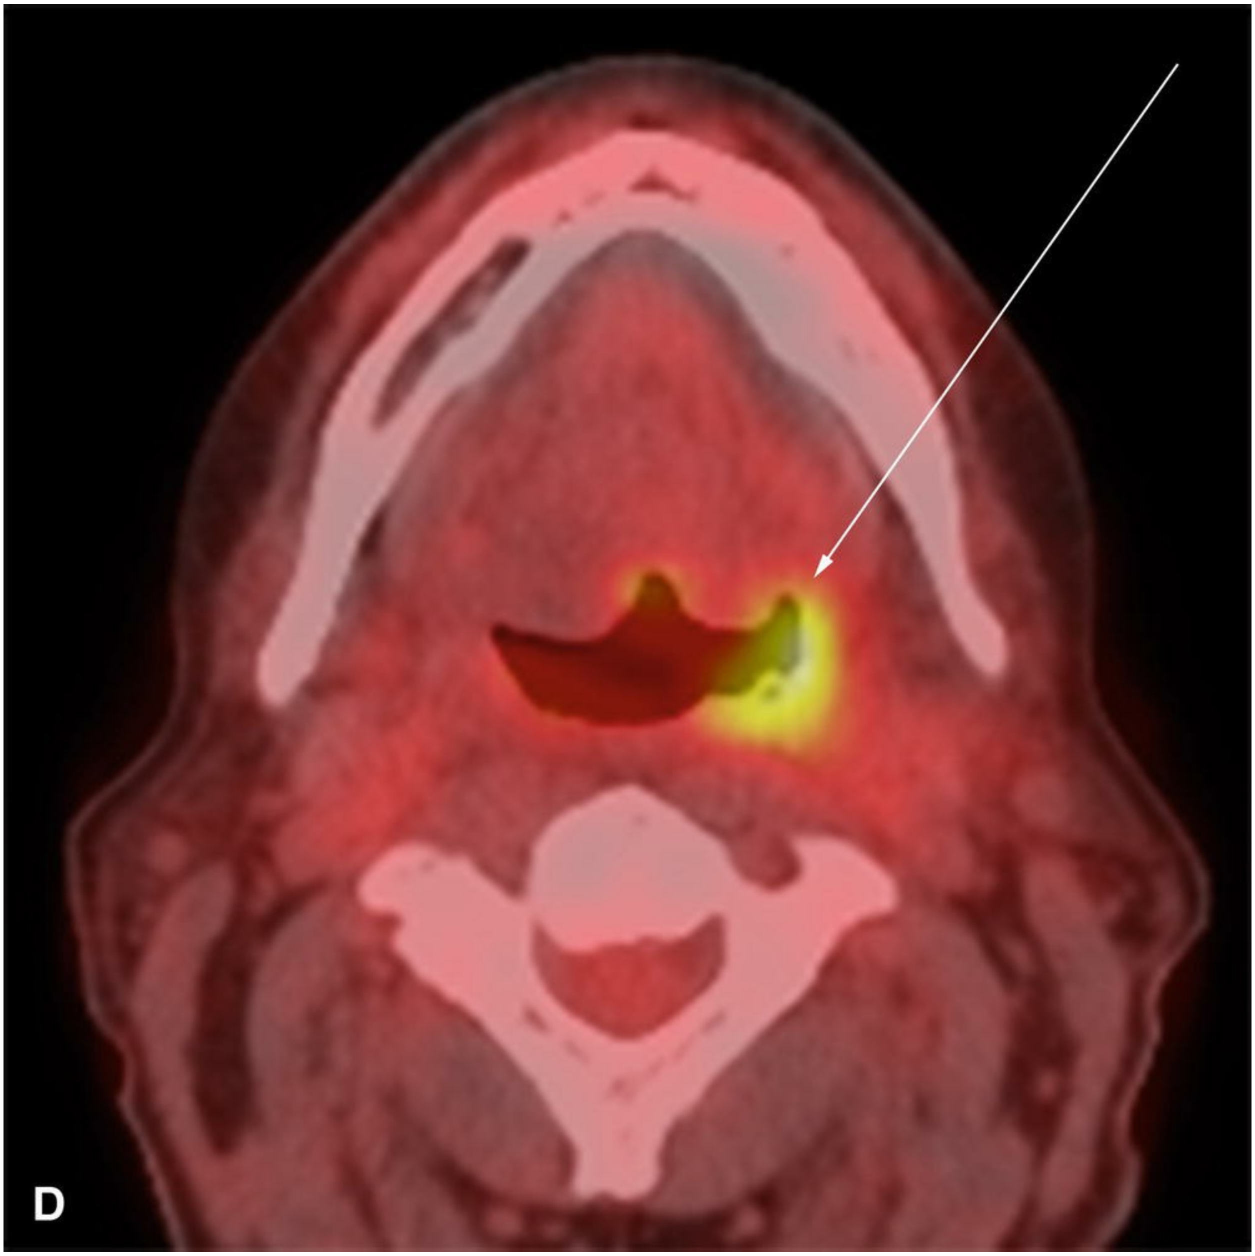


Figure 5.45. Postoperative mucosal changes including ulceration are common and can be difficult to differentiate from recurrent disease. In this 49-year-old man with squamous cell carcinoma of the left tonsil treated with chemoradiation and left neck dissection, posttreatment CT of the neck **(A)** 2 years following treatment shows an unremarkable appearance of the left oropharynx. A follow-up CT of the neck **(B)** with contrast 3 months later revealed development of nonenhancing ulceration (*arrow*), which was negative for locally recurrent disease. Similar findings are seen in this 53-year-old man with HPV-associated T3 squamous cell carcinoma of the left base of the tongue who was treated with chemoradiation. In this example, we

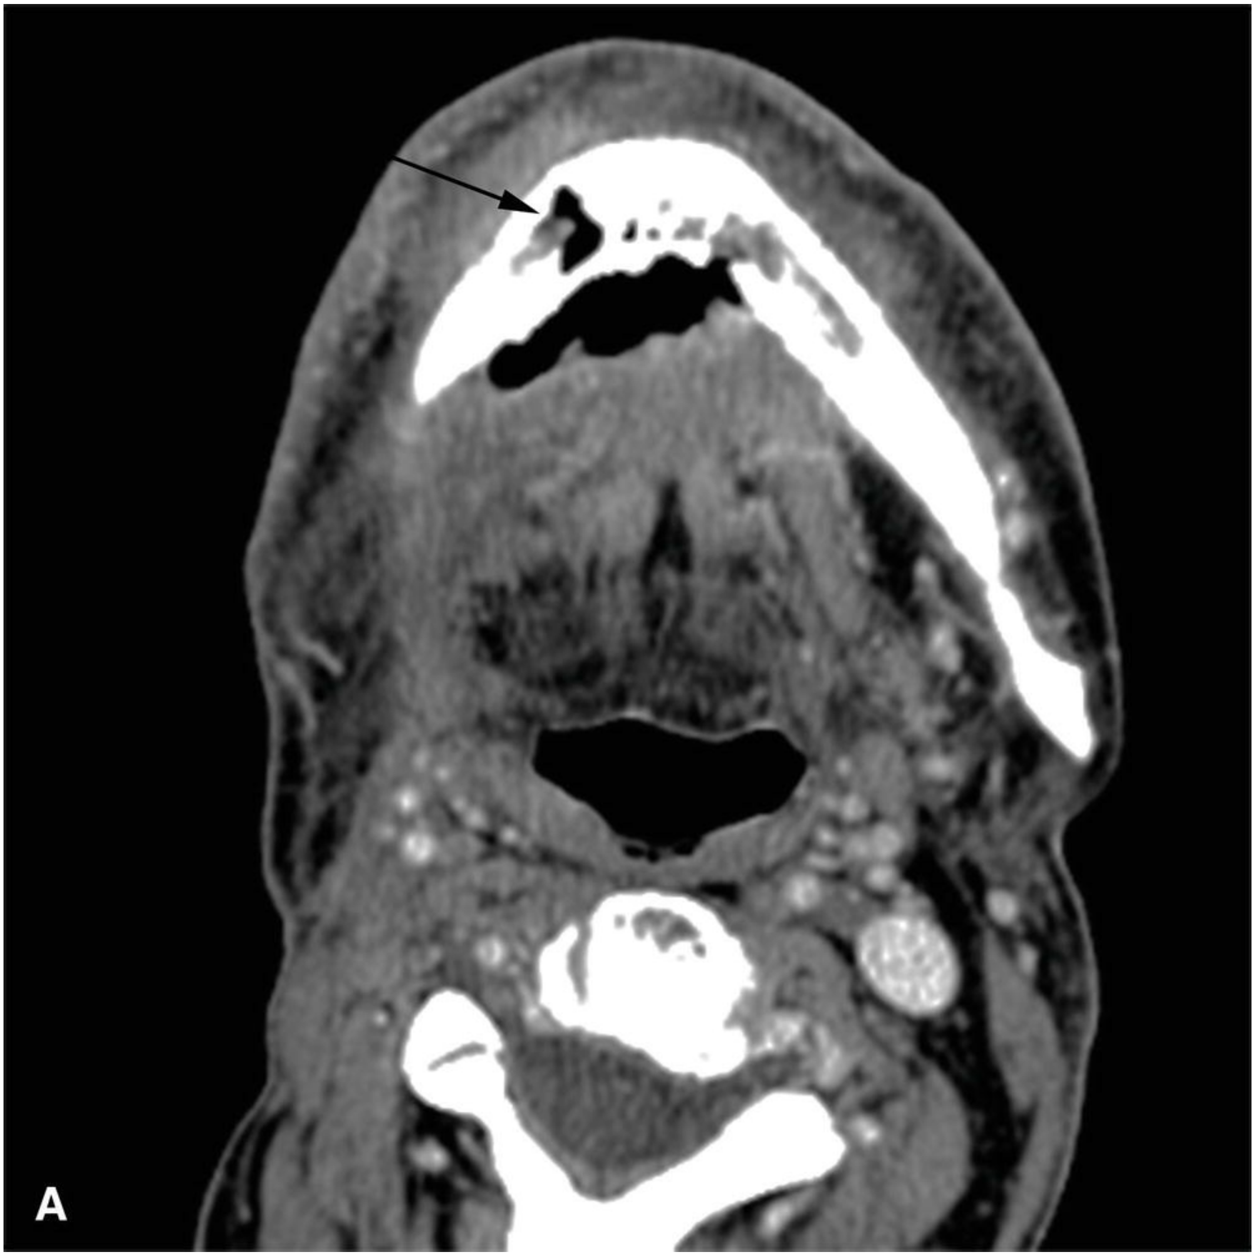
see **(C)** a similar appearing nonenhancing ulceration in the left oropharynx (*arrow*), which also displayed **(D)** hypermetabolism on FDG-PET/CT. This was later also proven to be negative for recurrence. Nonenhancement of an ulceration strongly argues against recurrent tumor.

Fistula

A fistulous tract is an abnormal pathway between an internal cavity or organ and the surface of the body. These may be caused by infection, tumor, radiation, or flap necrosis. Orocutaneous fistulas are not common, but may occur as a consequence of osteoradionecrosis (Fig. 5.46; see below). An orocutaneous fistula may lead to the continual leakage of saliva from the oral cavity to the face. Tumor can be difficult to exclude when fistulas are identified with adjacent enhancing soft tissue. Fistulas may close spontaneously, but some may require reoperation. Postoperative anemia, prior tracheotomy, and prior radiation therapy and neck dissection are associated risk factors for fistula formation. The severity and the duration of fistulas are greater in patients who have undergone prior radiation therapy than in those who have not.[112]



A

B

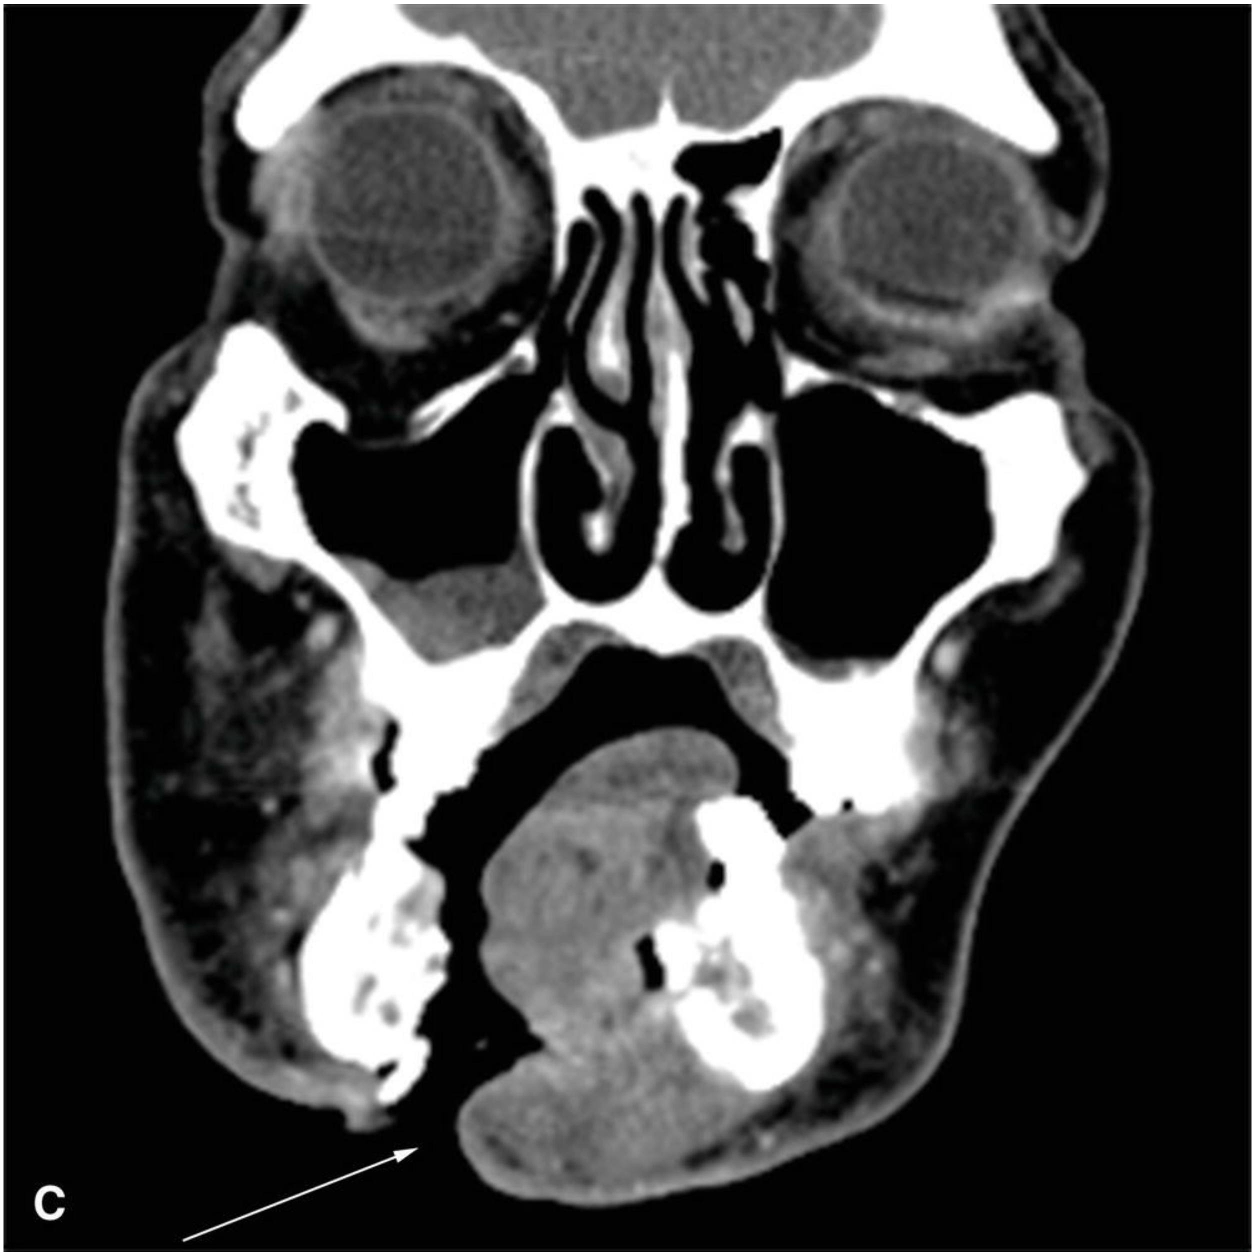


Figure 5.46. A 58-year-old man with squamous cell carcinoma of the right lateral tongue status post wide local excision, right neck dissection, and radiation therapy. **A:** A CT of the neck with contrast in soft tissue windows reveals intraosseous air in the mandibular marrow space (*arrow*). **B:** Bone windows better reveal irregular lytic changes within the mandible, compatible with osteoradionecrosis. The cortical disruption of the pathologic fracture is seen on this image (*arrow*). **C:** A coronal reconstructed image of the CT of the neck reveals orocutaneous fistula to the submental region (*arrow*).

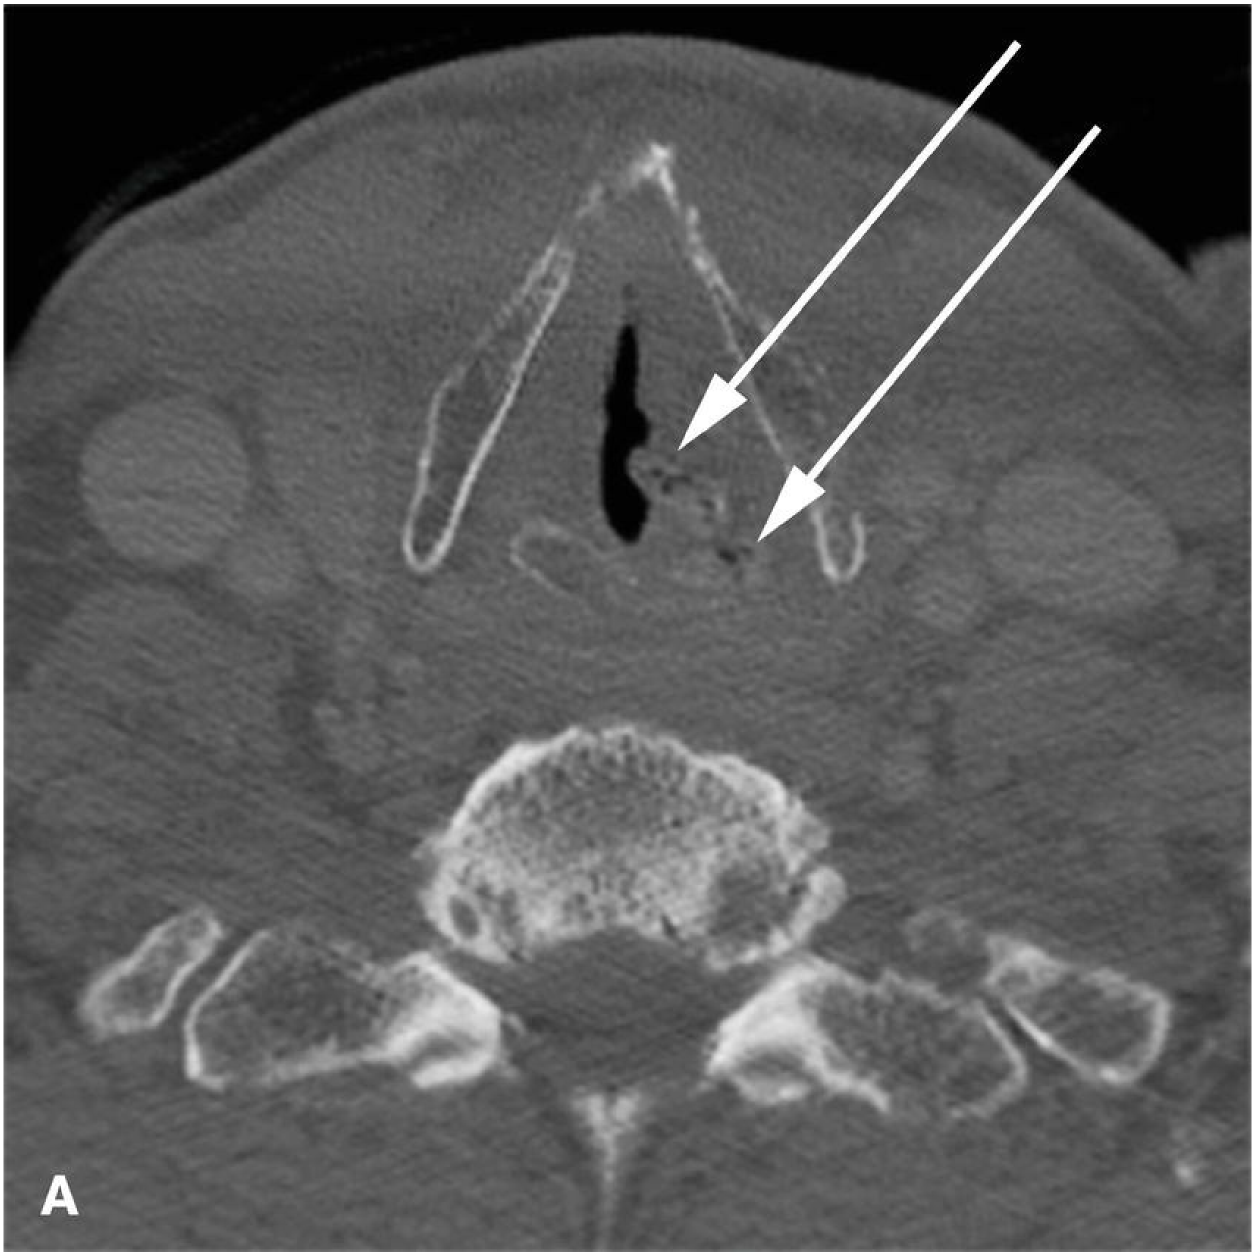
Osseous Complications

The exact definition of osteoradionecrosis is variable, but in general, it is a condition in which irradiated bone becomes devitalized and exposed through the overlying skin or mucosa, persisting without healing for at least 3 months. The reported incidence of osteoradionecrosis varies greatly in the literature, ranging from 0.4% to 22% in patients with head and neck cancer, and generally occurs within several years of radiation therapy (XRT).

Osteoradionecrosis is unlikely to occur if the radiation dose, delivered by standard fractions, is below 60 Gy. There is a higher likelihood of occurrence if the dose is higher than 65 to 75 Gy. Sites that can be affected by osteoradionecrosis in the head and neck region are the skull base, temporal bone, mandible, maxilla, and hyoid bone. The mandible is the most common site of osteoradionecrosis related to its superficial location and relatively poor blood supply (Fig. 5.46). The symptoms of osteoradionecrosis in the head and neck region are chronic focal pain, swelling, and facial deformation. In the case of the mandible, common signs and symptoms include dysphagia, drainage, and fistulization to the mucosa or skin. Laryngeal chondronecrosis can be considered a subtype of radionecrosis and is manifested clinically by dysphagia, odynophagia, respiratory obstruction, hoarseness, and aspiration (Fig. 5.47). The vast majority of patients develop symptoms within 1 year of treatment, but significantly delayed presentations of up to 25 years have been reported.[114]



A

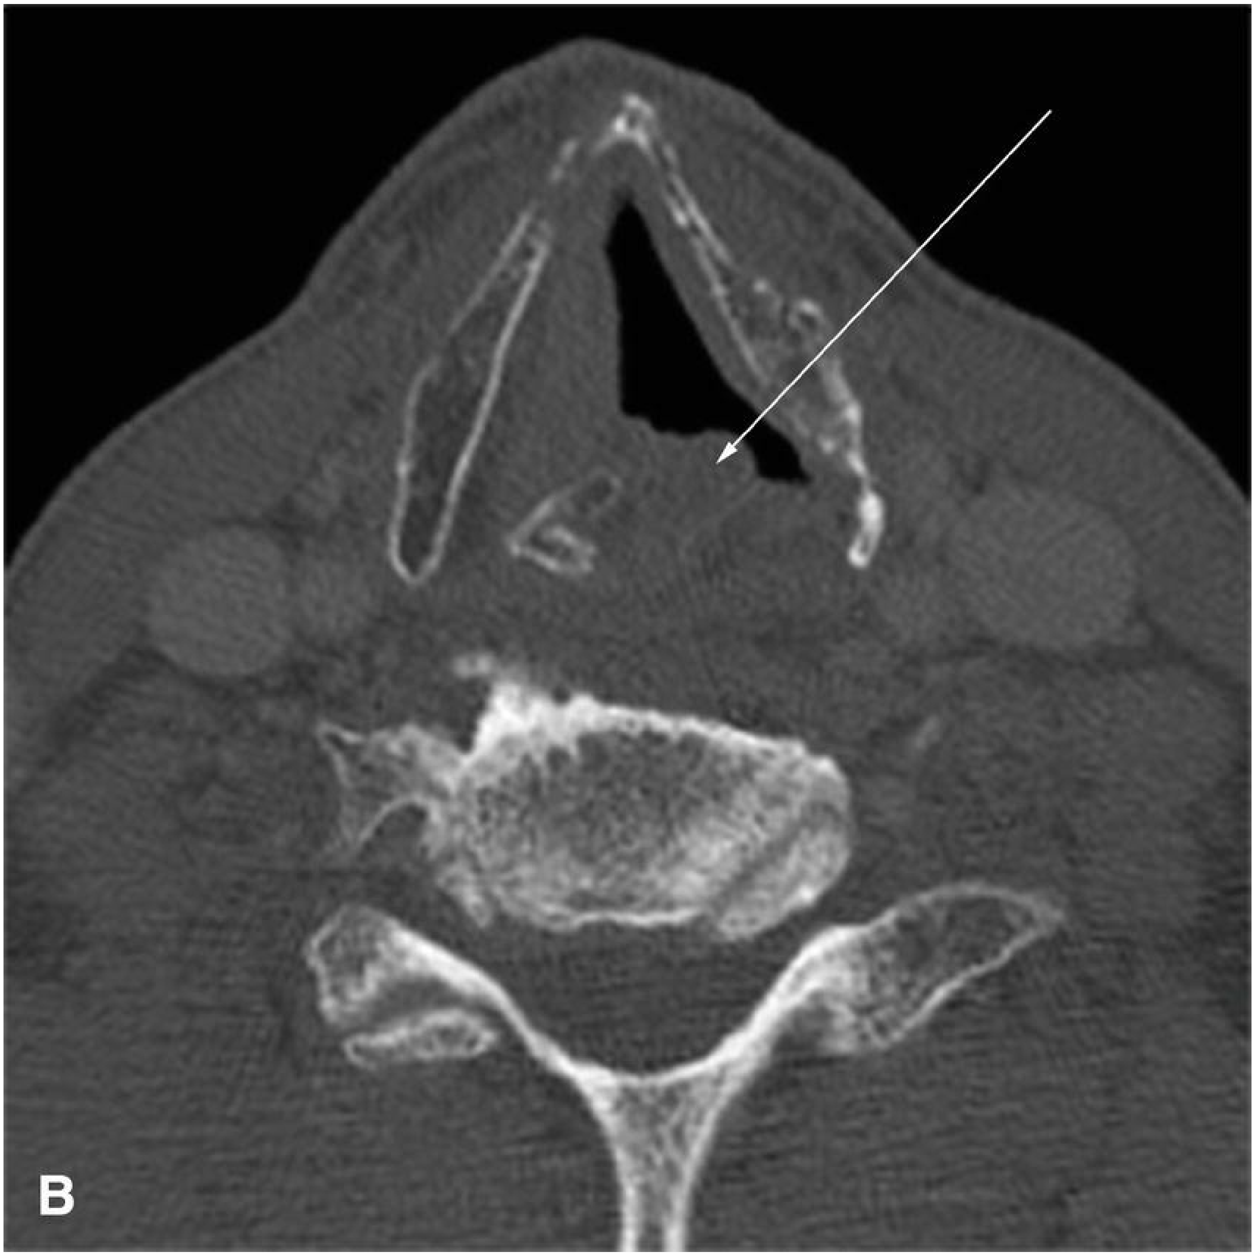


Figure 5.47. A 56-year-old man with a T2 squamous cell carcinoma of the right true vocal cord treated with radiation therapy subsequent development of chondroradionecrosis of the left arytenoid. CT of the neck with contrast in bone window **(A)** reveals small foci of air within a poorly outlined left arytenoid cartilage (*arrow*). Subsequent imaging **(B)** reveals autoamputation of the left arytenoid (*arrow*). The normal right arytenoid is well seen on this image.

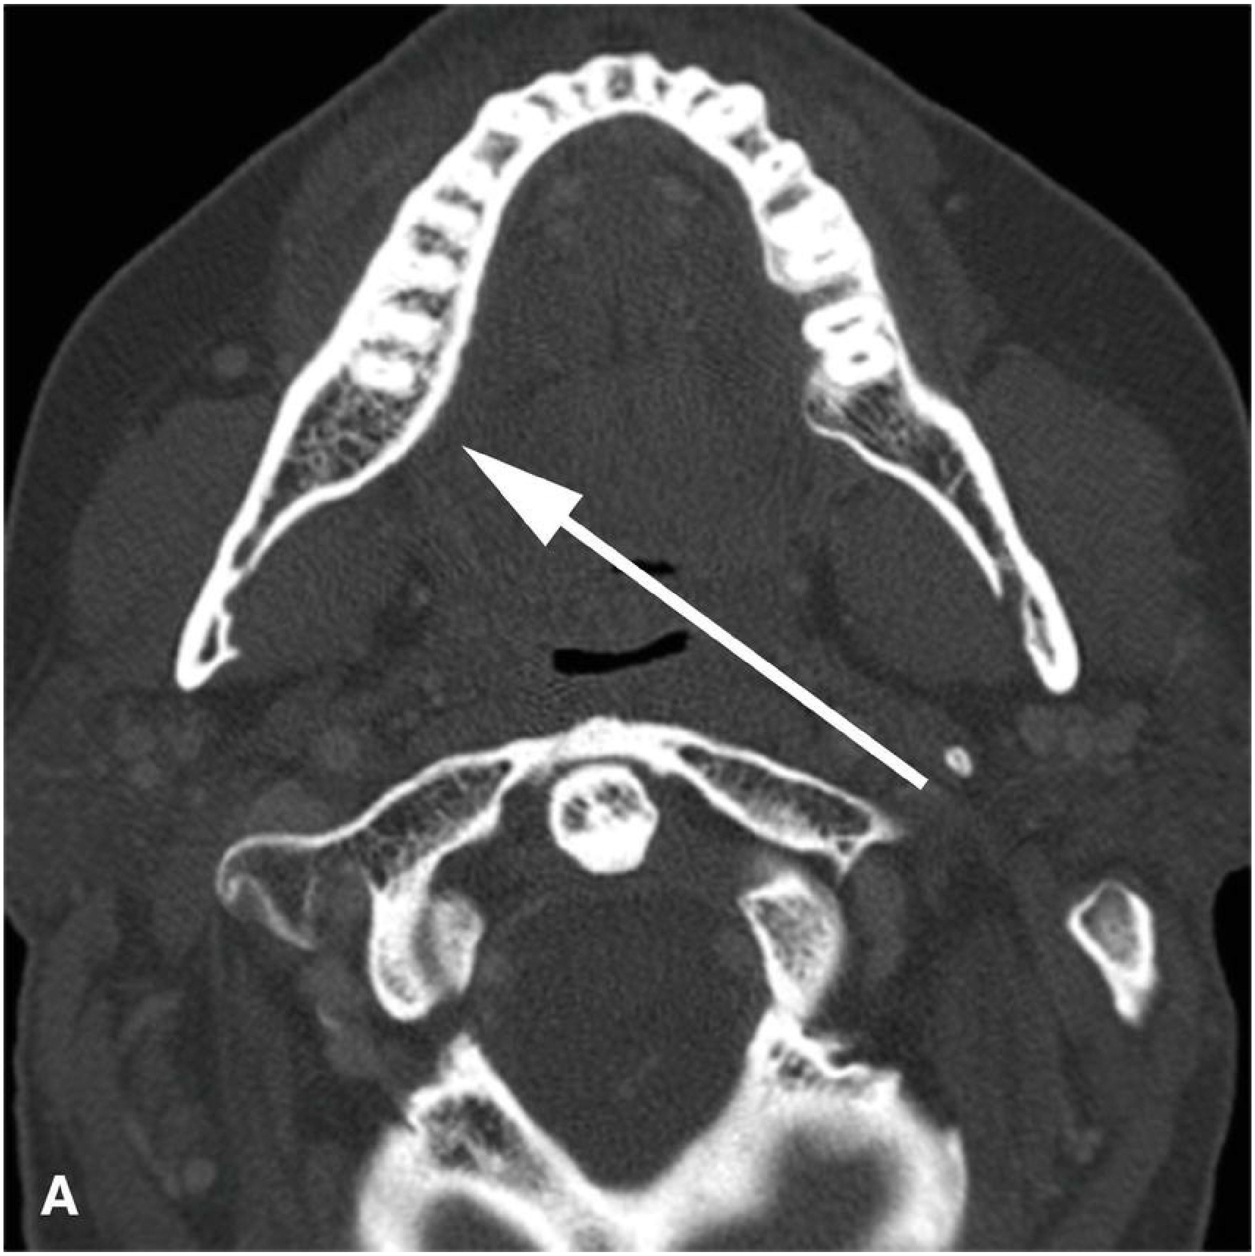
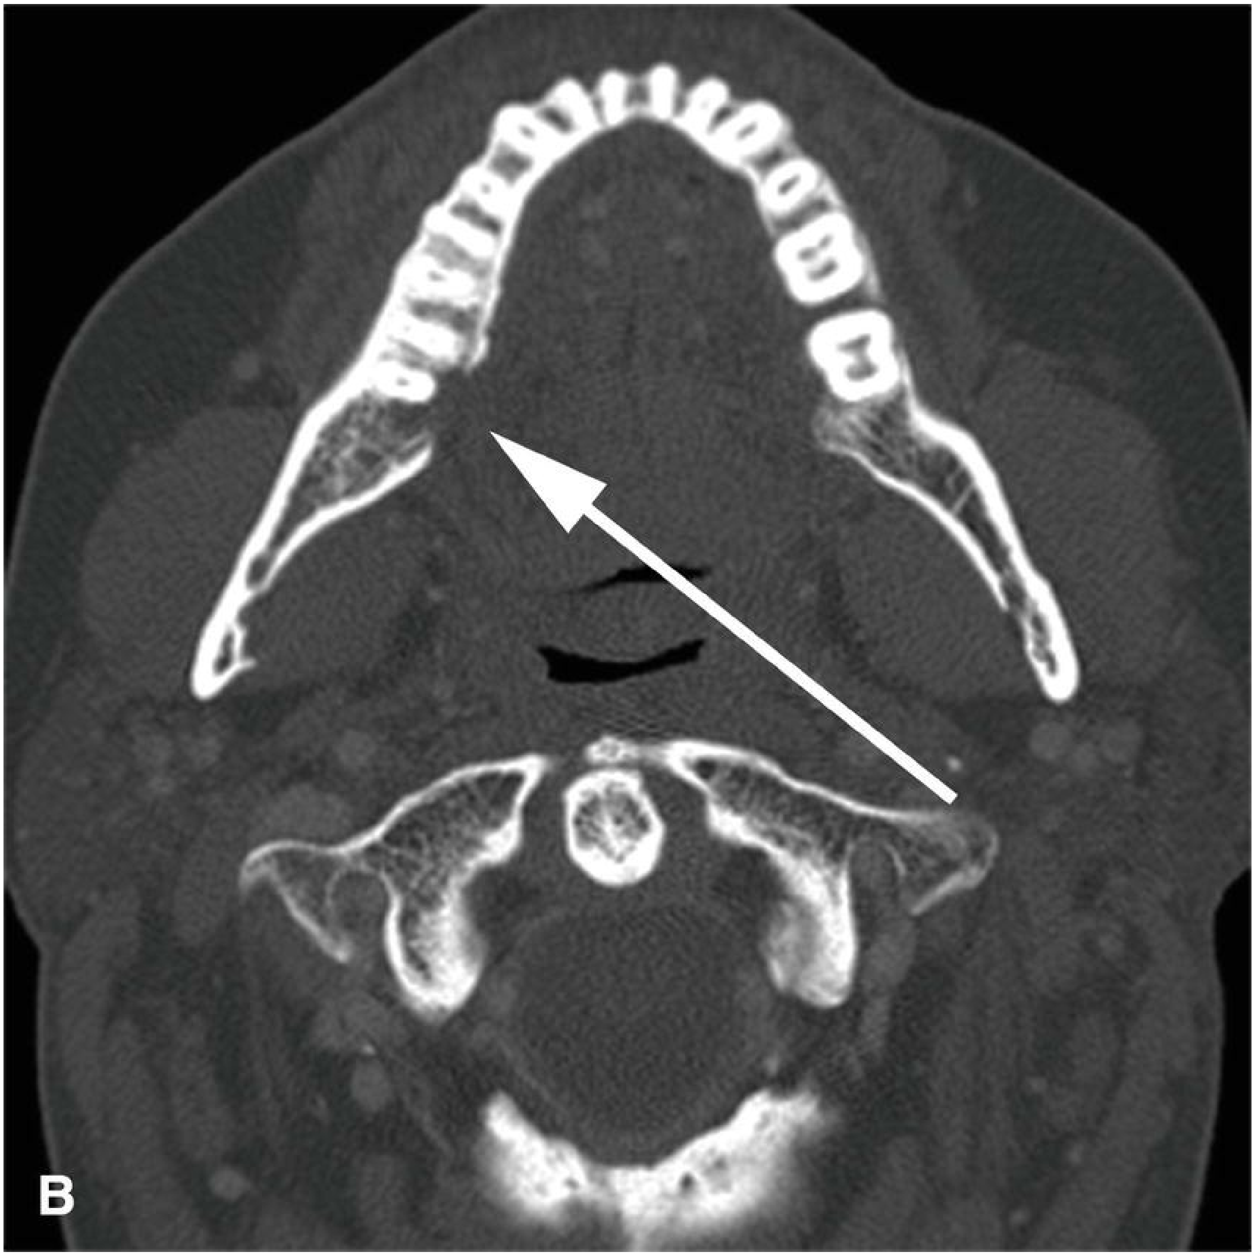
Osteoradionecrosis typically displays as a well-defined lytic region with cortical destruction, sequestrum formation, and loss of normal trabeculation

pattern. An early imaging finding is loss of lingual mandibular cortical bone (Fig. 5.48). MR images of osteoradionecrosis show abnormal signal intensity in the bone marrow, though the associated cortical disruption may be inapparent. Pathologic fracture, soft tissue thickening, and fistula formation are sometimes seen. Although these imaging findings can mimic those of tumor recurrence, the presence of an associated soft tissue mass favors a diagnosis of tumor recurrence. The identification of cortical defects remote from the primary tumor site can also help in the diagnosis of osteoradionecrosis. Synchronous or metachronous lesions can occur in cancer patients, but are rare, progressively destructive, and typically have an enhancing soft tissue component.[115]



A



B

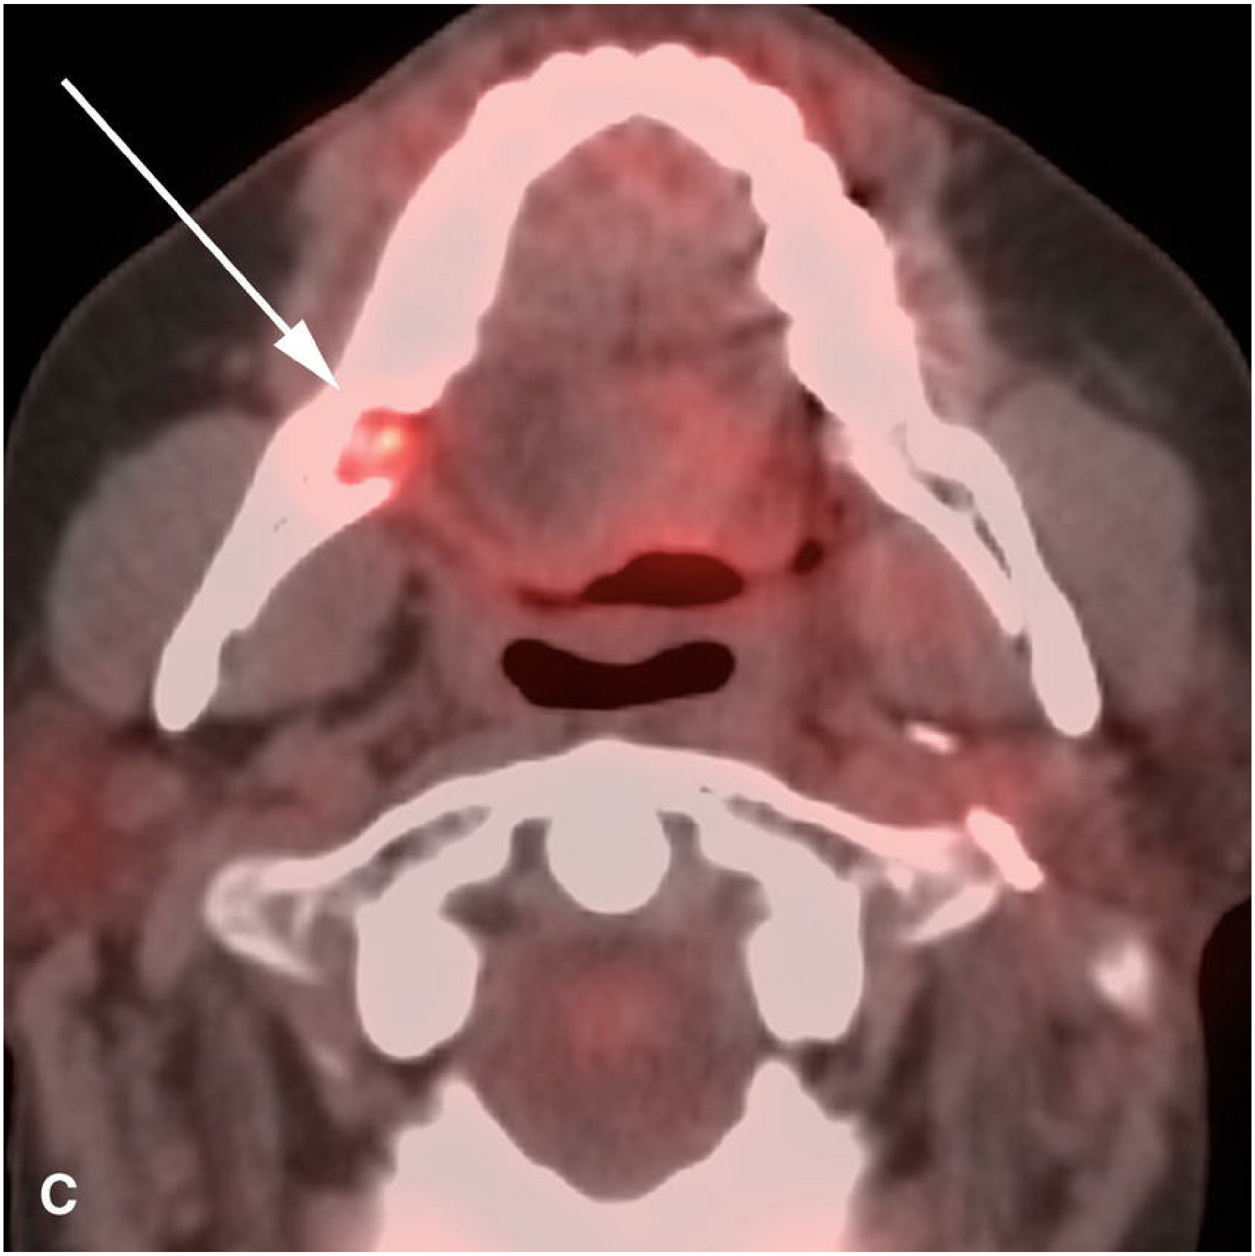


Figure 5.48. A 56-year-old man with T2 N2C squamous cell carcinoma of the left base of the tongue treated with chemoradiation and subsequent development of osteoradionecrosis of the mandible. **A:** Baseline postradiation CT of the neck with contrast in bone window shows a normal appearance of the right mandibular lingual cortex (*arrow*). **B:** Imaging 16 months following treatment reveals a lingual cortical defect in the right mandible (*arrow*), which was also noted to be hypermetabolic on FDG-PET/CT. **C:** The degree of hypermetabolism, although not striking, could be misinterpreted as tumor without CT and clinical correlation.

Vascular Complications

Accelerated atherosclerosis and thrombosis of the internal jugular vein or carotid artery are well-known vascular complications in patients with radiation therapy. Formation of a pseudoaneurysm of the internal carotid artery is reported to be a rare complication after radiation therapy. Radiation-induced vasculopathy occurs most often in patients who have undergone high-dose radiation therapy, with a latency period between 4 months and 20 years. However, most patients treated for head and neck cancer have preexisting ischemic vascular disease secondary to alcohol and tobacco consumption and elevated serum cholesterol and lipid levels. The imaging findings of radiation-induced vasculopathy mimic those of other atherosclerotic disease and cannot be differentiated based on imaging findings alone. Radiation-induced vasculopathy is often bilateral and related to the irradiated field.[116]

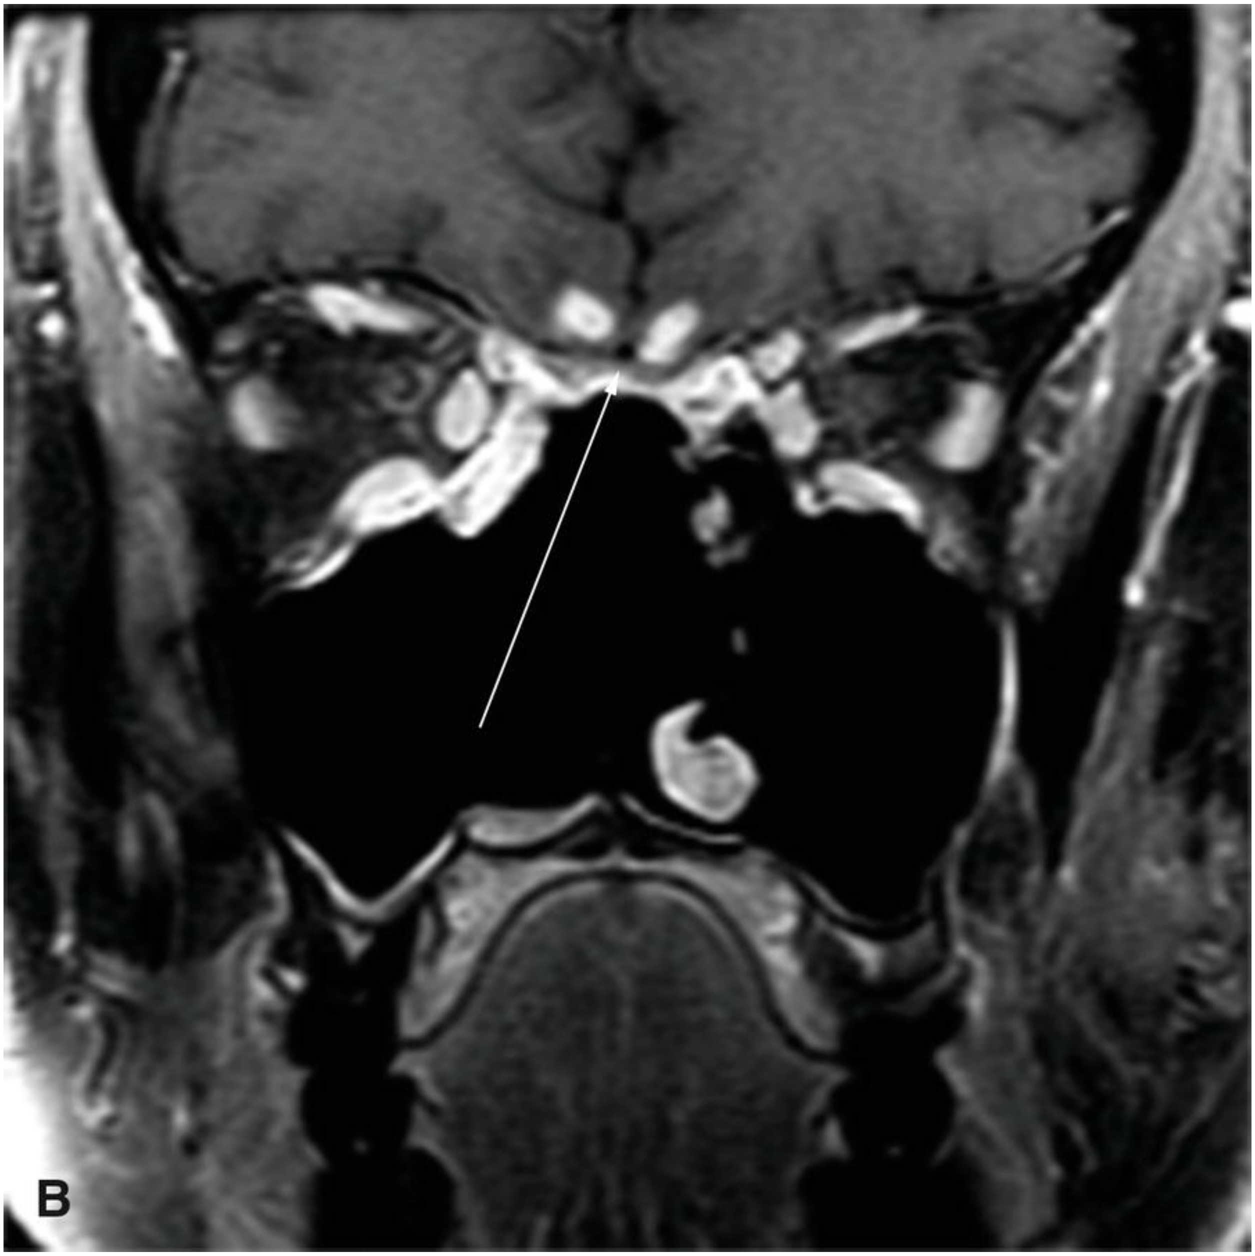
Radiation-Induced Lung Disease

Radiation therapy for patients with head and neck cancer often includes the apical aspect of the thorax, to encompass the supraclavicular nodes and level IV nodal areas, and results in bilateral apical radiation-induced lung changes. Clinically, these changes may manifest as acute radiation pneumonitis or late radiation lung fibrosis. Radiation pneumonitis occurs within 1 to 3 months after completion of radiation therapy, and radiation fibrosis occurs within 6 to 12 months after radiation therapy and can progress for as long as 2 years before stability occurs. Radiation pneumonitis appears as focal ground-glass attenuation and/or consolidation. Radiation pneumonitis gradually resolves but can progress to fibrosis if the damage is severe. Radiation lung fibrosis is shown to be a well-defined area of volume loss, linear scarring, and traction bronchiectasis.[117]

Radiation-Induced Brain Necrosis

Radiation-induced brain necrosis often occurs within 2 years after radiation therapy. Irradiation of skull base or external ear/other cutaneous tumors may result in radiation damage to adjacent brain tissue. Radiation therapy in patients with nasopharyngeal cancer is associated with temporal lobe necrosis in ~3% of patients. This condition was previously seen more commonly with

older irradiation techniques. The incidence of temporal lobe necrosis with intensity-modulated radiation therapy is now markedly lower because the brain is contoured as an avoidance structure and because maximal doses are maintained at <60 Gy. Focal brain necrosis can present as an enhancing mass with variable edema on imaging, often beginning as small, spotty areas of enhancement. An actual mass may come later if at all (Fig. 5.49). The knowledge of prior definite head and neck radiation along with the typical location involving the medial anterior temporal lobe should be sufficient in most patients to confidently make this diagnosis with imaging alone.[118]



B

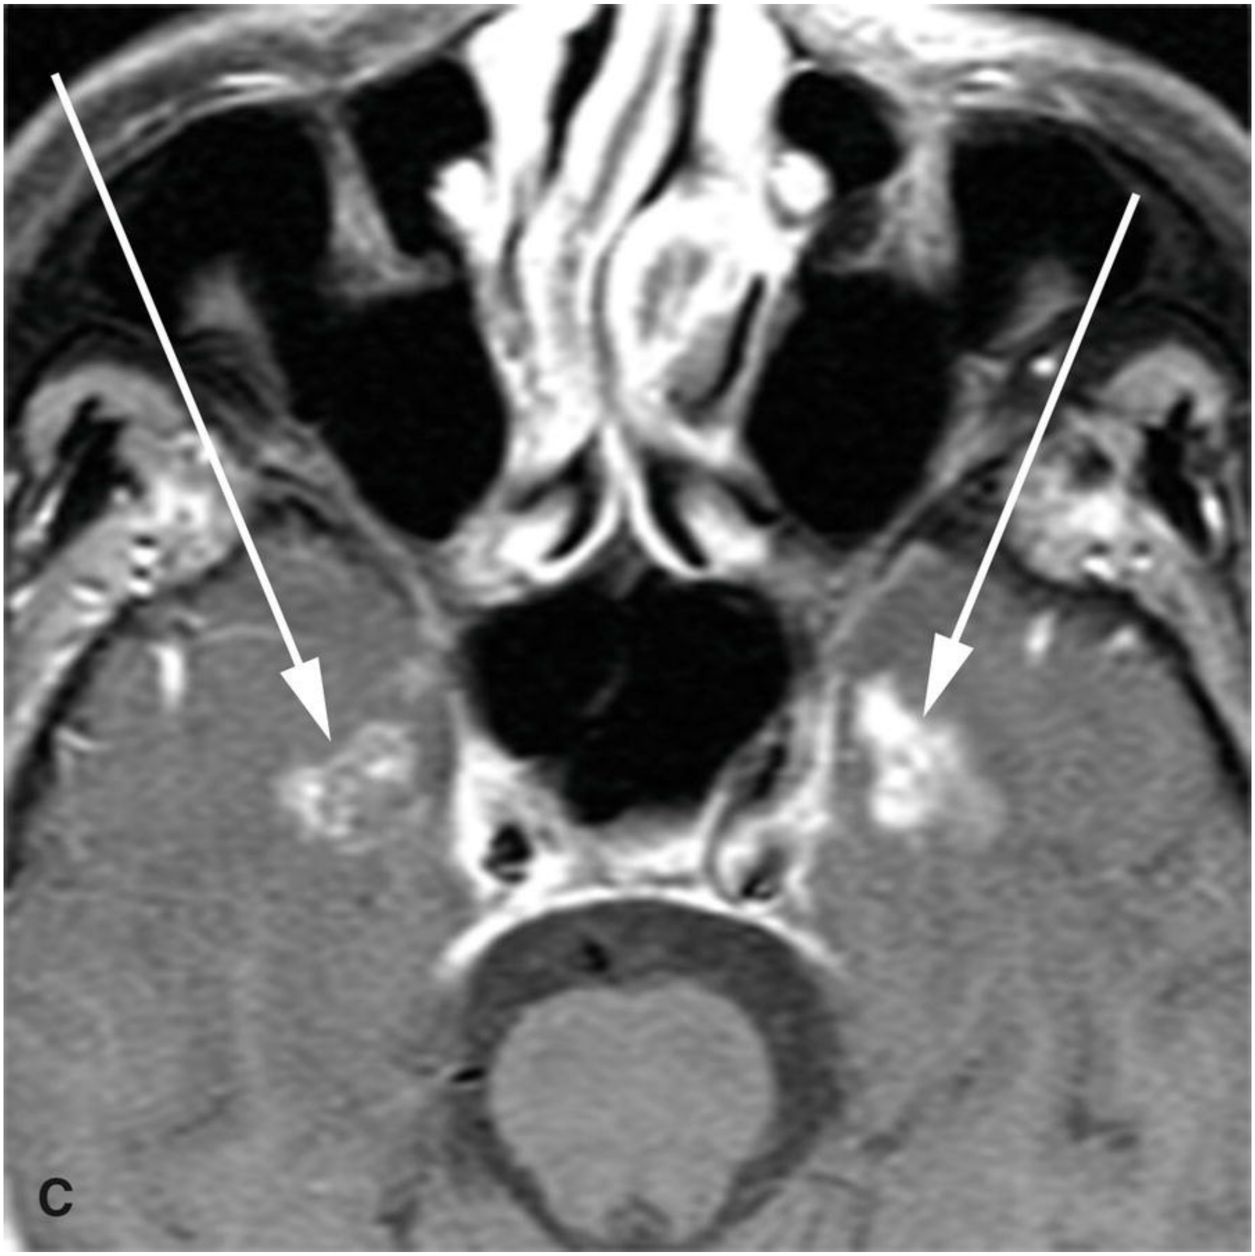


Figure 5.49. Cerebral radiation necrosis can have features suggestive of a primary brain neoplasm although it tends to occur in predictive sites following radiation treatment to the head and neck. In this 40-year-old man with sinonasal undifferentiated carcinoma treated with surgery and radiation, characteristic findings of cerebral radiation necrosis developed ~2 years after radiation completed. Axial **(A)** and coronal **(B)** T1-weighted postcontrast MR images of the brain reveal bilateral and relatively symmetric enhancing lesions (*arrow*) without mass effect in the gyrus rectus anteriorly. In this **(C)** 49-year-old man with T4 nasopharyngeal carcinoma treated with chemoradiation, there are similar findings on postcontrast T1-weighted MR

imaging although this time the lesion is seen within the bilateral medial anterior temporal lobes (*arrows*).

Radiation-Induced Neoplasm

Radiation-induced neoplasm is rare, with one group of investigators reporting an incidence rate of 0.04% for postirradiation sarcoma in patients who had undergone treatment for nasopharyngeal cancer. These investigators reported that the latency period ranged between 4 and 27 years. Various types of radiation-induced neoplasms have been reported, including meningioma, sarcoma (osteosarcoma, malignant fibrous histiocytoma), osteochondroma, schwannoma, osteoblastoma, SCC, and lymphoma. The diagnostic criteria of postirradiation osteosarcoma include a lesion centered in irradiated bone without a primary malignant osteoblastic lesion, arising after a latency period of at least 3 years after the completion of radiation therapy (Fig. 5.50). Imaging findings mimic those of primary osteosarcoma.[119]

A

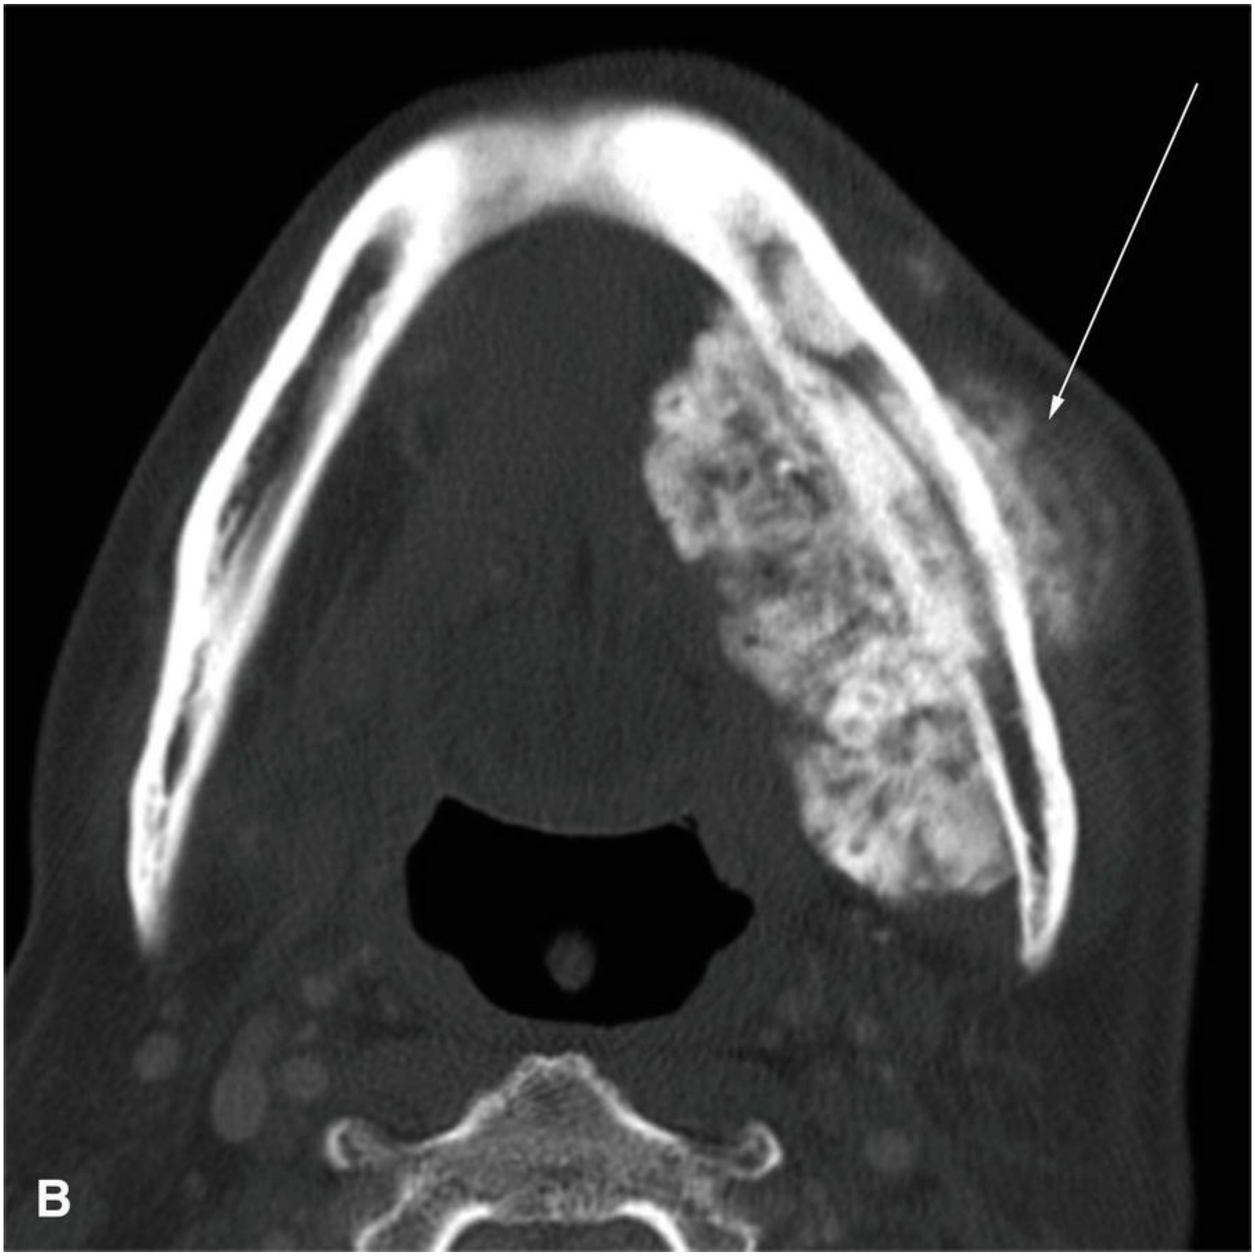

Figure 5.50. A 48-year-old man who originally presented with carcinoma of the left submandibular gland treated with resection and brachytherapy. Regional recurrent disease was later treated with neck dissection and radiation therapy. Approximately 7 years after original presentation, the patient developed a mass arising from his left mandible, which was biopsy-proven osteoblastic osteosarcoma arising within the radiation field. A CT of the neck in soft tissue **(A)** and bone window **(B)** reveals a bone-producing mandibular mass (*arrow*) arising from the left mandible with enhancing soft tissue along the margins (*arrow*).

Posttreatment Surveillance Imaging

As discussed earlier, the typical imaging modalities used for posttreatment surveillance include CT, US, MRI, and FDG-PET/CT. Imaging plays an important role in the early detection of recurrence, to allow early intervention and salvage treatment. The combination of clinical endoscopic and physical examination coupled with imaging is geared toward the early detection of recurrence (Fig. 5.51).

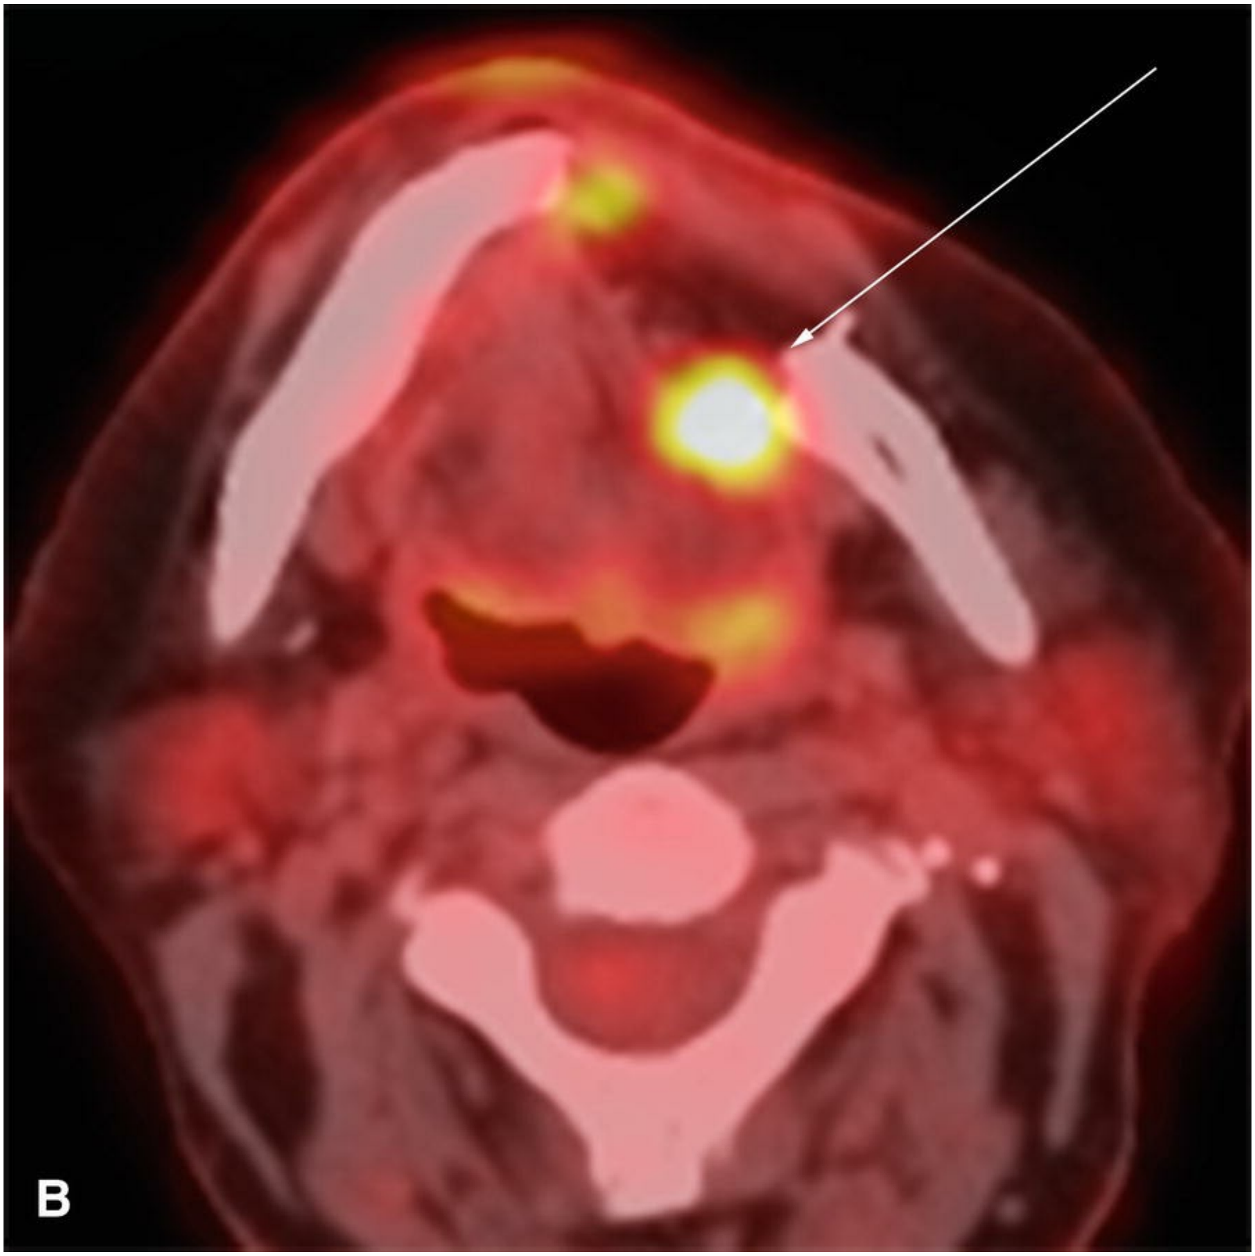

Figure 5.51. A 68-year-old-male with a squamous cell carcinoma of the left floor of mouth treated with resection, neck dissection, and flap reconstruction. Surveillance CT of the neck with contrast **(A)** and FDG-PET/CT **(B)** 3 months after surgery revealed findings of subsequent proven recurrent disease in the left anterior floor of the mouth (*arrow*).

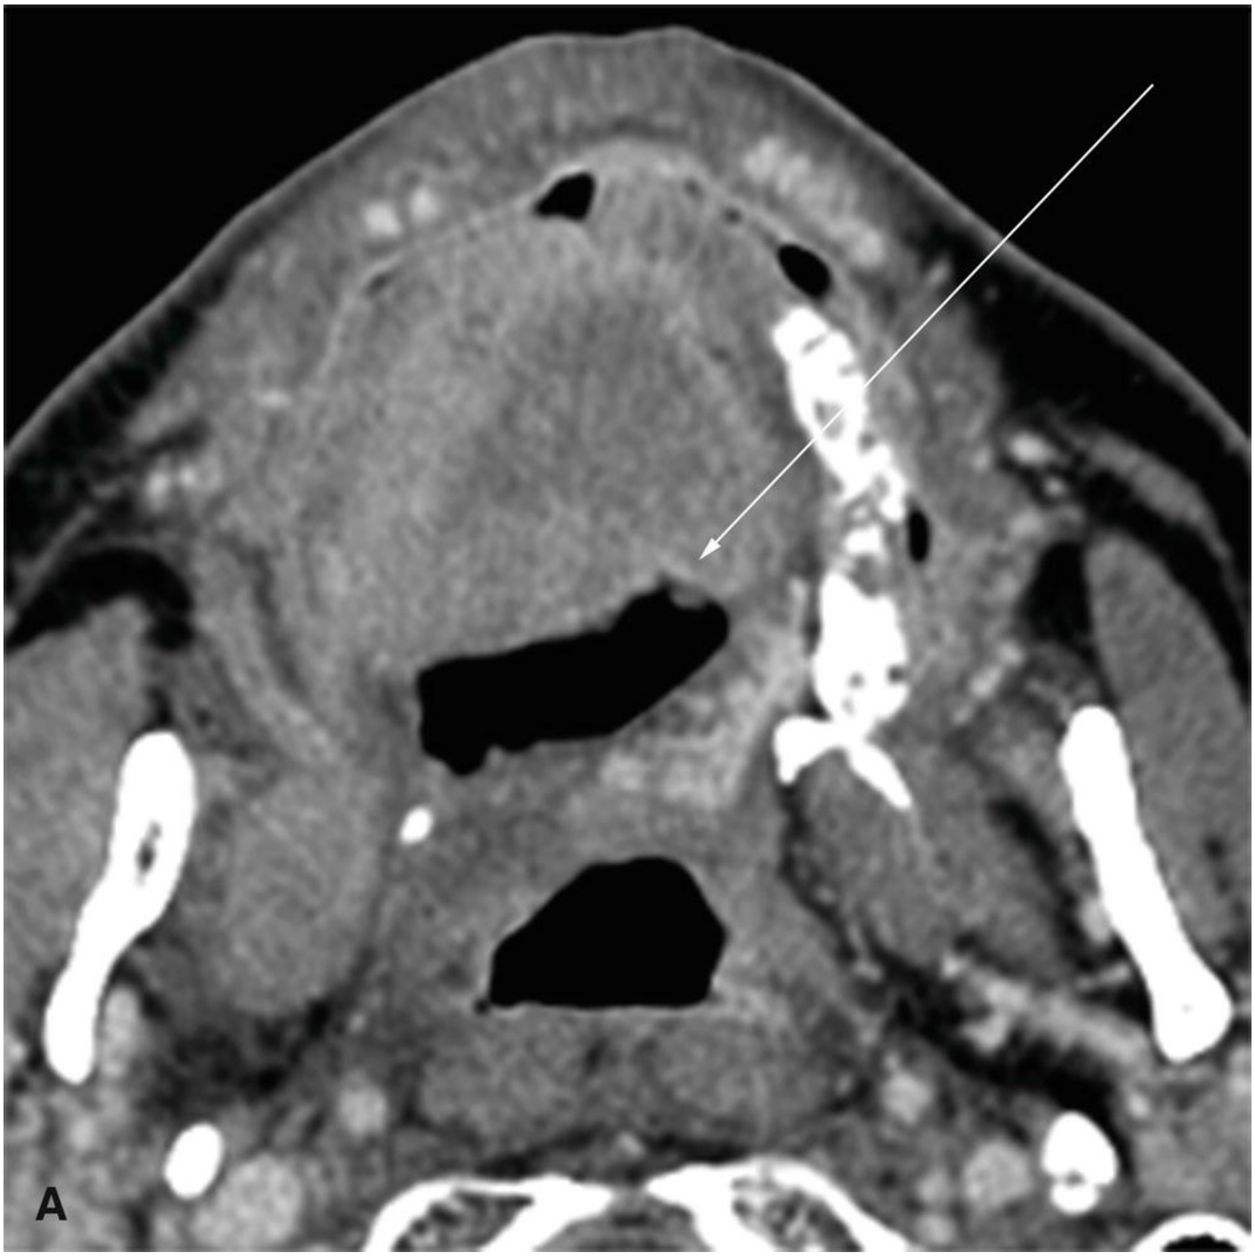
The acquisition of a baseline imaging examination is important to serve as a reference for evaluation in the posttreatment follow-up. Surgery alters the normal anatomy, tissue planes, and landmarks in the head and neck. Radiation treatment induces tissue distortion including edema, late

microvascular injury, and fibrosis. These posttreatment changes can make it difficult to distinguish expected treatment-induced changes from tumor recurrence or complications. The baseline imaging examination should optimally be performed at the time when most postoperative changes have resolved and when tumor recurrence rarely occurs. A baseline examination with CT or MR imaging can be performed between 8 and 10 weeks after treatment (Fig. 5.52).



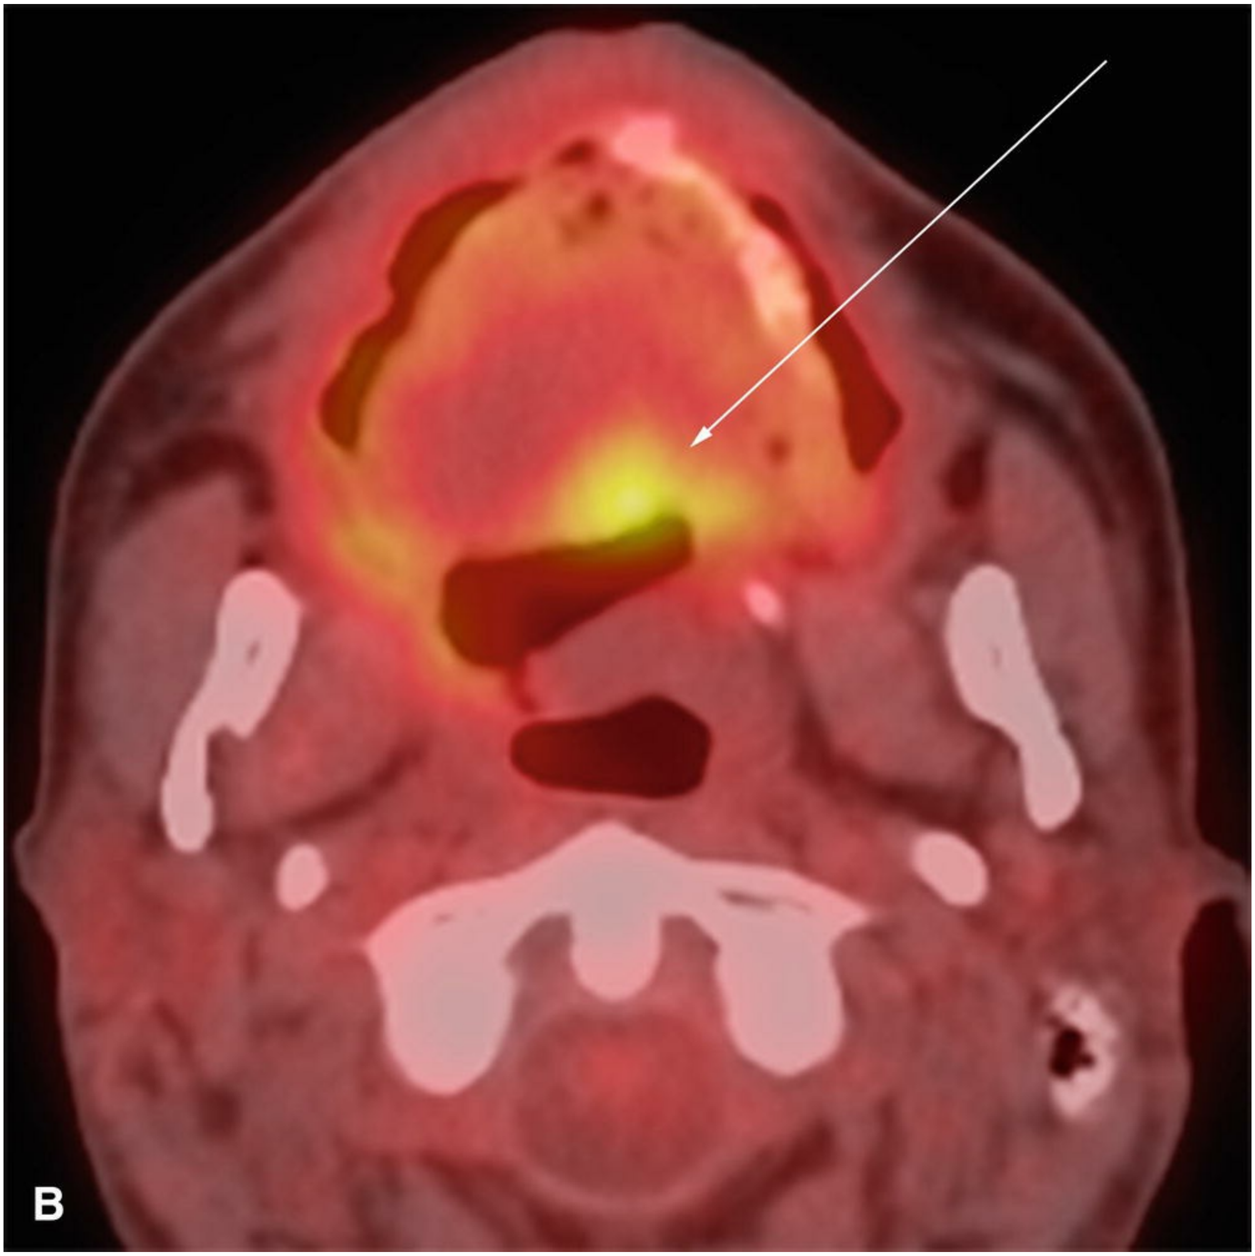


Figure 5.52. A 48-year-old man 2-month status post chemoradiation for oropharyngeal carcinoma was found to have a nonenhancing shallow ulceration along the left tongue base on **(A)** CT of the neck with contrast that was also noted to be hypermetabolic **(B)** on an FDG-PET/CT performed the same day (*arrow*). Continued surveillance showed resolution of this finding consistent with radiation-induced ulceration. It should be kept in mind that FDG avidity is typical in benign ulcerations and does not in and of itself suggest malignancy.

The imaging technique used for the baseline or surveillance examination

is often determined based on the primary site and stage. CT is widely used for follow-up because of its rapid image acquisition and adequate coverage of the cervical nodal basins. MR imaging, given its superior soft tissue contrast, is sometimes preferred for patients with sinonasal, salivary gland, nasopharyngeal, and skull base tumors. Although there is not widespread consensus on the frequency of surveillance, at many institutions, it is performed every 3 to 4 months in the first 2 years, every 4 to 6 months during years 2 to 5, and annually thereafter.

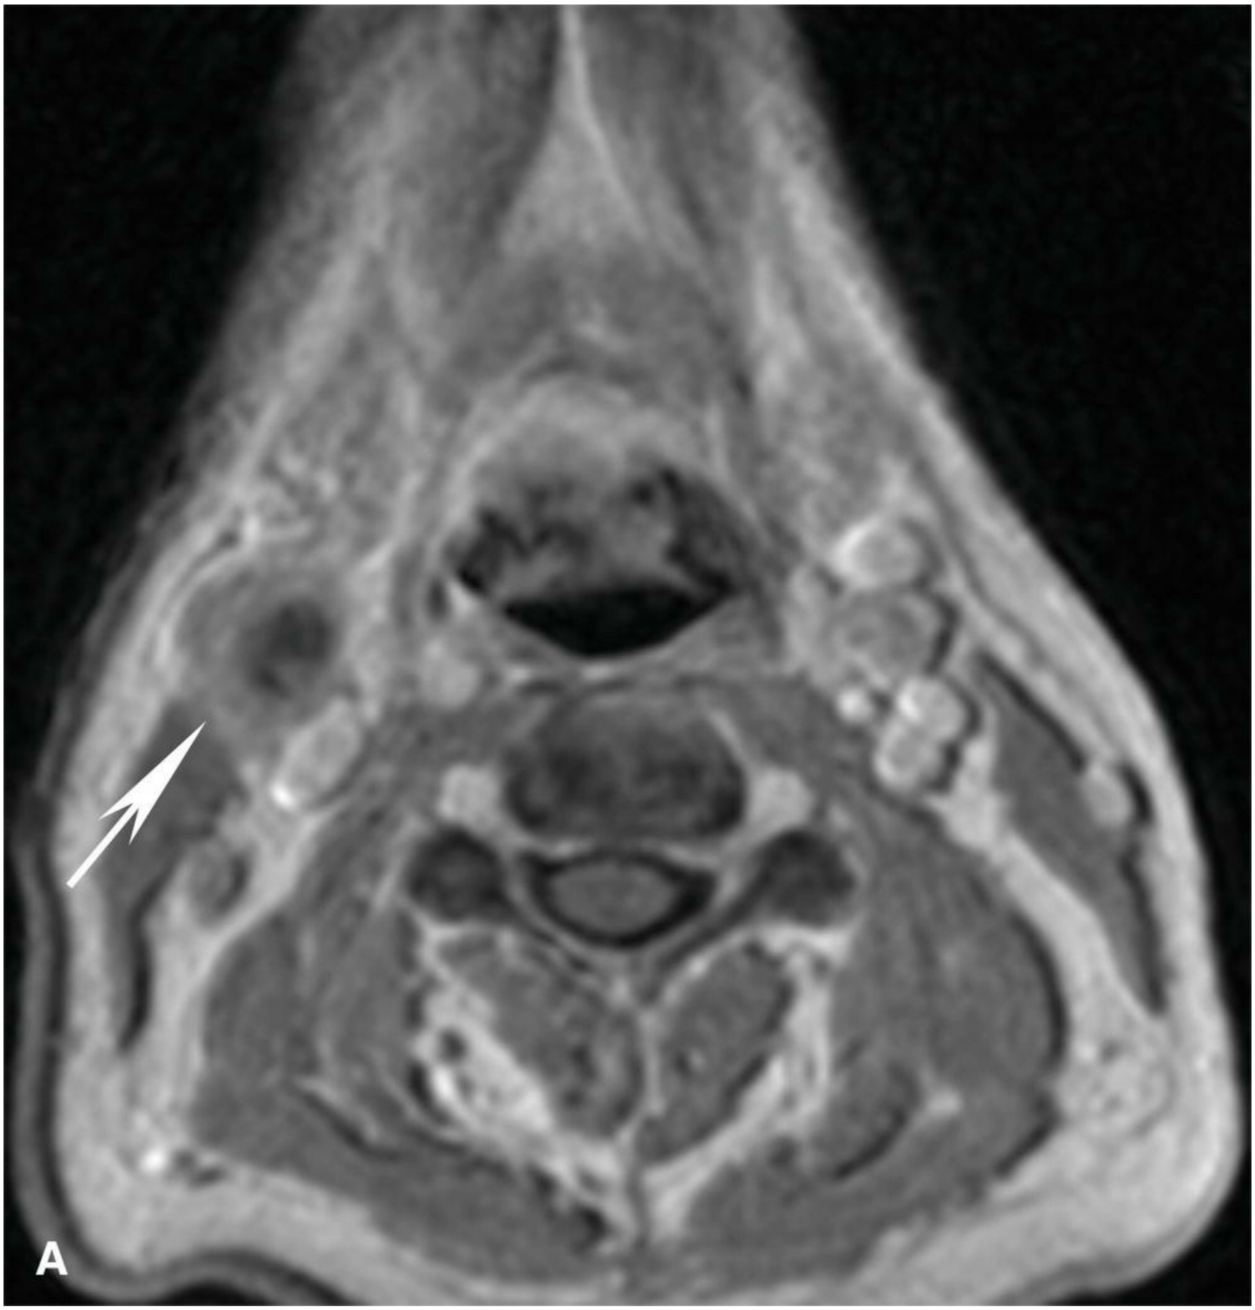
EMERGING IMAGING TECHNIQUES FOR EVALUATION OF HEAD AND NECK CANCER AND CONCLUSIONS

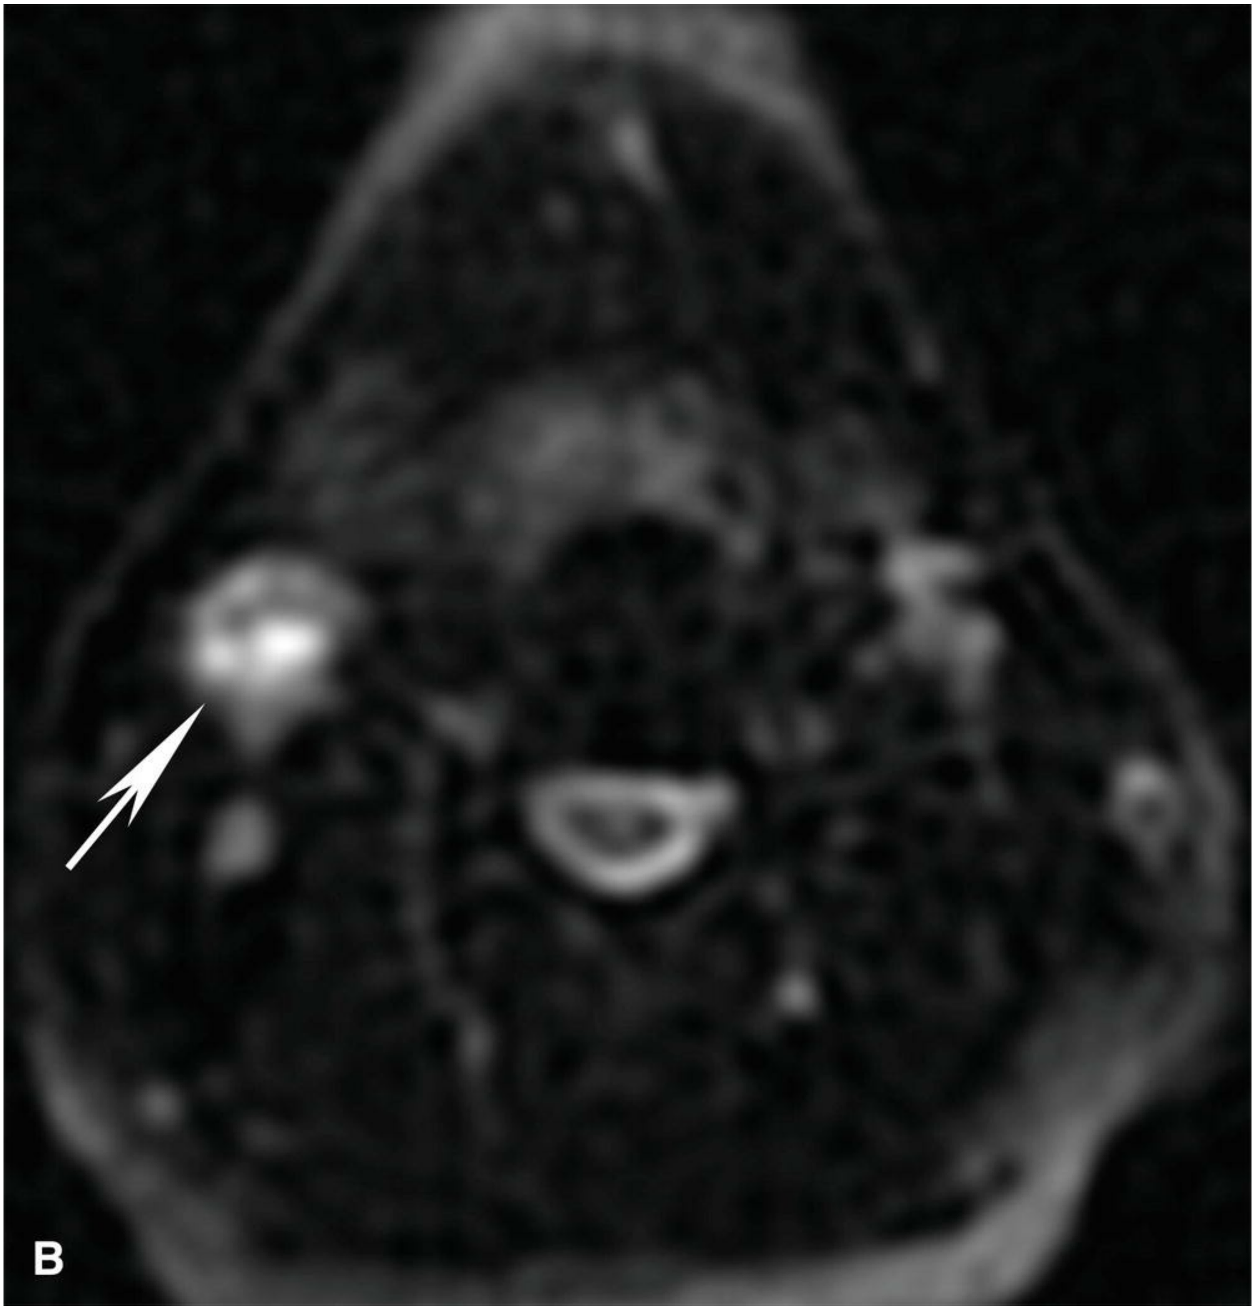
Emerging Imaging Techniques for Evaluation of Head and Neck Cancer

Diffusion-Weighted MR Imaging

Diffusion-weighted magnetic resonance imaging (DWI) is a technique used to evaluate the diffusion of water molecules in tissues with applications to a wide array of pathologic conditions.[120] DWI is widely used in brain imaging and is the most reliable imaging method for evaluation of acute brain ischemia. However, there are additional potential applications of DWI, including in imaging of tumors. When evaluating tumors, the basic principle behind DWI is that tissues with higher cellularity form a greater barrier to water diffusion compared to less cellular tumors.[120–123] A detailed discussion of the DWI imaging and specific maps generated is beyond the scope of this chapter. However, in general, malignant tumors tend to demonstrate greater restriction/barrier to water diffusion, reflected in a lower measured value of the ADC map. In addition to primary tumor, DWI has been used for evaluation of lymphadenopathy (Fig. 5.53), to predict prognosis, and to evaluate tumor response, and the initial results are encouraging.[121–126] One pitfall of DWI is that even though the trends between tumor and benign tissues are different, there can be significant overlap between individually measured ADC values. Quantitative mapping has the potential to improve

accuracy, but incorporation into routine clinical practice is a challenge that would have to be overcome. It should also be noted that DWI can be technically challenging to optimize in the neck and can be limited in its spatial resolution. At this time, DWI is not in routine use, and the added value of the technique and incorporation in routine daily practice for evaluation of head and neck cancer requires further investigation and validation.





B

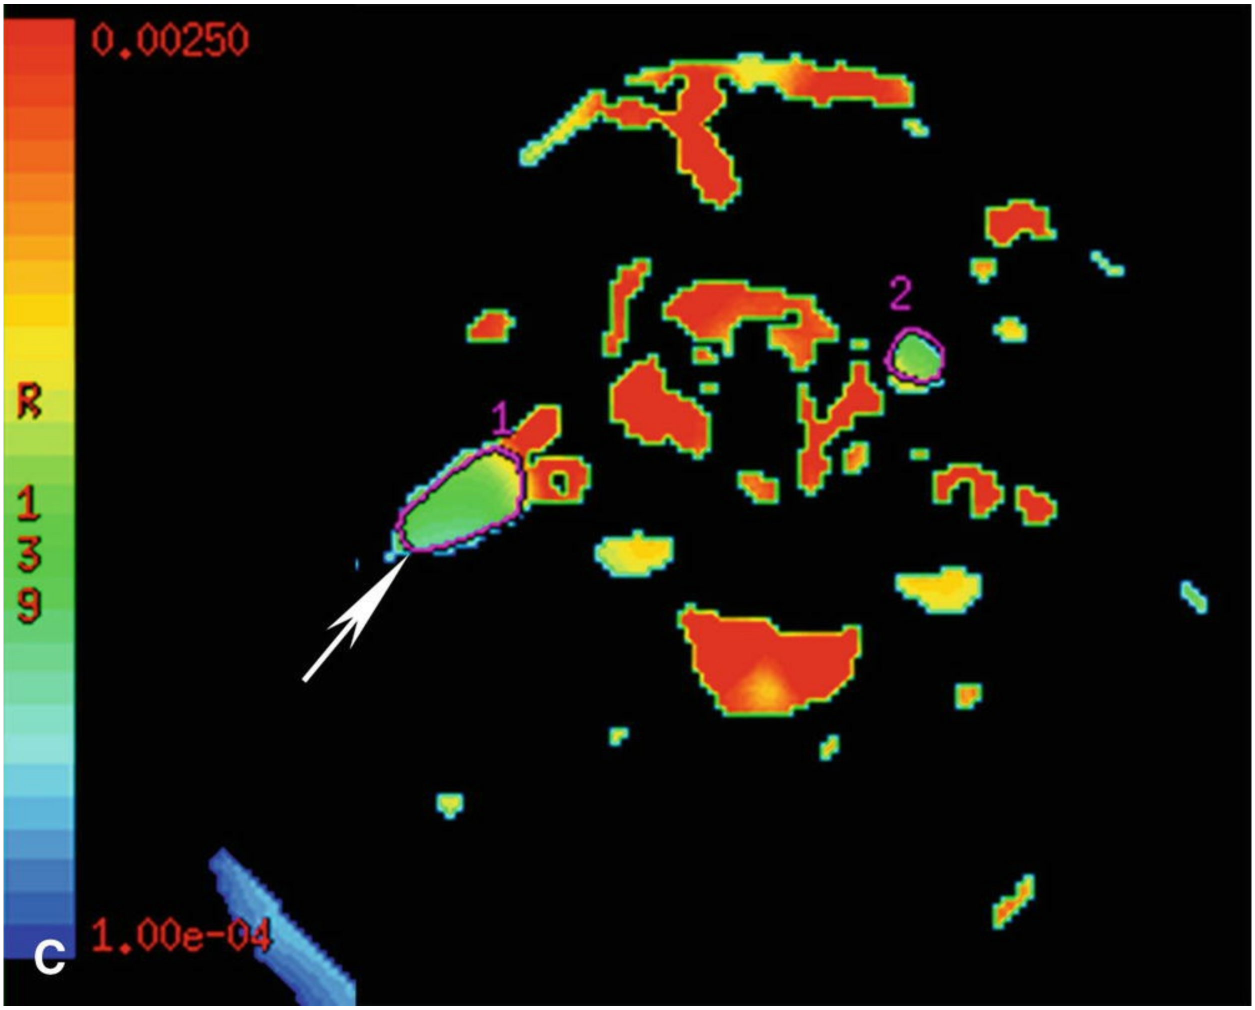


Figure 5.53. Diffusion-weighted imaging in head and neck cancer. Axial contrast-enhanced T1w **(A)** MRI image from a patient with a base of tongue cancer (not shown) demonstrates a pathologic right level II node (*arrow*). Standard **(B)** and color-coded ADC maps **(C)** (b = 500 mm/s^2) demonstrate areas of relative restriction (decreased ADC value) within the pathologic lymph node. On the standard ADC map shown in **(B)**, these appear as relatively dark areas intermixed with foci of high signal. On the color-coded map, the ADC value can be compared to other structures based on the color-coded scale provided on the left side. (Figures courtesy of Dr. A. Dmytriw.)

Dual-Energy Computed Tomography

Dual-energy CT (DECT) is a CT technique based on simultaneous or near-simultaneous acquisition of images at two different x-ray energies, enabling spectral evaluation of tissues and material tissue characterization beyond

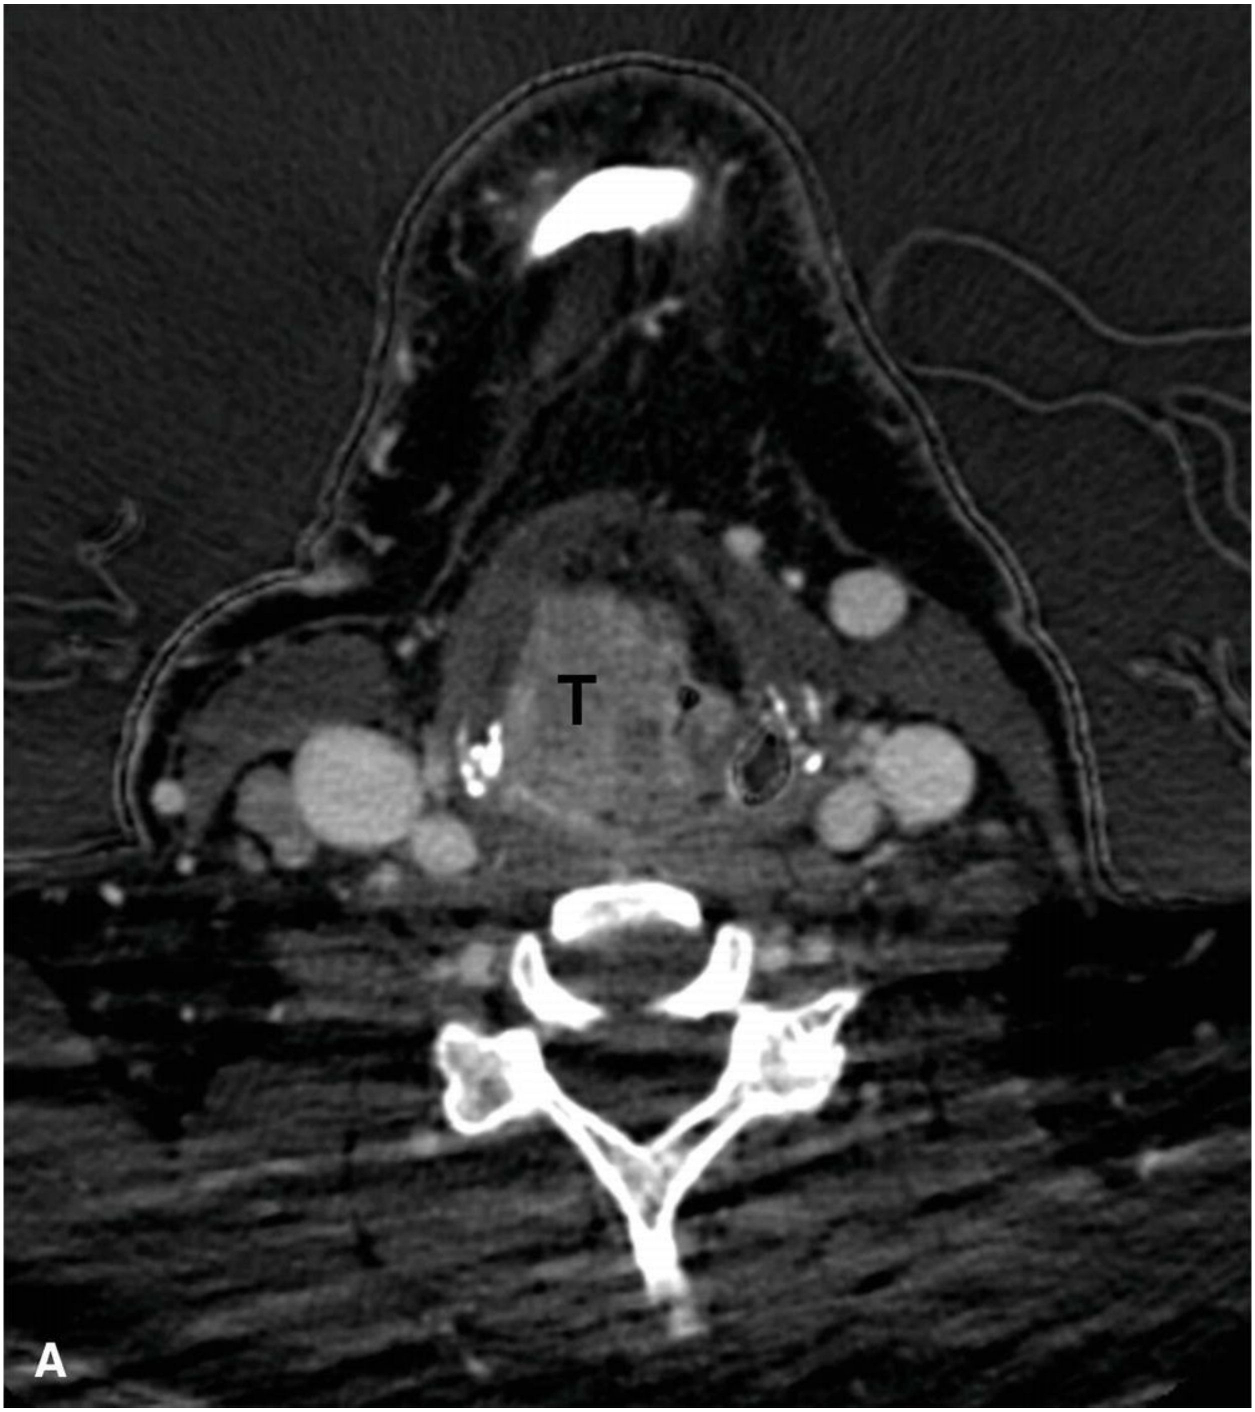
what can be done with a conventional CT scan.[127] There is emerging evidence that DECT may increase head and neck cancer tumor conspicuity, improve accuracy for determination of thyroid cartilage invasion, and may improve evaluation of areas degraded by artifacts due to dental fillings and implants.[96,128–139] In brief, scans acquired as a dual-energy scan can be processed to generate virtual monochromatic images (VMIs) and iodine maps, among other functionalities, for complementary evaluation of head and neck cancer.

VMIs are images reconstructed at different energy levels and can be used to accentuate different tissue characteristics. For example, lower energy VMIs accentuate iodine content and therefore can increase tumor conspicuity[132,134–137] (Fig. 5.54). Iodine overlay maps are color-coded maps that are mathematically extracted from the DECT data reflecting the iodine content of tissues and can be used to highlight the iodine content of enhancing tumor compared to background structures (Fig. 5.55). In one study, these have demonstrated to increase accuracy for determination of thyroid cartilage invasion.[128] In addition, nonossified thyroid cartilage has different characteristics than tumor on high-energy VMIs, and these reconstructions could also be helpful for the evaluation of thyroid cartilage[133] (Fig. 5.56). More advanced quantitative analysis can also be performed with DECT. As such, DECT is a promising technique for evaluation of head and neck cancer. However, it should be noted that DECT is not yet in widespread use and its added value requires further validation. Furthermore, for successful implementation into routine practice, it is important that the key reconstructions are automatically generated and readily available for interpretation.

T
A

Figure 5.54. Dual-energy CT (DECT) virtual monochromatic images (VMI) for increasing tumor conspicuity. DECT images from a patient with a right hypopharyngeal tumor (T) with lateral spread are shown. 70 keV VMI **(A)** (the energy level typically considered similar to conventional single-energy CT) and 40 keV VMI **(B)** of the same level are shown. The images are windowed similarly to provide a proper comparison (note the similar very

low dark density of subcutaneous fat). Note the increased conspicuity of the tumor and its margins on the 40 keV VMI **(B)** compared to the 70 keV VMI **(A)**.



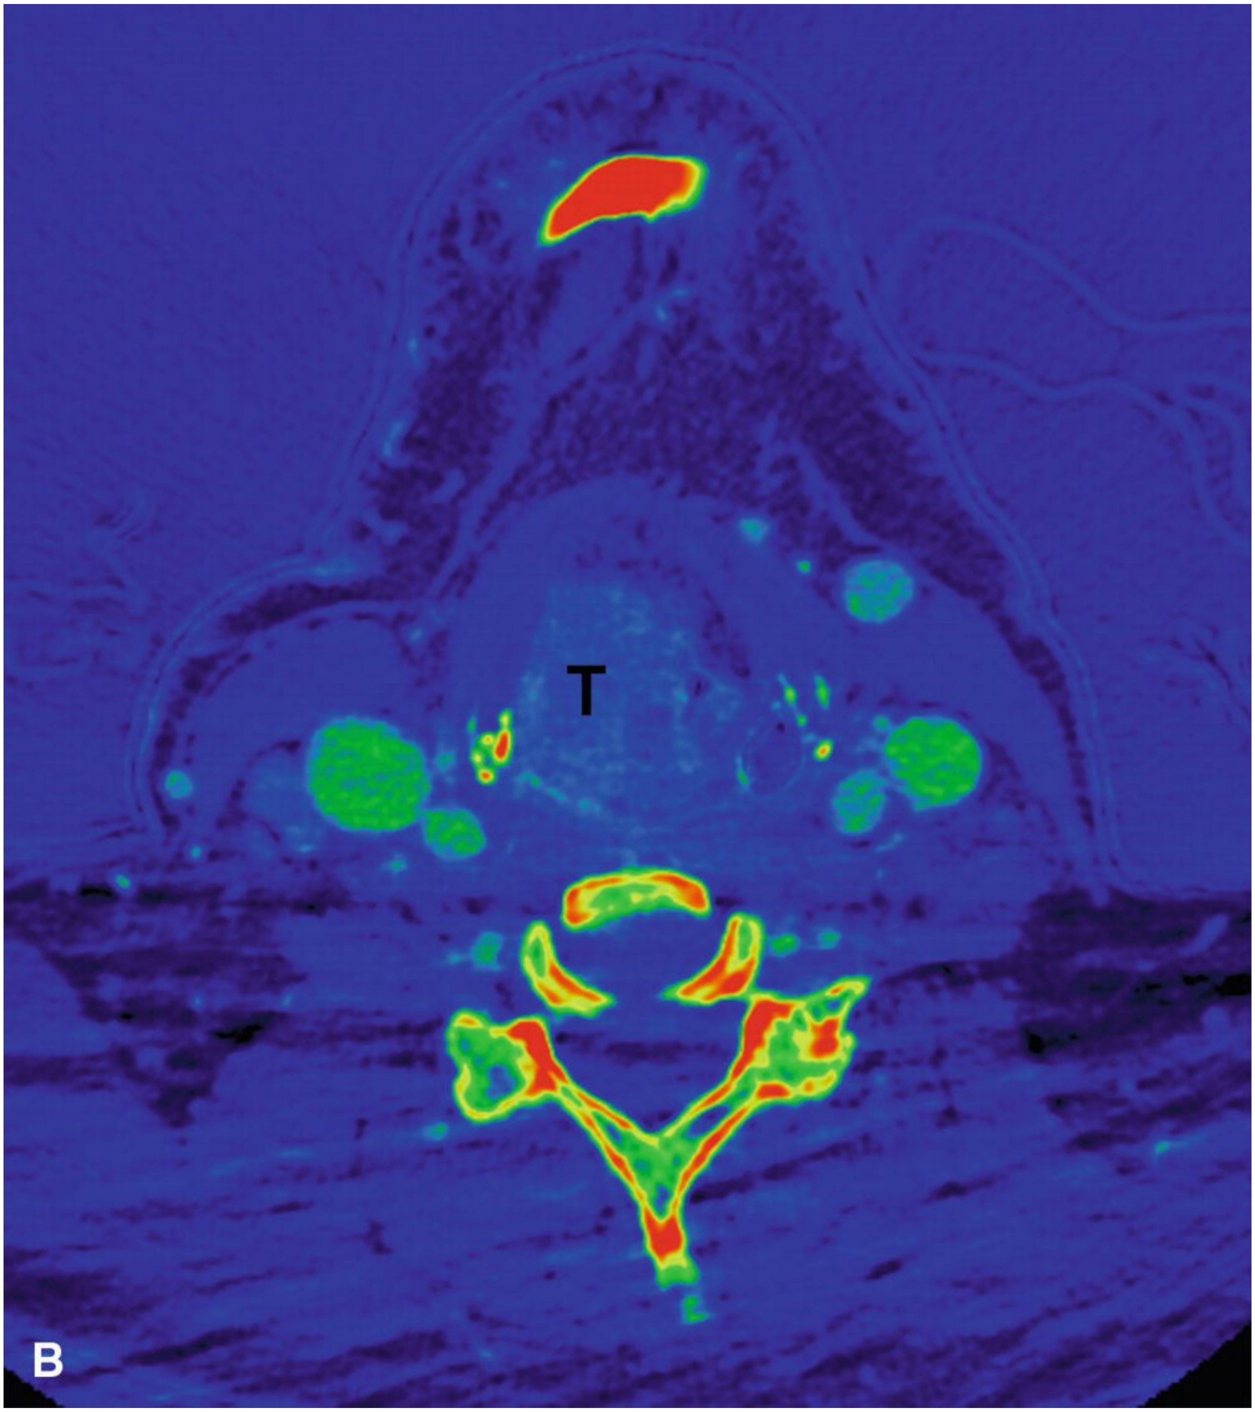


Figure 5.55. Dual-energy CT (DECT) iodine overlay maps. Iodine overlap map displayed in gray scale **(A)** and color **(B)** is shown from a patient with supraglottic squamous cell carcinoma (T). Note the increased iodine content of tumor (T), as reflected in the density/brightness, compared to muscles. As expected, the vessels have the greatest iodine content of the soft tissues.

T
A

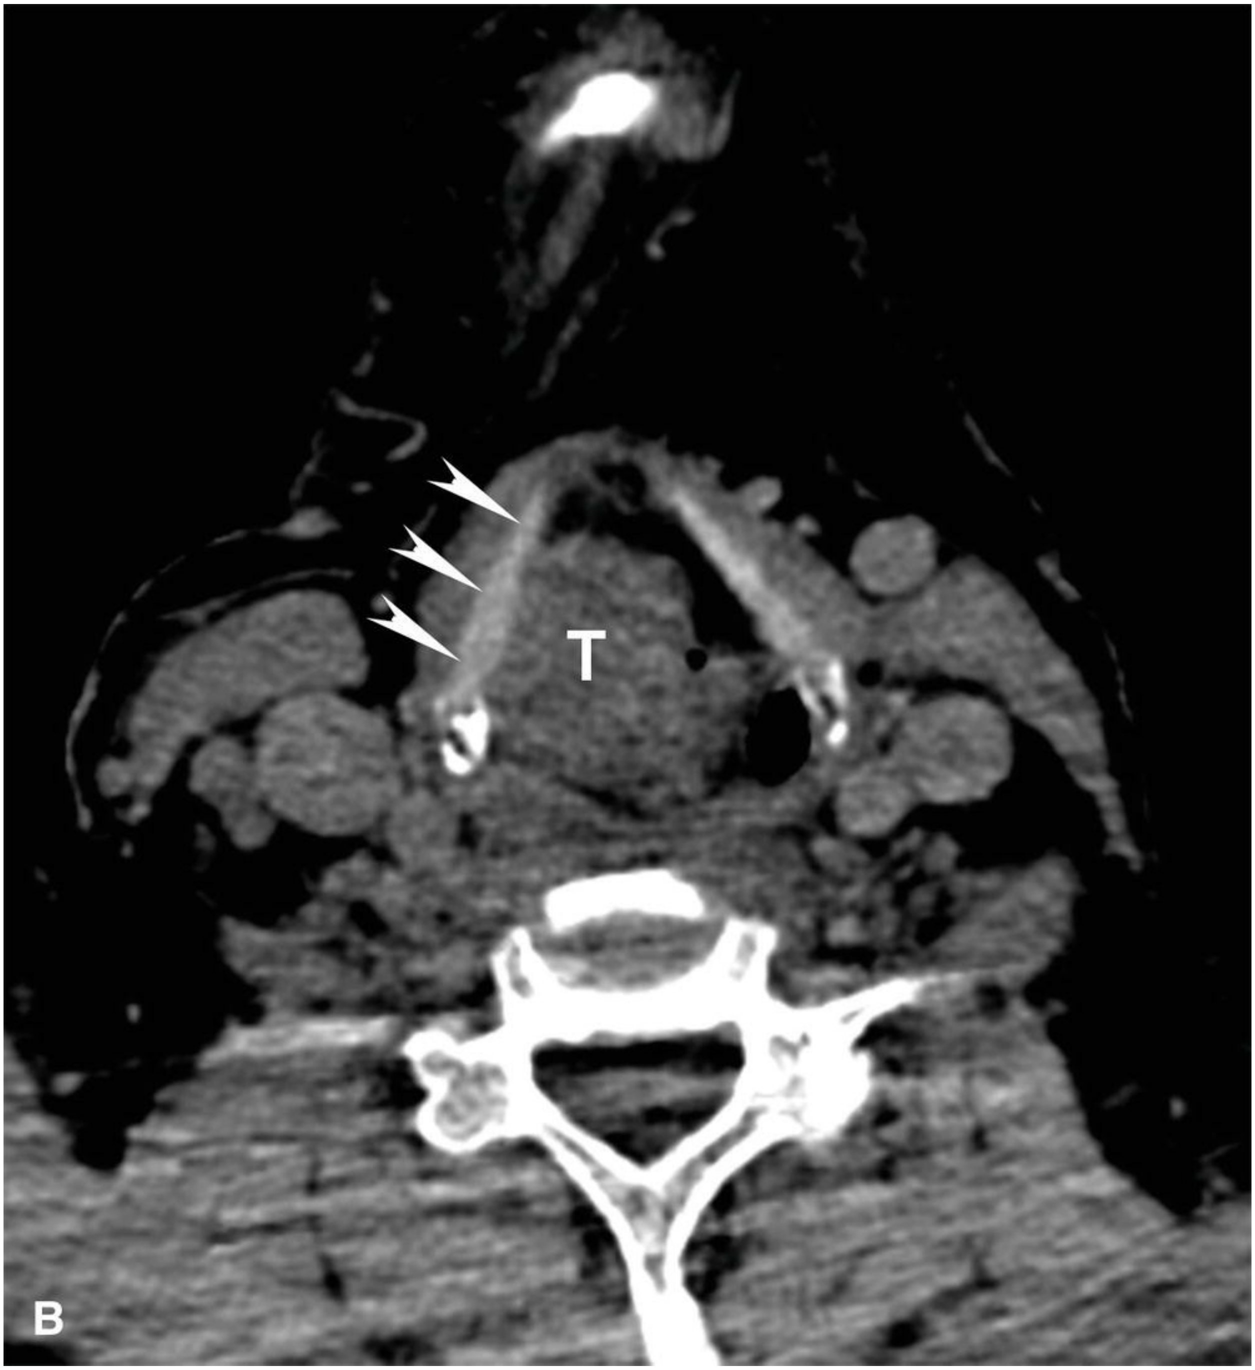

Figure 5.56. Dual-energy CT (DECT) virtual monochromatic images (VMI) for the evaluation of nonossified thyroid cartilage (NOTC). DECT images are shown from a patient with a right laryngeal cancer (T). **A:** On the 70 keV VMI, the NOTC (*arrowheads*) density is similar to tumor (T) and the interface with the abutting tumor is not very clearly seen. **B:** On high-energy 140 kev VMI, the density of iodine from tumor (T) is suppressed and a sharp interface seen between NOTC (*arrowheads*) and adjacent tumor (T).

Other Imaging Techniques for Evaluation of Head and Neck Cancer

Perfusion imaging, performed either with CT or MRI, has been investigated for evaluation of head and neck cancer. Although preliminary studies have suggested that perfusion imaging may be useful for predicting tumor response to treatment,[140,141] these studies require further validation and are currently not in routine use. With introduction of integrated PET-MRI units, this modality is also being explored for evaluation of head and neck cancer,[142,143] but so far, there are limited data available. Furthermore, with regard to the evaluation of the neck, PET-MRI will be prone to the same technical challenges that were described earlier for conventional MRI. In addition, obtaining whole-body coverage will be much more of a challenge with PET-MRI than CT. These represent interesting areas of future research.

CONCLUSIONS

Imaging is an integral part of proper staging, follow-up, and management of head and neck cancer. Optimal imaging of head and neck cancer patients requires familiarity with the different techniques, their strengths, and pitfalls and should be tailored to the primary site of interest based on results of the clinical assessment. Radiologic evaluation and interpretation of head and neck studies requires familiarity with the complex anatomy of the head and neck, patterns of spread of tumors at different sites, and the AJCC staging system. So armed, the radiologist can provide a clinically relevant evaluation and play a key role in determining optimal patient management as part of the multidisciplinary team.

6 Anesthetic Management for Head and Neck Cancer Surgery

Angela Truong and Dam-Thuy Truong

On October 16, 1846, in a public demonstration in the Ether Dome of the Massachusetts General Hospital, William T.G. Morton administered inhaled ether to Edward G. Abbott for resection of a neck tumor by John C. Warren.[1] This milestone revolutionized the practice of medicine and surgery. It is noteworthy that at the birth of anesthesiology as a brand-new medical specialty, general anesthesia (GA) was provided for a surgical procedure in the neck. Over the centuries, while considerable scientific and technological advances have been achieved, the professional bond between head and neck surgery and anesthesiology has not only been preserved but also strengthened.

Anesthesia management for head and neck cancer surgery presents unique and often formidable challenges. The main predisposing factors to head and neck cancers are tobacco consumption and alcohol consumption.[2] Consequently, head and neck cancer patients often present with respiratory and cardiovascular comorbidities, which increase the complexities and challenges of the perioperative management. Furthermore, difficult airways are encountered in head and neck cancer surgery more commonly than in any other type of surgery. The invasion of the airway by tumors and the sequelae of previous surgical resections and/or radiotherapy or chemoradiotherapy may render mask ventilation and tracheal intubation difficult or even impossible after induction of GA. Finally, surgical and anesthesia teams must share their work space in the restricted area of the head and neck and the narrow confines of the airway. Surgeons require optimal exposure and complete access to the head and neck area or the airway itself. Anesthesiologists must achieve access and control of the airway to ensure adequate ventilation, oxygenation, and delivery of inhalation anesthesia.

Therefore, the demands for surgery and anesthesia may be in direct conflict. For example, in laser surgery for laryngeal tumors, the anesthesiologist may need to provide a high inspired concentration of oxygen to ensure adequate oxygenation of the patient, whereas the surgeon requires a low concentration to prevent fire. Constant communication between surgical and anesthetic team members can prevent intraoperative airway issues such as accidental extubation or disconnection of breathing circuits. This chapter highlights our personal daily work experience providing anesthesia for a high volume of head and neck cancer surgeries performed at the MD Anderson Cancer Center. Special emphasis will focus on the recent innovations in clinical anesthesia, which are of special interest to our surgical colleagues.

PREOPERATIVE EVALUATION OF ANESTHETIC RISK

The perioperative management of anesthesia for head and neck cancer surgery encompasses preoperative assessment and intraoperative and postoperative anesthetic management. The American Society of Anesthesiologists (ASA) Practice Advisory for Preanesthesia Evaluation considers the preoperative evaluation as the first and most fundamental component of anesthetic practice and requires that all patients scheduled for surgery under anesthesia receive a preoperative anesthetic evaluation.[3] This assessment also serves as a medicolegal document to be incorporated in the patient’s medical record. The objectives are to assess anesthetic-related risks and predict the likelihood of complications during the perioperative period for each patient undergoing a specific surgical procedure.[4] Furthermore, active interventions may be undertaken to modify these risk factors in the hope of reducing morbidity and mortality and improving outcomes. The preoperative evaluation allows the anesthesiologist to formulate the most appropriate perioperative plan for anesthesia care and to discuss with the patient about the risks and benefits in order to obtain an informed consent.

ASSESSMENT OF COEXISTING MEDICAL DISEASES

The preanesthesia evaluation includes pertinent medical history obtained from medical records and the patient interview, physical examination, and laboratory investigations. Preoperative tests should not be ordered routinely, but only when indicated for the purpose of guiding perioperative management, and may include hemogram, coagulation studies, serum chemistries, electrocardiogram, chest radiograph, and urine pregnancy test for female patients of childbearing age.[5] The information obtained allows anesthesia providers to categorize the overall physical health or sickness of patients before surgery according to the ASA physical status classification[6]:

1. A normal healthy patient
2. A patient with mild systemic disease
3. A patient with severe systemic disease
4. A patient with severe systemic disease that is a constant threat to life
5. A moribund patient who is not expected to survive without the operation
6. A declared brain-dead patient whose organs are being removed for donor purposes

For emergency cases, the letter E is added after the physical status class.

Even though the original intent of the ASA was to design a simple physical status stratification, the ASA classification has been used by hospitals, law firms, and health care organizations as a scale to predict perioperative risk.[7] In general, for low-risk procedures, ASA class 1 and 2 patients may proceed to surgery without further delay. In contrast, patients classified in ASA class 3 or higher may require appropriate specialty consultations to further investigate coexisting morbidities.

MEDICAL SPECIALTY CONSULTATIONS

For patients with multiple medical diseases, an internal medicine consultation is valuable to assess the severity of comorbid conditions, elicit further investigations, and institute measures to optimize the patient prior to surgery. Thus, the adjustment of antihypertensive medication dosages for better control of blood pressure and diabetes medications for improved blood glucose control may be achieved. Similarly, patients with congestive heart failure may be prescribed inotropes or diuretics. Patients with chronic

obstructive pulmonary disease may be treated with appropriate antibiotics, steroids, and/or bronchodilators. For cancers involving endocrine glands such as the thyroid and parathyroids, optimization of hormonal functional status by endocrinology consultation is an integral part of the surgical evaluation.

Considering that more than 50% of deaths after surgery are related to cardiac events, a cardiology consultation is warranted if the patient presents with severe cardiovascular diseases.[8] The American College of Cardiology/American Heart Association Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery base the need for further investigations on the presence of risk predictors for perioperative cardiac events, the patient's functional status, and the level of risk of the planned surgical procedure.[9]

Clinical predictors of increased risk for perioperative cardiac complications are classified into major, intermediate, and minor predictors. Major predictors include unstable angina, recent myocardial infarction, severe valvular heart disease, decompensated congestive heart failure, and significant arrhythmias. Intermediate predictors include stable angina, prior myocardial infarction by history or by electrocardiogram, compensated congestive heart failure, diabetes mellitus, and renal insufficiency. Minor predictors include advanced age, abnormal electrocardiogram, history of stroke, and uncontrolled hypertension.

The patient's functional capacity is the second major determinant of perioperative cardiovascular complications. Functional capacity or ability to work is measured in metabolic equivalents (METs). One MET equals the oxygen consumption of a 70-kg, 40-year-old man in a resting state. It is a physiologic measure expressing the energy cost of physical activities and is defined as the ratio of metabolic rate (and therefore the rate of energy consumption) during a specific physical activity to a reference metabolic rate, set by convention as 3.5 mL O_2/kg/min.

The specific risk level inherent to the proposed surgical procedure must also be taken into consideration. High-risk surgeries include emergency, aortic, peripheral vascular, and radical head and neck cancer resection followed by complex free flap plastics procedures. Intermediate-risk surgeries include orthopedic, urologic, and uncomplicated abdominal and thoracic procedures. Many types of head and neck surgical procedures,

thyroidectomy, elective neck dissection, and parotidectomy also belong to this group. Low-risk surgeries include breast, cataract, and head and neck endoscopic procedures. As a rule, according to these guidelines, the planned surgery can proceed if it is an emergency surgery, if the surgical procedure is of low risk, or if the patient's functional status is equal to or greater than 4 METs without acute cardiopulmonary symptoms. In contrast, the presence of serious clinical predictors, low functional capacity, or high-risk surgery, either alone or in combination, indicates the need for further testing for left ventricular function or inducible coronary ischemia to determine if any intervention is indicated to optimize these risks before surgery.

PERIOPERATIVE MANAGEMENT OF PATIENTS WITH PACEMAKERS OR IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

Cardiac electronic devices such as pacemakers or implantable cardioverter defibrillators (ICDs) are encountered with increasing frequency in older patients presenting for head and neck surgery. The Heart Rhythm Society/American Society of Anesthesiologists suggests a preoperative check for these devices to determine the indication for implantation, adequate functioning of the device, and degree of pacemaker dependency.[10] Device malfunction or failure during surgery may result in serious injury and death. Prior to surgery, an ICD is programmed to a "monitor-only" mode to prevent inappropriate shock delivery from accidental sensing of electrical interference. To minimize the risk of intraoperative electromagnetic interference, the use of monopolar mode of operation of electrocautery should be avoided whenever possible.[11] When monopolar electrocautery is necessary, its use should be limited to intermittent short bursts. The electrocautery current return or grounding pad should be positioned so that the current pathway between the electrocautery electrode and return electrode is as far away from the device as possible. The application of a magnet over the pacemaker converts its function into a fixed rate mode. Unfortunately, the paced R wave may fall on the T wave of the patient's own beat and precipitate ventricular tachycardia or ventricular fibrillation due to R on T

phenomenon.[12] When the site of surgery is far from the chest, pads for an external pacing system should be applied. If the pacing pads are in the surgical field, a temporary transvenous pacing catheter should be inserted instead. Equipment for external pacing, defibrillation, and cardiopulmonary resuscitation should be immediately available. Close hemodynamic monitoring should be achieved with an arterial line and a cardiac output monitor. Hypoxia, acidosis, electrolyte abnormalities, and antiarrhythmic medications may cause pacemaker failure. Fentanyl, sufentanil, and remifentanil should be avoided because of risk of inducing severe bradycardia. Hydromorphone should be selected as the opioid of choice in these patients. At the conclusion of surgery, the device must be interrogated and reprogrammed to ensure proper functionality.

PREOPERATIVE OPTIMIZATION

In preparation for surgery, the patient's comorbidities should be medically optimized. Medications should be reevaluated and adjusted to achieve optimal blood pressure control in patients with hypertension and glycemic control in those with diabetes mellitus. Patients with severe chronic bronchitis and emphysema might require treatment with bronchodilators, steroids, and/or appropriate antibiotics. Congestive heart failure and unstable angina should be adequately treated. Cessation of smoking should be encouraged. Nutritional status should be improved. Preoperative psychological assessment and optimization is also crucial, yet often overlooked.[13] Many patients with head and neck cancer are clinically depressed at diagnosis. In addition to the anxiety related to being diagnosed with cancer, these patients must also deal with the disfiguring effects of craniofacial resection and loss of their natural voice in cases of laryngectomy.[14] Proper attention should be devoted to psychological preparation, particularly for children and young adults.

Preoperative Assessment of the Airway

Once the patient has been optimized and cleared for surgery, an assessment focused on specific intraoperative anesthetic considerations for anesthesia should be performed. The most important focus of the preanesthetic evaluation for head and neck cancer surgery is the assessment for a difficult

airway and formulation of a plan to secure the airway. Failure to secure the airway has been widely recognized as a leading cause of poor outcomes in the practice of anesthesia.[15] The single most important reason of failed airway management is the failure to properly assess the airway preoperatively and adequately anticipate difficulties in airway management.[16]

History obtained through review of medical charts and patient interview elicits information concerning previous general anesthetics and intubation difficulties. A history of difficult intubation should be taken into account even though the patient's airway may appear easy on routine examination. Furthermore, a past history of easy intubation does not guarantee that the patient remains easy to intubate because, in the interval, the tumor may have rapidly enlarged or postradiation trismus may have worsened. Special concern should be raised when the following warning signals about potential difficulties are encountered. By simply looking at the operating room schedule, the proposed surgical procedures may implicitly allude to a potentially difficult airway. Thus, emergency exploration of hematoma in the neck, drainage of a retropharyngeal abscess, and surgery for Ludwig angina often imply serious potential challenges with airway management. Even for elective cases, some of the planned procedures should raise alarm. For instance, total laryngectomy is scheduled usually because of extensive laryngeal involvement. Possible tracheostomy implies high risk of airway obstruction. Tracheal resection implies extensive involvement of the trachea by cancer that may impede passage of the tracheal tube. Physical examination of the patient also alerts anesthesia providers to the possibility of airway problems. Changes in the patient's voice may give valuable clues to the location of the tumor. A scratchy, raspy, hoarse voice often indicates a lesion of the vocal cords, whereas a muffled "hot potato" voice suggests a pharyngeal or supraglottic tumor. An anxious patient who is sitting up, leaning forward, drooling, and stridorous with use of accessory respiratory muscles is clearly in danger of impending complete airway obstruction. Tachycardia, tachypnea, and profuse sweating denote hypercapnia. Somnolence often heralds impending respiratory arrest. A foul-smelling odor should warn of a necrotic tumor. Grossly distorted anatomy with evidence of prior head and neck surgery and radiation therapy are all red flags. The presence of severe trismus, dysphagia, odynophagia, copious oral secretions, and bleeding from tumors indicate a high risk for airway difficulties.

The systematic airway assessment starts with the examination of the teeth to anticipate and prevent perioperative dental injury. Injury to the teeth is one of the most common anesthesia-related adverse outcomes.[17] It is also the most common cause for malpractice litigation against anesthesia providers.[18] Preexisting dental conditions that predispose to dental injury include severe gingivitis, capped teeth with veneers, permanent bridges, crowns, and implants. An isolated tooth adjacent to edentulous gums and preexisting loose tooth are susceptible to damage or dislodgement with even the slightest laryngoscope blade-tooth contact. Most dental damage occurs during intubation using rigid laryngoscopes. Dental injury may also occur during insertion and removal of an oral airway, intubating airway, tooth guard, or supraglottic device. The best method for prevention of dental injury is by performing fiberoptic nasal intubation.

Airway assessment for head and neck cancer surgery must take into consideration not only the features of the difficult airway common in previously untreated patients but also the potential difficulties in airway management caused by the effects of previous surgery and radiation therapy and the presence of tumor involving the airway. Many patients may have already undergone head and neck cancer surgeries. Common surgical procedures for neck and neck cancers such as thyroidectomy, parotidectomy, and neck dissection have relatively minor impact on subsequent management of the airway. In contrast, patients who have undergone extensive resection followed by complex free flap reconstruction, those with osteoradionecrosis of the mandible with exposed bone grafts and hardware, and patients with aggressive cancer recurrence often present with severely restricted mouth opening and bulky flaps in the oropharyngeal cavity. These changes distort the anatomy of the airway, rendering ventilation and intubation very challenging.

The majority of head and neck cancers are squamous cell carcinomas, which are relatively radiosensitive. Radiation therapy may cause severe burns followed by fibrosis of the local and regional tissues. Similarly, the effects of previous head and neck radiotherapy can render management of the airway extremely difficult. To compound this challenge, radiation effects are difficult to assess and often overlooked by anesthesia providers.[19] Acute radiation injury of the mucous membranes of the airway causes severe erythema, edema, and mucositis with thick white pseudomembranes.

Ulceration and necrosis may result in severe cases, with the affected area extremely vulnerable to mechanical trauma. The slightest mechanical injury during airway manipulation may cause bleeding and severe edema of the epiglottis and vocal cords, progressing rapidly to the inability to ventilate and to intubate. The fibrotic scar causes anatomic distortion and severe reduction in tissue flexibility and mobility: reduced mouth opening, limitation of neck motion, and laryngeal fibrosis.[20] Decreased secretion of saliva secondary to radiation burns of the salivary glands can result in xerostomia and fissures of the oral mucosa. Maintenance of oral hygiene is difficult, with resulting severe gingivitis and dental decay. Subacute and chronic effects involve the connective tissues and cause slow but progressive fibrosis. The affected skin appears retracted, discolored, atrophic, and cold. Involvement of the muscles of mastication and the temporomandibular joints can result in severely restricted mouth opening. The pharynx and supraglottic area may become fibrotic, fixed, and fused. The soft tissues of the airway lose elasticity, and the affected areas become indurated and retracted, resulting in severe limitation of neck extension. The submandibular area may become an irregular mass with a firm woody consistency to palpation. These affected structures are often immobile and unyielding to attempts at visualizing the larynx during laryngoscopy. For the same reasons, effective bag-mask ventilation and placement of an extraglottic device can be very challenging or even impossible.[21] Similarly, percutaneous cricothyrotomy or emergency tracheostomy to rescue the failed airway may encounter formidable difficulties due to the distorted anatomical landmarks and fibrotic tissue planes. An edentulous patient with Mallampati class I airway may appear deceptively easy to intubate. Overlooking the postradiation changes of the supraglottic area may rapidly lead to a “cannot intubate–cannot ventilate” crisis after induction of GA.

Tumors can cause difficulties in securing the airway because of their location, size and friability, and pathology. Location is the most important factor to consider. In general, tumors in the upper airway (nasal, oral, and pharyngeal lesions) are usually detected early and carry less risk of complete airway obstruction. In contrast, tumors involving the lower airway such as the supraglottic area, vocal cords, and trachea are more likely to cause greater challenges in airway management.[22] These tumors occupy a small volume space and may be more susceptible to causing complete obstruction.[23]

Fortunately, these lesions are usually detected early because of early symptoms. Epiglottic tumors are particularly insidious and deceptive. They can grow rapidly to reach a very large size and yet cause no respiratory symptoms.[24] Figure 6.1 depicts the laryngoscopic view after awake intubation showing the tracheal tube (A), epiglottis (B), and a large supraglottic Merkel cell carcinoma (C) covering the glottic opening. Carcinomas that are bulky, friable, and actively bleeding carry the risk of aspiration of tumor fragments and blood during traumatic intubation attempts.

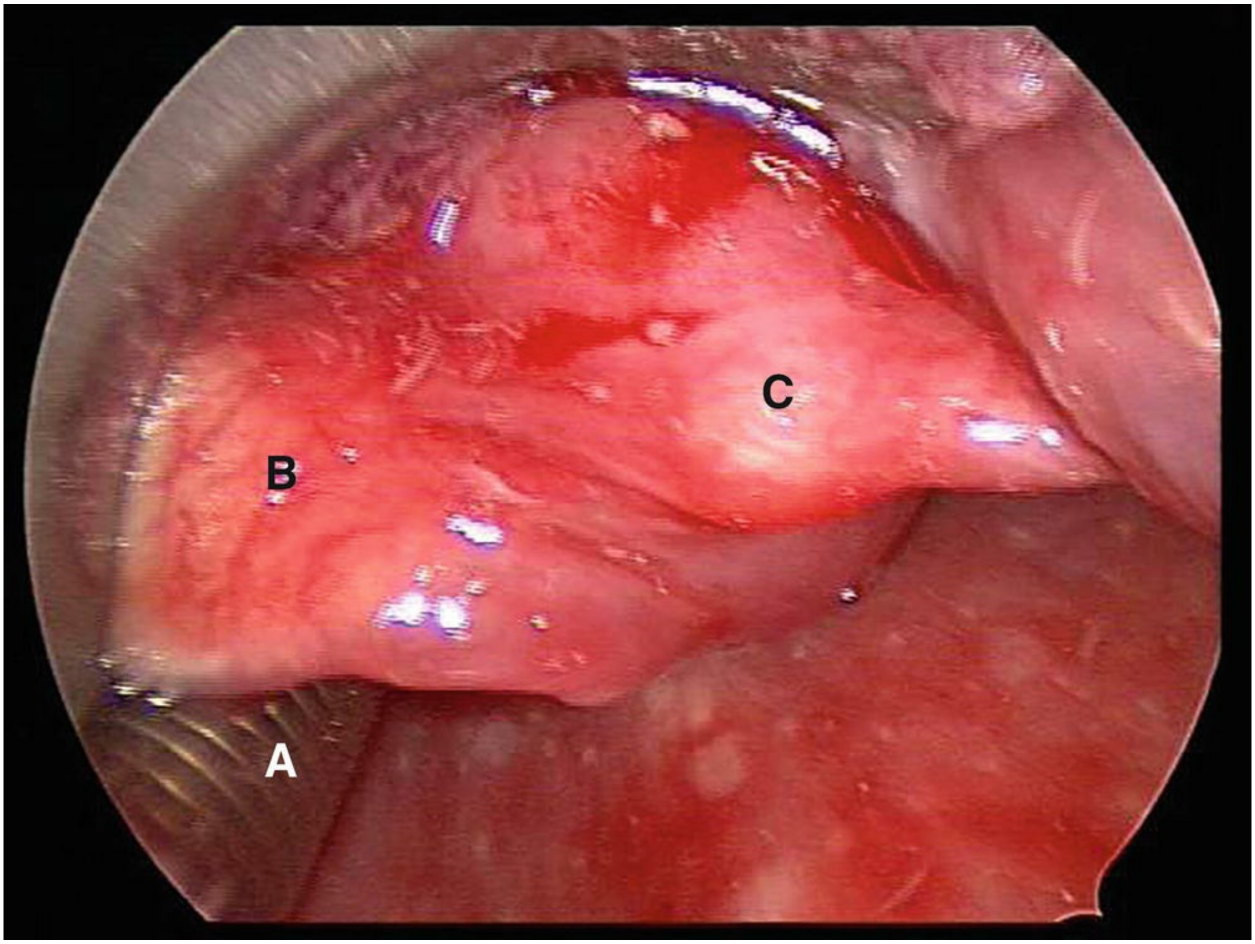

Figure 6.1. Laryngoscopic view of a supraglottic carcinoma.

Carcinomas deep inside the airway, which cannot be detected by visual inspection, require further investigation by diagnostic imaging and endoscopy. Chest radiographs of patients may show tracheal narrowing and/or deviation or widening of the superior mediastinum. CT scans of the

neck and chest are better able to assess the extent of the tumor and its effect on surrounding structures, especially tracheal compression, deviation, or invasion. Virtual bronchoscopy combines CT with computer-assisted image processing to produce intra- and extraluminal views of the airways as they would appear during actual bronchoscopy. Magnetic resonance imaging offers better assessment of cartilaginous and soft tissue anatomical structures in the evaluation of tumor extension and degree of airway obstruction.

Nasopharyngoscopy performed in the head and neck surgery clinic provides the anesthesiologist with valuable information about the location, size, and degree of airway obstruction caused by the tumor. For lesions in the glottic area, laryngoscopy videos show the tumor and the motion of the vocal cords during the respiratory cycle. If there is a long interval between these studies and the day of surgery, the attending anesthesiologist can perform nasopharyngoscopy under local anesthesia in the operating room before induction of GA to help decide on the best approach of securing the airway.[25] It is important to keep in mind, however, that the ability to visualize the glottic opening in an awake, spontaneously breathing patient does not guarantee that similar views can be obtained once the same patient is rendered unconscious, paralyzed, and apneic.

Airway Assessment Mnemonics

There is no substitute for a thorough systematic assessment of the airway. Nevertheless, in daily practice, aids such as airway mnemonics[26] are very useful as concise checklists specifically designed to quickly identify the features that may cause difficulties in various aspects of airway management. The most important mnemonics that help anticipate difficulty regarding ventilation, intubation, and risk of aspiration are MOANS, LEMON, and AEIOU. These should be used for every patient during routine preoperative airway assessment.

MOANS: To predict difficult bag-mask ventilation

M: Mask seal made difficult by the presence of facial hair

O: Obese with BMI > 26

A: Age older than 55 years

N: No teeth

S: Snores, sleep apnea

LEMON: To predict difficult rigid laryngoscopy and intubation

L: Looks difficult

E: Evaluate with 3-3-2: Able to insert 3 fingerbreadths inside the mouth; 3 fingerbreadths between the tip of the mentum and the junction of the mandible and the neck; 2 fingerbreadths between the base of the tongue and the larynx

M: Mallampati class[27]: Patient seated, mouth opening as large as possible, able to visualize the following structures:

Class I: Soft palate, tonsils, uvula, pillars

Class II: Soft palate, tonsils, uvula

Class III: Soft palate, uvula base

Class IV: Hard palate only

O: Obstruction of the upper airway

N: Neck mobility: Limited cervical spine mobility

AEIOU: To predict high risk of aspiration

A: Abscess, especially retropharyngeal abscess

E: Esophageal cancer, status post esophagectomy, esophageal reflux

I: Intubation difficulty necessitating prolonged mask ventilation and gastric insufflation

O: Obstruction: Gastric outlet and bowel obstruction

U: Unresponsive, lethargic, altered mental status

For head and neck cancer surgery, patients with exceptionally challenging airways may require airway control by surgical means. In these cases, the mnemonic SHORT may help to determine if cricothyrotomy or tracheostomy will be technically difficult.

SHORT: To predict difficult cricothyrotomy and tracheostomy

S: Surgical scar

H: Hematoma

O: Obese

R: Radiation

T: Tumor

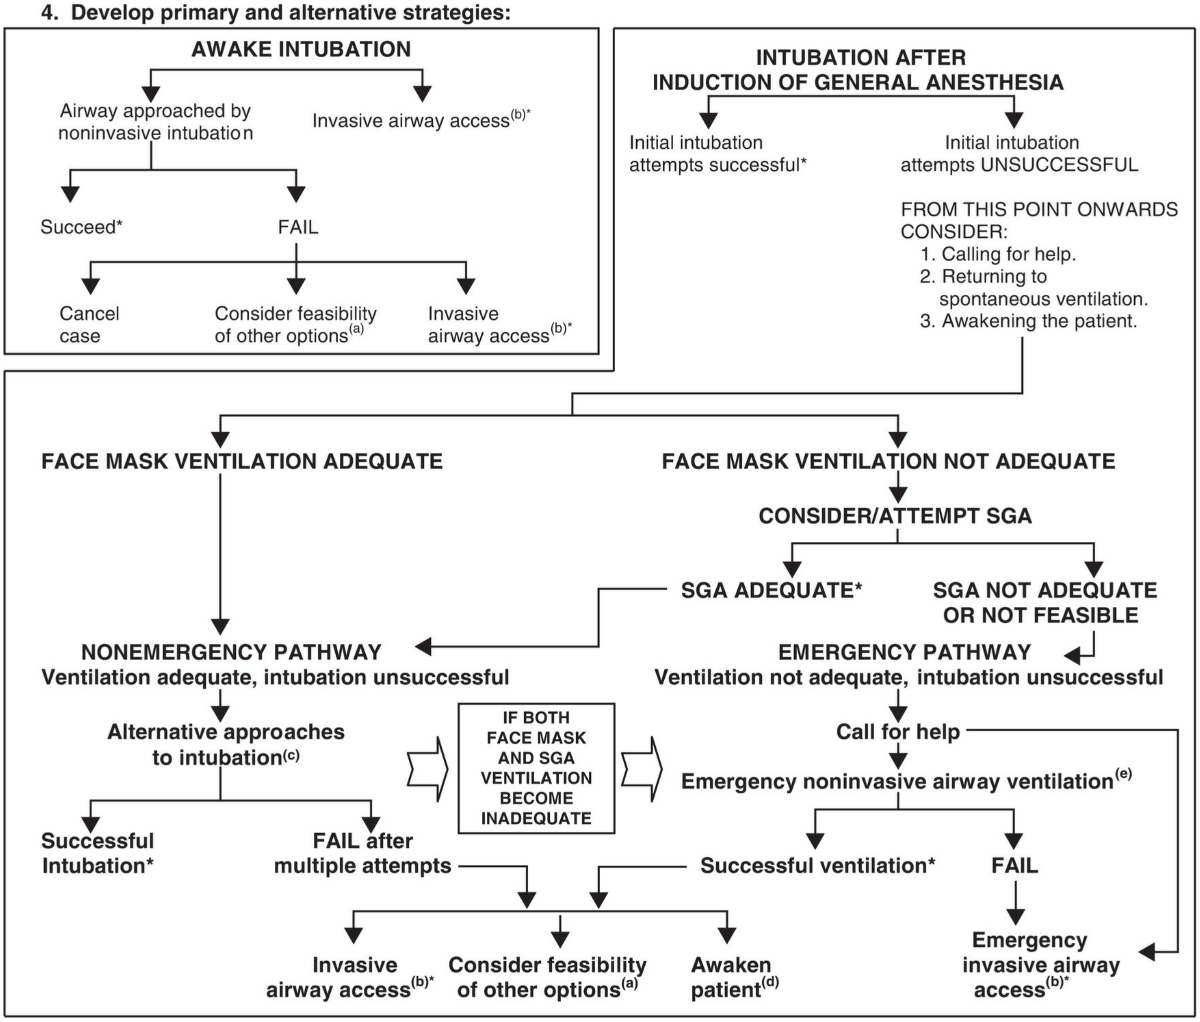
To reduce the need for multiple overlapping mnemonics, we propose a simplified yet comprehensive mnemonic, VIA, as will be discussed below.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS DIFFICULT AIRWAY ALGORITHM

Anesthesia providers are regarded as the experts in airway management. In the vast majority of cases, management of the airway is a routine part of our daily clinical practice, accomplished without problems. Unfortunately, failure to secure the airway occurs surprisingly often. Difficult mask ventilation has been reported to be as high as 5%[28] and failed ventilation in 0.1% of cases[29]. Furthermore, difficult intubation with a laryngoscope occurs in 1% to 4% and failed intubation in 0.05% to 0.35%. The incidence of “cannot intubate–cannot ventilate” situations that result in brain damage or death has been reported as 0.01 to 2.0 per 10,000 patients.[30] The potential for airway disasters continues to hang over our heads, like the sword of Damocles.

The ASA, recognizing the need to reduce the incidence of failed airways, published practice guidelines and an algorithm for management of the difficult airway in 1993, with a subsequent revision in 2003 and updated in 2013.[31–33] The purpose of this algorithm is to assist in the decision-making process to manage the difficult airway. This comprehensive algorithm presents an organized, systematic approach to various difficult airway scenarios and the management options available (Fig. 6.2). Unfortunately, the algorithm is not truly binary and for any given situation allows several management options, without clear specifications to what would be the best option under the circumstances. Its multiplicity of pathways drastically reduces its practical usefulness in real-life difficult airway scenarios, especially in a crisis situation. Adequate ventilation rather than successful intubation should be stressed as the end point. Patients die because of the inability to ventilate and not the inability to intubate. Often, adequate ventilation from use of an extraglottic device such as a laryngeal mask airway or waking the patient to resume spontaneous breathing can avert death by asphyxia, without the need for successful endotracheal intubation.

1. **Assess the likelihood and clinical impact of basic management problems:**
    - **Difficulty with patient cooperation or consent**
    - **Difficult mask ventilation**
    - **Difficult supraglottic airway placement**
    - **Difficult laryngoscopy**
    - **Difficult intubation**
    - **Difficult surgical airway access**
2. **Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.**
3. **Consider the relative merits and feasibility of basic management choices:**
    - **Awake intubation *vs.* intubation after induction of general anesthesia**
    - **Non-invasive technique *vs.* invasive techniques for the initial approach to intubation**
    - **Video-assisted laryngoscopy as an initial approach to intubation**
    - **Presvation *vs.* ablation of spontaneous ventilation**
4. **Develop primary and alternative strategies:**



***Confirm ventilation, tracheal intubation, or SGA placement with exhaled CO_2.**

a. Other options include (but are not limited to): surgery utilizing face mask or supraglottic airway (SGA) anesthesia (e.g., LMA, ILMA, laryngeal tube), local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous airway, jet ventilation, and retrograde intubation.

c. Alternative difficult intubation approaches include (but are not limited to): video-assisted laryngoscopy, alternative laryngoscope blades, SGA (e.g., LMA or ILMA) as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Emergency non-invasive airway ventilation consists of a SGA.

Figure 6.2. ASA Difficult Airway Algorithm. (From Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 2013;118:251–270, with permission.)

While the ASA algorithm may be viewed as cumbersome and difficult to apply to daily clinical practice, this decision-making tree provides evidence-based guidelines to make appropriate airway management decisions. Most airway disasters occur after induction of GA and administration of muscle relaxants, which result in loss of consciousness, apnea, and airway obstruction. Problems arise from the inability to intubate and inability to ventilate. In retrospect, these catastrophes could have been prevented by performing an awake fiberoptic intubation (FOI) to secure the airway before inducing GA. Choosing to perform an awake FOI has very clear advantages. Spontaneous ventilation is maintained at all times by a cooperative patient who is able to protect his or her airway against aspiration. During administration of topical anesthesia to the airway and awake FOI, an awake patient is better able to cooperate, generate deep inspiratory efforts, protrude the tongue, and perform other maneuvers that will help the anesthesiologist successfully visualize the glottis. With effective topical airway anesthesia and judicious administration of sedation, excellent success rates of awake intubation can be achieved.

The disadvantages of awake FOI include the time required to properly topicalize the airway, the potential risk of local anesthetic toxicity if excessive amounts of local anesthetic are used, and in uncooperative patients, this procedure may be very difficult to perform. Finally, the real possibility of recall of the procedure may occur in cases when not enough amnestic medications are given. For these reasons, awake intubation should not be done routinely in most cases. It should be chosen only for appropriate situations when it is deemed necessary. The main reason why this option is not selected in cases of unanticipated difficult airway is the lack of clear guidelines or criteria for awake intubation. The ASA Difficult Airway Algorithm does not address this important issue.

THE "VIA" SCORING SYSTEM FOR

DIFFICULT AIRWAY

In an effort to address this need, we have designed a novel approach to assess the difficult airway that takes into consideration the impact of head and neck cancers on each of the three determinants that underlie causes of morbidity and mortality during airway management: ability to ventilate (V), ability to intubate (I), and risk of gastric aspiration (A). Each of these determinants can potentially cause detrimental effects on another determinant. For example, a case of difficult intubation with multiple attempts at laryngoscopy may lead to difficult ventilation from ensuing airway edema. In turn, prolonged ineffective mask ventilation results in gastric insufflation, leading to aspiration (Fig. 6.3). By devising a scoring system that takes into account the severity of each of these factors, we can stratify the risks and make a logical decision on which technique of airway management is most appropriate for each individual case. The VIA scoring system helps anesthesiologists to make a systematic and rational decision regarding airway management by focusing on all three determinants of airway management. It serves as a concise, quick-to-perform “time-out” before proceeding with induction of GA. In contrast to other airway assessment approaches, which evaluate airway difficulty only in awake patients, the new emphasis of this scoring system focuses on anticipating these risks of airway problems after loss of consciousness is induced by general anesthesia. Depending on the severity of risk of difficulty to ventilate, difficulty to intubate, and risk of aspiration, a numerical grade is assigned to each determinant.

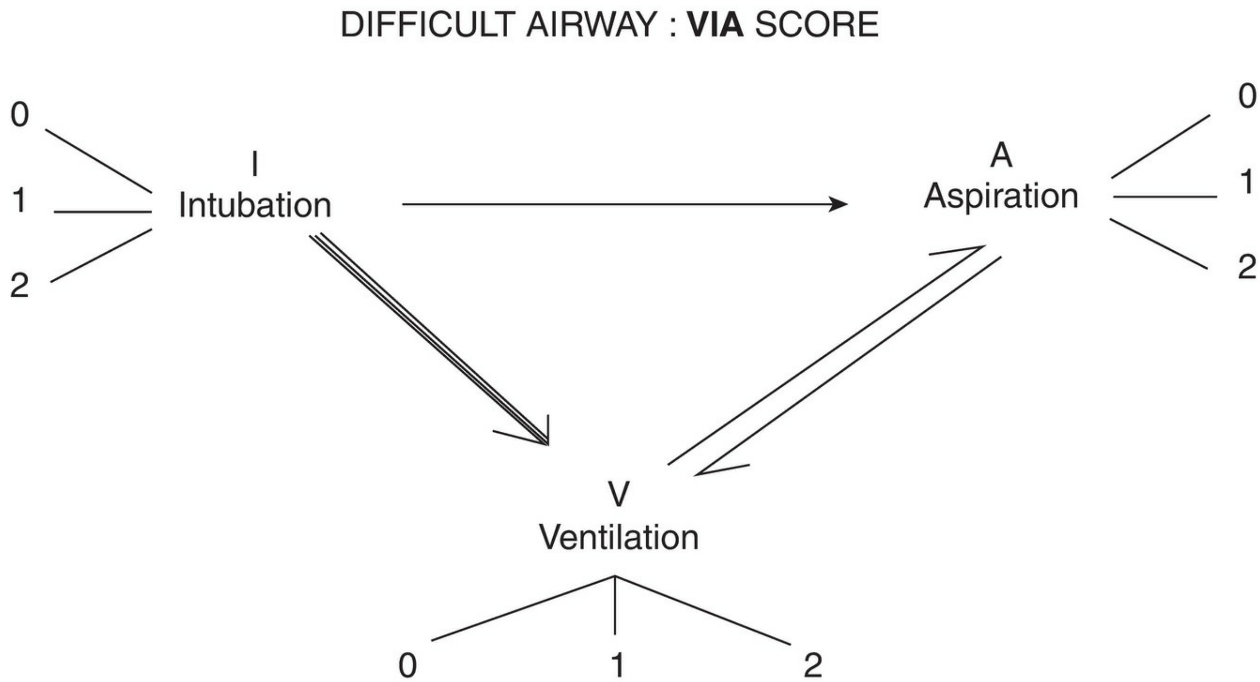


Figure 6.3. VIA score.

Each determinant V, I, and A is graded separately and assigned a numerical score according to severity: 0 = no risk; 1 = potential risk of difficulty, believed to be readily overcome by routine maneuvers; 2 = definite risk of difficulty, which may not be overcome by routine maneuvers.

For ventilation:

0 = bag-mask ventilation effective; 1 = extraglottic device needed to ensure adequate ventilation; 2 = impossible to ventilate after induction of GA

For intubation:

0 = successful with rigid laryngoscopes; 1 = flexible fiberoptic bronchoscope needed; 2 = impossible to intubate after induction of GA

For aspiration:

0 = no special risk; 1 = risk of aspiration can be overcome by rapid sequence induction and cricoid pressure; 2 = high risk of aspiration

After each factor is graded, their summation results in a total score from 0 to 6. From this total VIA score, a more rational approach to managing the difficult airway is proposed:

Total Score

0–1 Low risk for adverse respiratory events; may proceed with conventional induction of GA and conventional airway management

2–3 Moderate risk for adverse respiratory events; proceed with awake FOI

4–6 High risk of adverse respiratory events; proceed with awake tracheostomy

In order to prevent unilateral decision-making and misunderstanding, the preoperative communication and collaboration between anesthesiologist and surgeon to elaborate a joint perioperative plan will contribute to the mutual understanding of each other's needs. The anesthesiologist should be made aware of all the successive steps and demands of the surgical procedure. Likewise, the surgeon should be informed of the patient's significant medical conditions and the need for special intraoperative monitoring or treatment. In unusually complex or challenging cases, senior colleagues with greater experience and expertise should be consulted to discuss the anesthetic plan and request technical assistance in securing the airway.

Intraoperative Airway Management: Ventilation

Management of the airway should focus first and foremost on ensuring adequate ventilation and oxygenation.[34] It is surprisingly difficult to predict difficult or impossible mask ventilation.[35] If bag-mask ventilation is not adequate with use of an oral or nasopharyngeal airway, insertion of a supraglottic device such as the laryngeal mask airway or LMA (Teleflex Medical, Research Triangle Park, NC) can provide rescue ventilation. In contrast to a face mask held over the face for conventional bag-mask ventilation, a supraglottic device bypasses tissues of the oropharyngeal cavity and establishes a direct conduit to the glottic opening, enabling more effective ventilation. Furthermore, the LMA may serve to provide GA without an endotracheal tube (ETT) and functions as an adjunct to facilitate orotracheal intubation. Compared to the ETT, the LMA is easier to place correctly, causes minimal hemodynamic response upon insertion, is better tolerated, and is associated with reduced coughing and bucking on emergence. The original LMA Classic is too rigid and has too a high profile to allow adequate field avoidance in head and neck surgery. In contrast, the LMA Flexible has a flexible wire-reinforced airway tube that allows it to be positioned away from the surgical field without kinking and without loss of cuff seal. Consequently, it is most appropriate for short head and neck

procedures. Finally, thanks to a tighter seal of the cull around the glottis, it has been used safely for adenotonsillectomy, dentoalveolar, and nasal surgery. The other popular LMA models are the LMA Unique designed for single use, the intubating LMA Fastrach, the LMA Proseal equipped with a separate gastric drainage channel to help prevent aspiration, and the LMA Supreme combining the advantages of the designs of the Fastrach and the Proseal. In contrast to the LMA, the I-Gel (Intersurgical, Wokingham, UK) is a new supraglottic device with a noninflatable mask made of gel-like thermoplastic elastomer and a gastric drainage channel similar to the Proseal.

Intraoperative Airway Management: Intubation

The major intraoperative problems that may arise concerning the ETT involve dislodgement or kinking. These problems may occur during any type of surgery, but occur much more frequently in head and neck surgery because the ETT is very close to the surgical field. For short cases, standard clear polyvinyl chloride (PVC) tracheal tubes are usually adequate. For most head and neck cases, these high-profile tubes are too rigid to be effectively directed away from the surgical field without kinking. To minimize these risks, the RAE (Ring, Adair, Elwyn) tube (Mallinckrodt, Pleasanton, CA) was specifically designed with preformed bends shaped to closely follow the natural contour of the patient's facial features so it can assume a low profile and minimize intrusion into the surgical field. Oral RAE tubes are positioned and taped down on the chin or at the corner of the mouth away from the surgical field. They are most useful for nasal, ophthalmic, and craniofacial surgeries. In contrast, nasal RAE tubes are positioned upward, directed toward the forehead for oral and maxillofacial procedures. Both oral and nasal RAE tubes can be temporarily straightened and armed onto a flexible bronchoscope for FOI. This preformed design presents an important problem in certain patients, depending on their particular individual airway anatomy. Once inserted into the trachea, the preformed tube tip may be too long, resulting in endobronchial intubation, or too short, resulting in accidental extubation. Surgical manipulation such as head extension or flexion after taping the tube may also cause tube malposition. For some patients with an unusually long or short trachea, there may not be a commercially available preformed RAE tube that would fit their airway anatomy. Furthermore, because of its tight bend, passage of a suction catheter through the tube is often difficult or even impossible. Finally, like any PVC tube, these tubes

may become softened by body heat during long cases and can become easily compressed and collapsed.

Complete airway control throughout the procedure is absolutely necessary in head and neck surgery. In our practice, we use almost exclusively the Parker Flex-Tip (Anandic Medical Systems AG, Diessenhofen, Switzerland) tracheal tube. This reinforced tube is designed with a spiral of wire embedded into the wall of the tube to confer strength and flexibility without kinking. It can be easily bent and taped down away from the field to improve surgical access. In addition, its curved, tapered ski-tip–shaped and centered distal tip was designed to minimize the tube from impaction with the anterior tracheal rings. This symmetric tip also prevents the tube from being hung up by laryngeal structures during passage through the glottic opening. This feature is especially useful for FOI because, even though insertion of the bronchoscope into the trachea is performed under direct vision, the actual insertion of the tube into the trachea is a blind maneuver and these tubes significantly decrease the incidence of tube hang-ups.

Used for recurrent laryngeal nerve monitoring to minimize the risk of vocal cord palsy, the NIM EMG ETT (Medtronic, Minneapolis, MN) is a flexible silicone tube fitted with four stainless steel wire electrodes embedded in the wall of the tube.[36] The short segment of these electrodes exposed just above the cuff must be in contact with the vocal cords to enable proper monitoring of electromyographic activity of the intrinsic laryngeal musculature. Avoiding the use of lidocaine gel or cream to lubricate the tube or lidocaine spray on the vocal cords is advised. Similarly, muscle relaxants are not used to preserve optimal laryngeal muscle function.

To minimize the risk of fire and tracheal tube being burned by the laser beams, some tubes specifically designed for laser surgery use metallic covering to protect the tubes made of rubber or polyvinylchloride tubes. The Xomed Laser-Shield II (Medtronic, Minneapolis, MN) tube incorporates an aluminum wrap around the silicone based tube. Similarly, the Laser-Trach Sheridan red rubber tube (Teleflex Medical, Research Triangle Park, NC) is covered with copper. These tubes are still vulnerable to being punctured by the laser beam. In contrast, tubes that are made entirely of flexible stainless steel such as the Laser-Flex (Mallinckrodt, Glen Falls, NY) offer much more secure protection against laser-induced fire. Because the shaft of a Laser-Flex

tube is unmarked, before intubation, it should be marked by comparing it to a similar sized marked tube to identify the length of intubation needed to achieve optimal tube positioning and prevent endobronchial intubation. Most laser tubes come with two PVC cuffs, which should be filled with water. Even if one cuff gets punctured by the laser beam, the cuff seal is maintained by the second cuff, and the leaking water will help extinguish fire in the vicinity. Methylene blue may be added to the cuff to facilitate detection of cuff rupture.

For patients with easy airways, rigid laryngoscopes using Macintosh curved or Miller straight blades are usually used for tracheal intubation. These “direct” laryngoscopes rely on the ability to expose and achieve a straight direct line of sight from the operator’s eyes to the larynx. Unfortunately, the glottis opening is difficult to visualize in 10.7% of patients with the head in simple extension position and 11.4% in the sniffing position.[37] Repeated unsuccessful attempts may lead to airway trauma and complete airway obstruction. This limitation led to the development of indirect rigid fiberoptic laryngoscopes, which allow easier visualization of the larynx through fiberoptic bundles. The image of the glottis is conveyed to an eyepiece or to a video display. The images on the video screen are invaluable for teaching and research. The AirTraq optical laryngoscope (Prodol Meditec S.A., Vizcaya, Spain) is a single-use indirect fiberoptic intubating device that allows visualization of the glottic opening without the need to align the oral with the pharyngeal and laryngeal axes. Consequently, successful tracheal intubation can be achieved with minimal head manipulation. The insertion of the blade requires a minimal mouth opening of 18 mm for the regular size and 16 mm for the small AirTraq. This device is most useful in patient with limited neck mobility, restricted mouth opening, and an anterior placed larynx. The cost of this fully disposable unit is equivalent to the cost of processing a standard laryngoscope blade and handle. The C-MAC video laryngoscope (Karl Storz Endoscope, Stafford, TX) is available in both Macintosh and Miller blade shapes. The image on the distal lens is acquired using a complementary metal-oxide semiconductor chip. A diffuse light-emitting diode with a high light output ensures adequate illumination of the application area. The GlideScope (Saturn Biochemical Systems, Burnaby, BC) incorporates a high-resolution digital camera with a video cable to a liquid crystal display (LCD) monitor. This laryngoscope consists of a medical-grade plastic modified Macintosh-type blade with its distal half

angled upward 60 degrees to improve the view of the glottis by reducing the requirement for anterior displacement of the tongue. The blade also incorporates a miniature video chip and light-emitting diodes providing adjustable illumination and contrast. The video image is transmitted by a cable to a dedicated LCD video display.

FLEXIBLE FIBEROPTIC INTUBATION TECHNIQUES

Flexible FOI is generally considered the gold standard for management of the difficult airway, especially when the degree of difficulty is compounded by invasion of the airway by tumors.[38] Life-threatening “cannot intubate–cannot ventilate” scenarios usually occur from repeated unsuccessful traumatic intubation attempts using rigid laryngoscopes. In contrast, flexible FOI is less traumatic and ventilation often preserved even after repeated attempts. There is much less risk of trauma to lips, teeth, tongue, and lesions of the oropharyngeal cavity compared to rigid techniques. Similarly, intubation injury to oropharyngeal free flaps or other reconstructed areas is minimized. This procedure causes less sympathetic stimulation than rigid laryngoscopy, an effect especially beneficial in patients with ischemic heart disease. The small diameter (3.5 to 6 mm) of the bronchoscope’s shaft allows it to be inserted in small openings such as the nostrils, the mouth in cases of trismus, and even in patients with jaws completely clenched using the retromolar space. Its flexibility permits the bronchoscopist to follow the anatomy of the airway in cases distorted by tumor, radiation therapy, or previous surgery. Finally, the use of the flexible fiberoptic bronchoscope before actual intubation permits a complete airway assessment from above and below the glottic opening. Not only is the larynx visualized but also subglottic lesions such tracheal strictures, tracheomalacia, and compression by goiter or an anterior mediastinal tumor may be detected.

Awake Intubation for Anticipated Difficult Airway

Awake FOI is the gold standard for the patient with an anticipated difficult airway. Unfortunately, this procedure is often an unpleasant and frightening ordeal for the patient. Conscious sedation is often needed to supplement topical anesthesia of the airway. The goal is to provide comfort for the patient

while preserving patient safety. The mucosa of the nose, pharynx, and larynx is exquisitely sensitive. Topical application of local anesthetics and/or performance of nerve blocks is needed to minimize the patient's discomfort and obtund gag and cough reflexes. Adequate anesthesia of the airway mucosa with local anesthetics constitutes the most important requirement for successful awake intubation, making in many cases the difference between success and failure.[39] Drying the airway serves two important purposes in awake intubation. Copious secretions in the airway may make adequate topicalization impossible, and secretions also render flexible FOI difficult. Glycopyrrolate 0.2 mg IV given before topicalization is most commonly used because of its antisialagogue effect. Compared to other anticholinergic agents such as scopolamine or atropine, its rapid onset, strong drying properties, and lack of sedation make it an ideal choice. Glycopyrrolate also enhances absorption of topical lidocaine and prolongs its duration of action.[40]

Topical Anesthesia of the Airway for Awake Intubation

A solution of 4% lidocaine is the local anesthetic most commonly used[41] because of its rapid onset (2 to 5 minutes), duration of action (30 to 60 minutes), and excellent safety record and effectiveness.[42] The effect of topical 2% lidocaine administered with an atomizer[43] using the "spray-as-you-go" technique through the bronchoscope[44] has been reported to be as satisfactory as 4% lidocaine. In contrast, topical anesthesia with atomized 1% lidocaine has been proven to be insufficient for airway manipulation.[45] The maximum recommended dose for topicalization is 6 mg/kg.[46] The most effective method of application is by atomization. The location where atomized droplets are deposited and absorbed depends on their size. Droplets diameter of 2 μm reach the farthest to the alveoli, 8 μm to the bronchioles, and 15 μm to the bronchi. The optimal droplet size that provides good topicalization of the vocal cords and upper trachea is 40 to 60 μm.[47] This is best achieved with a nebulizer such as the EZ-Spray (Alcove Medical, Houston, TX) with an oxygen flow rate set at 6 to 8 L/min.[48] Following the application of a vasoconstrictor to the naris, a nasopharyngeal trumpet coated with lidocaine jelly is inserted to serve as a conduit to spray local anesthetic deeper within the pharynx using the EZ-Spray. Finally, the MADgic Laryngo-Tracheal Mucosal Atomisation Device (Wolfe Tory Medical, Salt Lake City, UT) inserted deep into the trumpet and positioned just above the

vocal cords to spray 3 mL of atomized lidocaine will propel local anesthetic directly toward the glottic opening. For oral intubation, supplemental anesthesia may be achieved with 4% lidocaine gargle for oropharyngeal anesthesia. In cases of supraglottic tumors and distorted airways that may impede local anesthetic from reaching the larynx, topicalization can be performed by injecting lidocaine through the suction channel of the bronchoscope as it is advanced toward the glottis. To avoid the loss of local anesthetic along the lumen of the bronchoscope, this "spray-as-you-go" technique can be accomplished by threading an epidural catheter through the bronchoscope suction channel and used for spraying. When rapid airway topicalization is required, Cetacaine, a topical anesthetic mixture of 14% benzocaine and 2% tetracaine, is a popular option. Supplied with a convenient Jetco cannula, its onset of action is within 30 seconds, faster than lidocaine. Side effects include hypersensitivity reactions and risk of methemoglobinemia. Cocaine is a unique local anesthetic that produces vasoconstriction of the nasal mucosa. Severe coronary artery vasoconstriction and hypertension make this controlled substance much less routinely used.

Regional anesthesia of the upper airway by blockade of the branches of the trigeminal, glossopharyngeal, superior laryngeal, and recurrent laryngeal nerves provides effective anesthesia for awake intubation. In the presence of tumors in the airway along the path of the needle, regional nerve blocks are generally contraindicated. In very extensive supraglottic tumors, the bulky tumors impede topical anesthesia from reaching the vocal cords. Intubation may be unsuccessful due to patient coughing when the bronchoscope comes into contact with the supraglottic area. To overcome this problem, we described the retrograde translaryngeal injection of lidocaine. Directing the angiocatheter cephalad toward the vocal cords and deliberately timing the injection of lidocaine with the patient's forceful exhalation boosts the entrainment of local anesthetic upward to the supraglottic area (Fig. 6.4). These modifications allow upward flow of lidocaine across the vocal cords, reminiscent of a geyser's eruption.[49]

Impossible awake intubation turned successful: topical anesthesia of the supraglottic area by retrograde translaryngeal injection of lidocaine timed with forceful exhalation. *Anesthesiology News: Guide to Airway Management.* 2012;66–67, with permission.)

INTRAVENOUS AGENTS FOR CONSCIOUS SEDATION

Even with adequate topical anesthesia of the airway, awake intubation may be a distressing and frightening ordeal for patients. In most cases, conscious sedation must be carefully tailored to the needs of the patient. Intravenous drugs should not be used to compensate for inadequate topical anesthesia of the airway mucosa. Sedation should be used very sparingly in cases of high risk of airway obstruction to ensure adequate spontaneous breathing and patient cooperation. In very anxious patients, midazolam 1 to 2 mg IV may be titrated to effect. Besides relieving anxiety, it also provides amnesia and may raise the threshold for convulsions in the event of local anesthetic toxicity. Different pharmacologic agents including hypnotics, narcotic analgesics, and alpha-2 adrenoceptor agonists have been used either alone or in combination for conscious sedation during awake intubation.[50] Surprisingly, propofol, the most commonly used drug for routine GA and monitored anesthetic care, is not well suited for awake intubation because of the high incidence of frequent coughing, abrupt loss of consciousness, apnea, and airway obstruction. Compared to propofol, a target-controlled infusion of remifentanil provides safer and better intubating conditions with less coughing and less airway obstruction.[51] Compared to remifentanil, dexmedetomidine provides comparable intubating conditions but fewer tachycardia episodes, less recall, and better patient satisfaction.[52] If there is no danger of impending airway obstruction, we routinely use dexmedetomidine as a continuous infusion from 0.1 to 0.7 μg/kg/min. This alpha-2 adrenoceptor agonist provides adequate sedation for the patient able to maintain airway patency and remain easily arousable in order to cooperate during the procedure.

RETROMOLAR FIBEROPTIC INTUBATION IN SEVERE TRISMUS

Tracheal intubation ensures control and protection of the airway for surgical procedures requiring GA. The approach, oral or nasal, depends on surgical requirements and the patient's ability to open the mouth fully. Orotracheal intubation is usually the preferred option. This procedure may be difficult or even impossible if mouth opening is restricted enough to preclude the insertion of a laryngoscope or an ETT between the teeth.

Originally defined as reduced opening of the jaws caused by spasm of the muscles of mastication, trismus now refers to limited mouth opening from any cause. Patients with this condition are encountered with increasing frequency in clinical practice. The prevalence of trismus has been reported to be from 5% to 38% after surgery and radiotherapy for head and neck malignancies.[53] In these cases, nasal intubation constitutes the customary alternative. Unfortunately, in some patients, there exist concomitant contraindications to nasal intubation. These include surgical procedures involving the nose, nasal pathology, history of basal skull fractures, and coagulopathy. Consequently, in patients with significant trismus and contraindications to nasal intubation, access to the airway through a surgical tracheostomy is an option of last resort. To avoid the need for tracheostomy, an invasive procedure with many potential serious complications, we described a novel technique using the retromolar space (Fig. 6.5) as an entry to perform flexible fiberoptic orotracheal intubation. We have reported three cases of retromolar placement of tracheal tubes in patients with severe trismus and difficult airways. The first report described retromolar fiberoptic orotracheal intubation (Fig. 6.6) in a patient with severe trismus undergoing nasal surgery.[54] This technique was also used successfully in a pediatric patient with a difficult airway and bilateral nasal stenoses.[55] Finally, we used the retromolar space to insert a double-lumen tube for lung isolation in a patient with a difficult airway.[56] We have also used this technique in patients with poor dentition to prevent dental injury. The retromolar approach offers several significant advantages. It can be performed in extreme cases of trismus, even in complete mandibular occlusion. By bypassing the oral cavity, the path to the glottic opening is shorter as compared to the midline oral approach. Consequently, intubation trauma to the lips, teeth, tongue, and

intraoral lesions can be avoided. Furthermore, the availability of the right and left retromolar space offers two locations for intubation to choose from. Even in the presence of tumor involvement of one retromolar space, the contralateral space may be used for intubation. The decision to perform retromolar intubation in the awake patient versus after induction of anesthesia should be made on an individual case-by-case basis. If there is any concern about difficult ventilation after induction of GA, awake FOI should be selected for patient safety. Finally, based on our experience teaching residents in training, this technique is surprisingly easy to learn. The skills required to perform flexible fiberoptic retromolar intubation are essentially the same needed for conventional oral and nasal FOI. By obviating the need for nasal intubation or tracheostomy, the retromolar approach should be considered as a valuable option for flexible bronchoscopic intubation in patients with severe trismus.

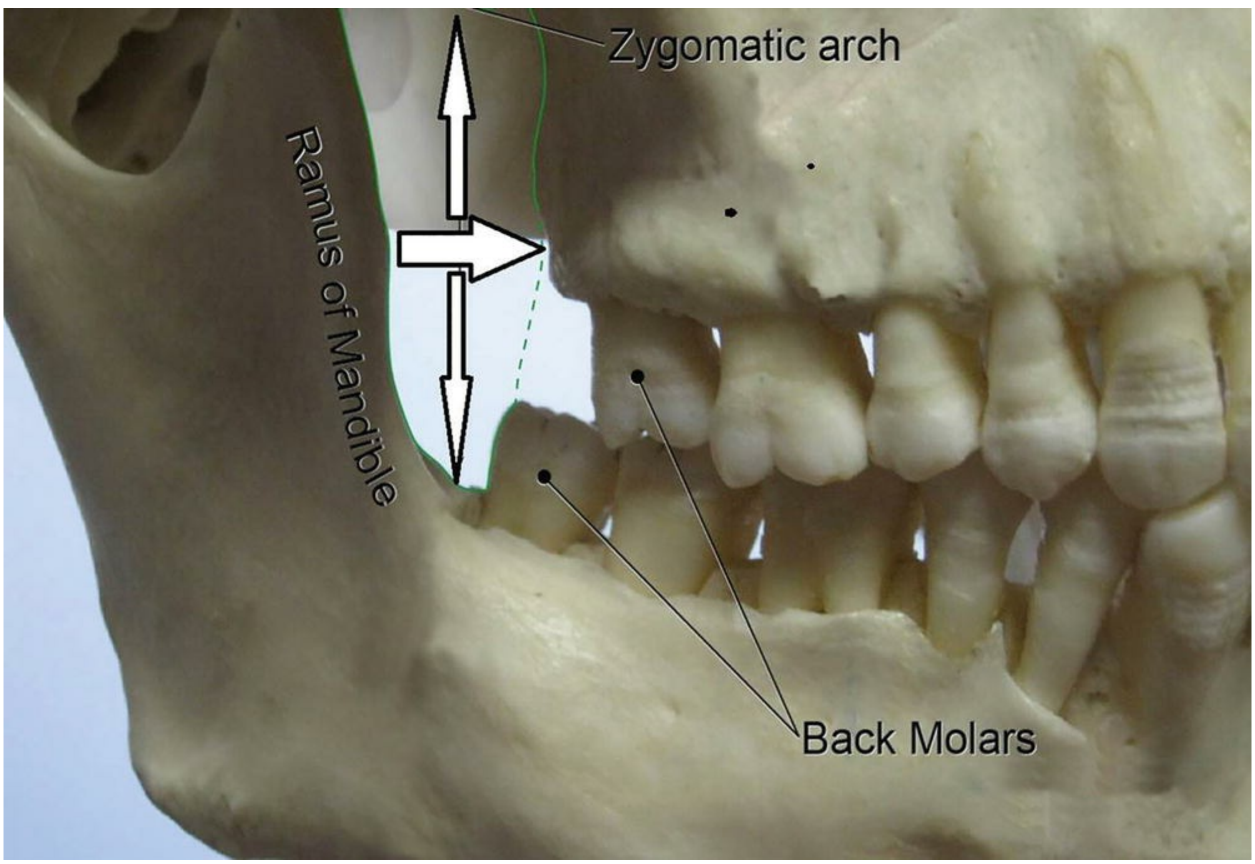

Figure 6.5. Retromolar space. (From Truong A, Truong DT. Retromolar fibreoptic orotracheal intubation in a patient with severe trismus undergoing nasal surgery. *Can J Anaesth.* 2011;58:460–463, with permission.)

Figure 6.6. Retromolar intubation. (From Truong A, Truong DT. Retromolar fibreoptic orotracheal intubation in a patient with severe trismus undergoing nasal surgery. *Can J Anaesth.* 2011;58:460–463, with permission.)

In case of unfamiliarity with the retromolar approach, we modified an Ovassapian Fiberoptic Intubating Airway (Bay Medical, Brisbane, CA) to increase mouth opening in patients with trismus enough to accommodate the passage of an ETT.[57] The minimum mouth opening that allows passage of the 6.0 mm ETT with an outside diameter of 8.2 mm is about 9 to 10 mm. In patients with maximal mouth opening of 7 to 8 mm, an Ovassapian airway can be modified by cutting out the proximal ring of the intubating channel and used as a slanted wedge (Fig. 6.7). Inserted between the teeth and gently advanced in the oral cavity (Fig. 6.8), mouth opening may be increased by 2 to 3 mm to reach 10 mm, wide enough to accommodate successful oral intubation between the teeth.

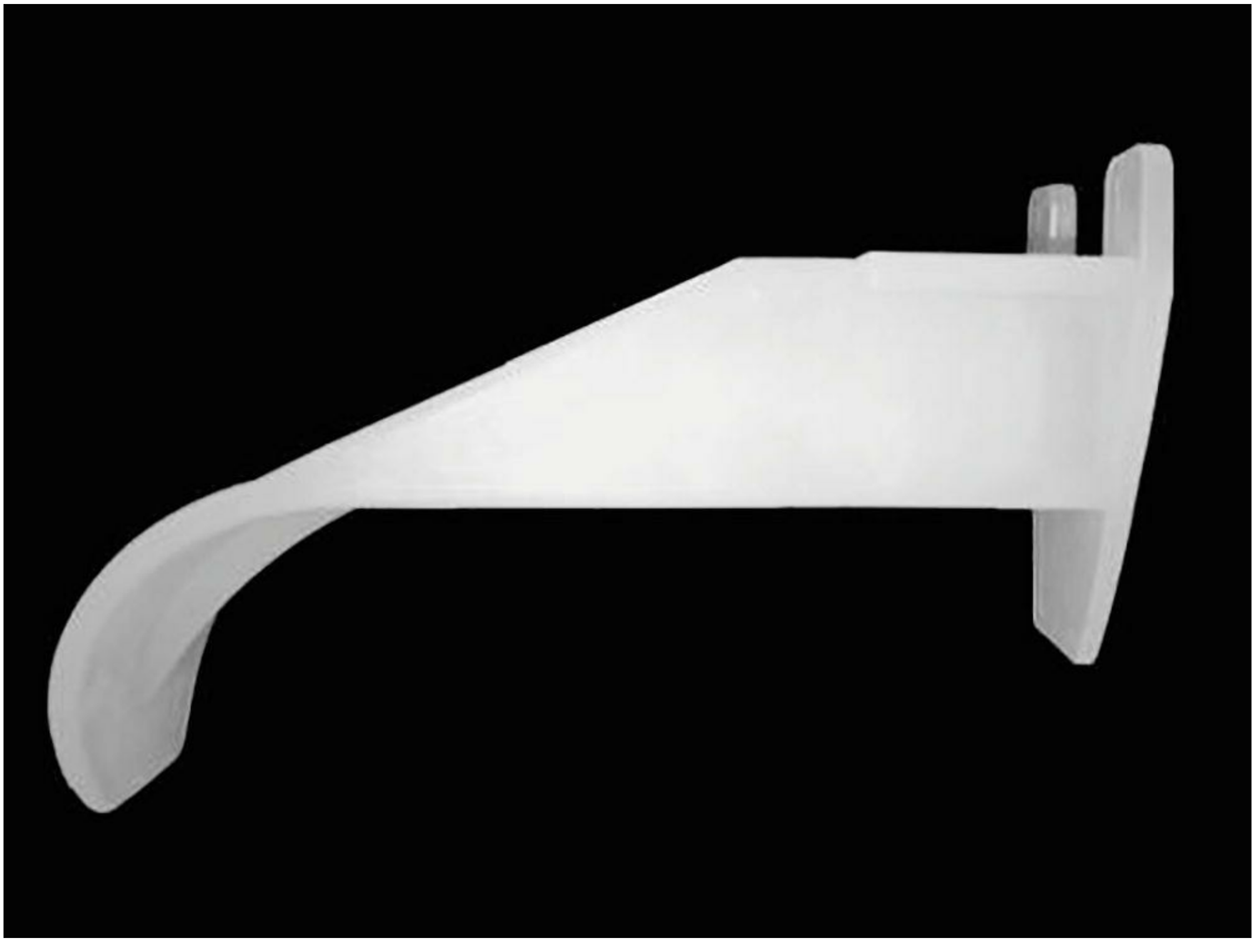

Figure 6.7. Modified Ovassapian airway.

Unanticipated Difficult Intubation

Despite the multitude of schemes for airway assessment and prediction of difficult intubation, unanticipated difficulty with exposure of the larynx after induction of GA and muscle paralysis still sporadically occurs. Current airway assessment methods do not always reliably predict when the glottic opening can be adequately visualized by direct laryngoscopy. Furthermore, even if the glottis can be visualized with fiberoptic indirect laryngoscopy, it is not uncommon that tracheal intubation cannot be successfully achieved because of the nonlinear path from the operator's eyes to the larynx. Failed intubation attempts can deteriorate rapidly and suddenly to life-threatening "cannot intubate–cannot ventilate" disasters.[58] Preplanning with a backup strategy will help to avoid impulsive decision-making under severe

stress.[59,60]

After calling for expert assistance, the first priority should be to ensure adequate ventilation and oxygenation. If bag-mask ventilation is not adequate, a supraglottic device should be inserted to overcome oropharyngeal obstruction. Once ventilation and oxygenation are achieved, the second priority is to avoid further airway trauma that may precipitate complete airway obstruction. Intubation techniques selected for these difficult situations should have the least risk of trauma and high rates of success. Consequently, blind intubation techniques and repeated attempts using rigid laryngoscopy should be discouraged. A rational and orderly progression from the rigid direct laryngoscope to the video laryngoscope or flexible fiberoptic bronchoscope should be followed. In case fiberoptic bronchoscopy attempt also fails, it is important to resist the urge to revert back to rigid laryngoscopy. Failed intubation under these circumstances stems from increasing airway edema after each unsuccessful attempt. Each subsequent intubation attempt using the same technique will have even less chance to succeed than the previous one. To compound the difficulty, it becomes increasingly difficult to maintain adequate oxygenation. Rapid desaturation not only severely limits the time available to succeed intubation but also adds a terrifying sense of urgency while trying to perform a very difficult procedure. In our experience, the combined technique using the LMA, fiberoptic bronchoscope, and Aintree intubation catheter (AIC) is the safest and the best option to secure the airway. A well-seated LMA ensures adequate ventilation and oxygenation. A swivel adapter placed between the LMA and anesthesia circuit allows access to the trachea while ventilation through the LMA is continuously maintained. The AIC (Cook Medical, Bloomington, IN) is a modified airway exchange catheter with a larger internal diameter of 4.8 mm that is preloaded onto a pediatric bronchoscope. This bougie tube was designed specifically for use with a fiberoptic bronchoscope to facilitate endotracheal intubation through an LMA. The bronchoscope armed with the AIC is inserted into the LMA, and under direct vision, the glottic opening is identified, passing the AIC to the tracheal lumen. Using the AIC as a guide, the ETT is then advanced over the AIC into the trachea for intubation. This combined technique is our favorite approach when called to assist failed intubation. The greatest advantage is that ventilation is adequately assured during intubation attempts. Unlike other techniques, this combined approach takes advantage of the useful features of

multiple airway equipment. This technique is essentially atraumatic and does not lead to complete airway obstruction even during repeated attempts. Finally, the success for airway control is almost always assured. By bypassing oropharyngeal edema, the LMA not only ensures adequate ventilation but also allows effective suctioning of the supraglottic area and serves as a straight conduit leading to the larynx. Furthermore, by displacing away the surrounding edematous soft tissues, the elliptical rim of the LMA provides valuable exposure of the laryngeal inlet for easy bronchoscopic visualization of the vocal cords.

PERIOPERATIVE CARE OF PATIENTS WITH A LARYNGECTOMY STOMA

Occasionally, patients present for surgery with laryngectomy stoma. Often mistaken by anesthesia providers as a tracheostomy, a permanent stoma after total laryngectomy presents important perioperative implications for anesthesia. Because there is no longer a communication between the tracheobronchial system and the digestive tract, aspiration of gastric contents is physically impossible.[61] Regrettably, the ASA practice guidelines for preoperative fasting do not take this fact into consideration. Therefore, these patients are often subjected to unnecessary prolonged fasting before surgery.[62] In contrast, the risk of pulmonary aspiration of small objects into the stoma is often overlooked. Because of the large stoma opening with smooth downsloping rim contour, there is a significant risk of aspiration of foreign bodies by strong negative pressure generated during deep inspirations. Small foreign bodies such as vial covers and needle caps may be at risk of accidental inhalation into the trachea or lungs. Extra care should be taken by anesthesiologists in handling small objects in the vicinity of an uncovered stoma (Fig. 6.9). Many laryngectomees undergoing surgery also present with a tracheoesophageal prosthesis (TEP) for esophageal speech. If intubation is required, the TEP may either be removed or left in place. During insertion of a cuffed ETT into the stoma to enable positive pressure ventilation, utmost caution should be exercised to avoid dislodgment of the prosthesis. Finally, after extubation, it is necessary to check again with a bronchoscope to ascertain that the TEP is still in place. Accidental dislodgement and pulmonary aspiration of the voice prosthesis are not

uncommon and, if unrecognized, may result in serious complications.

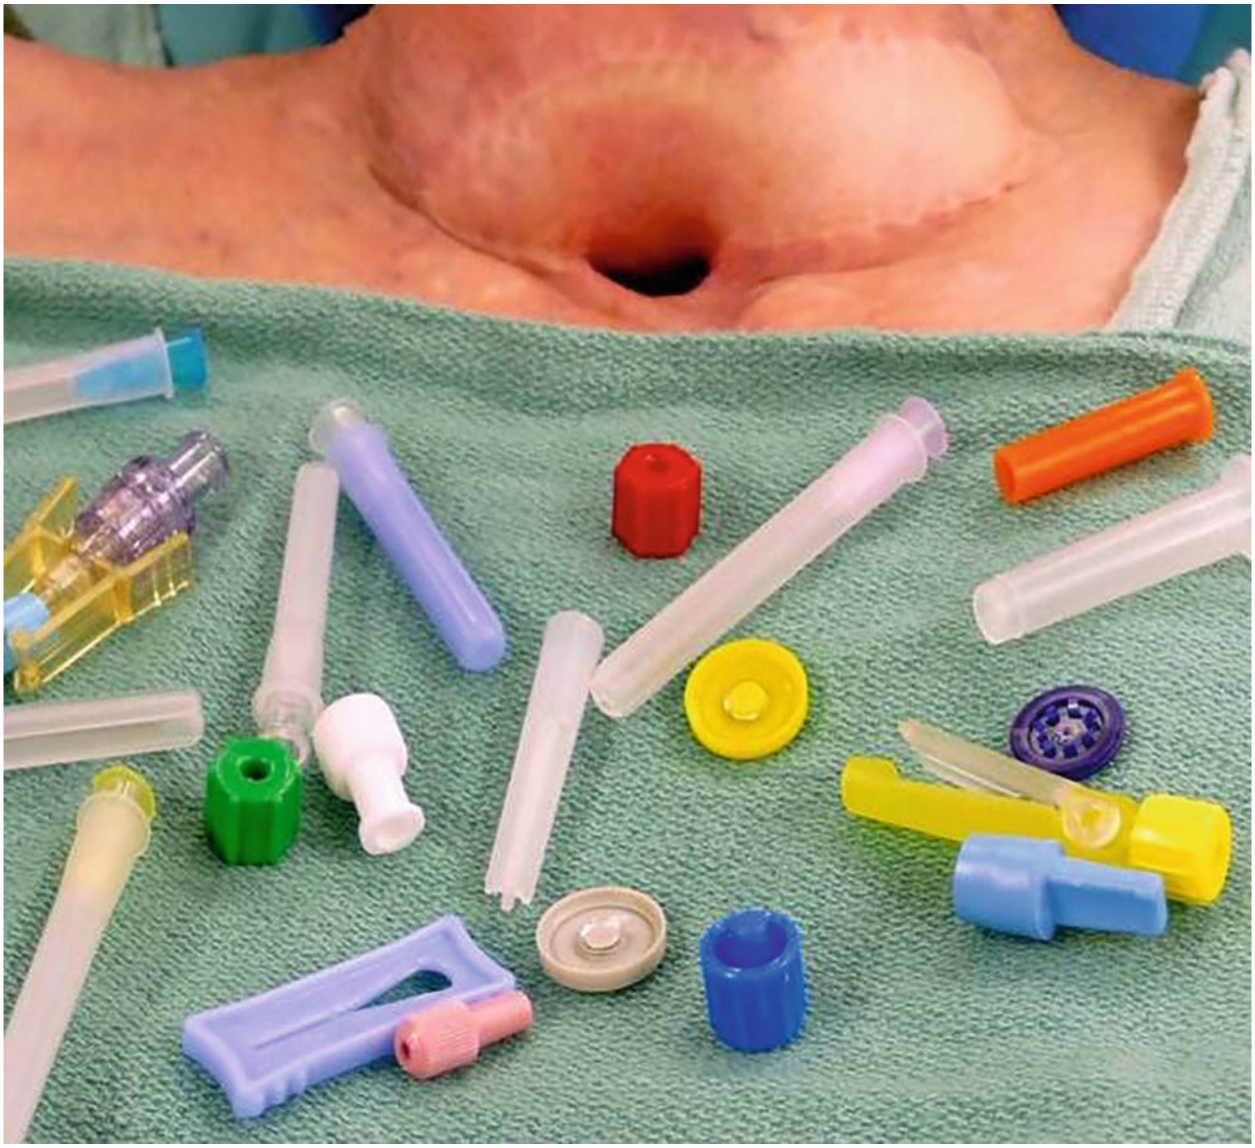

Figure 6.9. Stoma with objects.

INTRAOPERATIVE ANESTHETIC MANAGEMENT: VASCULAR ACCESS AND MONITORING

Vascular Access

For fluid and intravenous drug administration, peripheral vascular access for head and neck surgery is obtained by cannulation of an upper extremity vein with a large-bore catheter. A second peripheral intravenous catheter is usually inserted after induction in case the first peripheral line infiltrates or does not flow well after patient positioning with arms tucked at the sides. In the majority of cases, blood transfusion for combined head and neck and plastic reconstruction procedures may be given using a standard fluid warmer such as the enFlow fluid/blood warming system (GE Healthcare, Little Chalfont, UK). For cases with anticipated massive blood loss such as carotid body paragangliomas, a central venous catheter may be needed. The internal jugular and subclavian veins are common choices for cannulation. Catheters in these large vessels are often undesirable in head and neck surgery due to their intrusion into the surgical field. Femoral vein catheters offer the benefit of being far from the surgical field and also serve as a reliable central access in cases of surgical bleeding originating from the vessels of the neck. Rapid blood transfusion devices such as the Belmont Rapid Infuser (Belmont Instrument, Billerica, MA) are available to rapidly infuse blood at rates from 2.5 to 1,000 mL/min with the touch of a button.

Monitoring is an essential component of intraoperative anesthetic care. The standards for basic intraoperative anesthetic monitoring were established by the ASA in 2005.[63] Routine intraoperative electronic monitors include inspired oxygen concentration, pulse oximetry, end-tidal CO_2 by capnography, blood pressure, heart rate and rhythm, and airway pressure.

For hemodynamic monitoring, blood pressure measurements every 3 minutes with a sphygmomanometer are usually adequate for most cases. For long cases, the CNAP Monitor 500 (CNSystems Medizintechnik AG, Graz, Austria) allows noninvasive continuous beat-to-beat hemodynamic monitoring without the need for arterial cannulation. Based on the principle of arterial wall unloading, this monitor uses two finger cuff sensors wrapped around the index and middle finger to obtain a blood pressure signal that is calibrated using a special transfer function. After processing, the monitor provides a real-time continuous display of systolic, mean, and diastolic blood pressure, left ventricular stroke volume, and cardiac output and pulse pressure variability.

For patients with uncontrolled hypertension, congestive heart failure, or ischemic heart disease, invasive monitoring of the arterial pressure by an

indwelling arterial catheter is beneficial. Blood samples for determination of arterial blood gases, hemogram, and other blood chemistries can be taken from the arterial line. Complications from arterial cannulation such as ischemia and infections are fortunately rare.

Central venous pressure monitoring is useful to optimize blood volume status in patients with a history of congestive heart failure. Similarly, monitoring of pulmonary artery pressure and cardiac output with a pulmonary artery catheter is occasionally required for critically ill patients. These monitoring modalities are not practical for head and neck surgery. As an alternative to these invasive procedures, beat-to-beat left ventricular output and stroke volume can be measured much less invasively by arterial line tracing contour analysis. Complex computer algorithms serve to calculate the area under the systolic portion of the arterial pulse waveform. This technique has been shown to be accurate and reliable when compared to cardiac output measurements by a pulmonary artery catheter. This noninvasive technique is also useful in predicting the hemodynamic response to intravenous fluid administration. Cyclical fluctuations of the arterial blood pressure tracing related to the expiratory and inspiratory phases of the respiratory cycle have been used to detect hypovolemia when the difference is >10 mm Hg. Because low blood volume decreases right ventricular preload, increases right ventricular afterload, and decreases left ventricular afterload, a marked variability in stroke volume can be used as a predictor of responsiveness to fluid administration in low cardiac output states. Because the accuracy of this technique depends on the quality of the arterial waveforms, this technique is not reliable in the presence of frequent atrial or ventricular arrhythmias, especially atrial fibrillation. Intraoperative transesophageal echocardiography examinations routinely performed by cardiovascular anesthesiologists are seldom needed for head and neck surgery, except for very rare cases of cardiogenic shock.

Monitoring of Depth of Anesthesia and Brain Function

The concept of depth of anesthesia is fundamental to the science and art of providing GA. Yet, paradoxically, it is also the least well understood. Although GA first became widely practiced in late 1846, it took close to one century later in 1937 for Guedel to describe the four stages of anesthesia.[64] He based these four stages empirically on observed clinical signs such as loss

of consciousness, regular breathing, and eyelid reflex. This primitive and imprecise scheme often led to anesthetic overdose and terrifying intraoperative patient awareness and recall.

It was only in 1994 that the bispectral index (BIS brain function monitor, Covidien, Dublin, Ireland) was introduced to gauge the depth of anesthesia and to help adjust doses or concentrations of anesthetic agents accordingly to achieve optimal depth.[65] The goal is a plane of unconsciousness deep enough to prevent intraoperative awareness and light enough to allow rapid emergence from anesthesia. Using a complex algorithmic analysis of several electroencephalographic parameters, the BIS monitor provides a single dimensionless number ranging from zero to 100. A BIS value between 40 and 60 indicates an appropriate level of anesthesia. The BIS monitor probes must be applied on the patient’s frontal and temporal areas. For this reason, this monitor is not as commonly used in head and neck surgery compared to other surgical specialties.

Occasionally, a standard 19-scalp electrodes continuous real-time electroencephalogram EEG is needed for intraoperative monitoring of brain function. Typically, this is needed in cases presenting with high risk for intraoperative strokes such as complex surgical resection involving the carotid arteries or in patients with known critical carotid stenosis.

PATIENT POSITIONING FOR SURGERY

Patient positioning is intended to improve access of the surgeon to the target operative field. The desired position may impose potentially harmful anatomical and physiologic changes to the patient. Furthermore, patients are often placed in these positions after the induction of GA. The anesthetized and paralyzed patient may be subjected to exaggerated postures, which they would not be able to tolerate if they were awake. Therefore, there should be a compromise between surgical needs and patient’s ability to withstand the desired position. In doubt, before induction of GA, the patient should be allowed to assume the proposed position while still awake to assess the limits of his comfort. All pressure points and prominent bony parts, especially elbows and heels, should be free from direct contact with the cold steel

operating table. These vulnerable areas should be protected by careful padding with foam pads to prevent peripheral nerve injuries.[66] Injuries to the brachial plexus and its main branches, in particular the ulnar nerve, are best prevented by positioning the well-padded arms, elbows, wrists, and hands comfortably tucked alongside the trunk. In large patients, a well-padded arm protector toboggan can be placed to protect the arms from being leaned upon by surgical assistants. Leg compression devices should be applied for thromboprophylaxis. The operating room table is often turned 90 or 180 degrees from the anesthetic machine to allow free access around the head and neck not only for the attending surgeon, but for all the surgical assistants. The patient is usually positioned in the supine position with the back of the table elevated 30 degrees to improve surgical access. Elevation of the head and thorax shifts abdominal contents away from the diaphragm, decreases atelectasis of the lower lobes of the lungs, and improves functional residual capacity. It also facilitates venous drainage away from the operative site, resulting in a less bloody operative field and decreased tissue edema. Side effects include decreased cerebral perfusion, risk of air embolism, and concealed blood loss trickling down unnoticed under the surgical drapes. When neck extension is needed to improve surgical access, mechanical compression of the carotid sinus located at the bifurcation of the common carotid artery may lead to the carotid sinus reflex. Stimulation of the vagus nerve precipitates bradycardia or asystole. In patients with carotid sinus hypersensitivity, this reflex is greatly exaggerated and can be triggered by simple extension of the neck without direct manual compression of the carotid sinus.[67]

SPECIAL INTRAOPERATIVE AIRWAY MANAGEMENT

Laser Surgery

By focusing the laser beam impact on a tight pinpoint target, laser surgery confers many important advantages: precise surgical resection, preservation of neighboring tissues, and less bleeding and tissue edema. The most widely used laser in head and neck surgery of the upper airway is the carbon dioxide (CO_2) laser. It can be used either to cut or to vaporize the lesion depending on

the laser settings. It is especially useful in resecting bulky tumors of the epiglottis and vocal cords. The Nd:YAG laser transmitted by fiberoptic cables is more flexible and better adapted to tumors of the lower airway. Surgical lasers have the potential for inadvertent tissue damage and for causing fires. Eye injuries vary depending on the depth of penetration of the beam. CO_2 lasers cause corneal injuries, whereas Nd:YAG lasers can damage the retina. The eyes of the patient must be protected with moist eye pads or special laser eye covers. As oil-based ointments are flammable, water-soluble eye ointments should be used. To prevent sudden patient movement and inadvertent impact of the beam, muscle relaxation is usually required to help ensure an immobile surgical field. The laser beam like any light beam can be deflected. Instruments with a polished surface can reflect laser beams to an unintended destination and thus cause injury, especially to eyes of operating room personnel. Protective goggles should be worn by everyone in the operating room. A clear warning sign of laser use must be posted on the operating room door. Equipment and instruments inside the room should have nonreflective surfaces.[68] To prevent fire in the upper airway, the lowest inspired concentration of oxygen should be delivered, ideally not higher than 30%. Nitrous oxide also should not be used because it supports combustion.[69] Laser vaporization of tumors, especially from CO_2 lasers, often results in a plume, which contains not only smoke and particulate debris but also cancer cells, viruses, and carcinogens. A smoke evacuator system with a high-efficiency particulate air filter should be positioned at the surgical site. Specially designed laser plume face masks should be worn. A protocol to manage airway fire should be in place and periodically reviewed and rehearsed. In the event of airway fire, positive pressure ventilation should be stopped immediately to prevent fanning the fire down the tracheobronchial tree. The burning tracheal tube should be removed and any fire should be extinguished with water. Intravenous dexamethasone should be administered to reduce airway edema. Complications related to laser surgery are potentially catastrophic. They are also highly preventable. Consequently, all the precautions about laser safety should be scrupulously adhered to by all personnel involved.

Tracheal Resection and Reconstruction

Management of the airway for tracheal resection is one of the most formidable challenges in anesthesia practice.[70] Airway obstruction caused by the tracheal lesion, the differences in location of the segment to be resected from the cricoid to the carina, and the various phases of the resection and reconstruction require different techniques of airway control. Depending on the degree of airway obstruction, an intravenous, inhalational induction, or awake intubation may be selected. After ensuring adequate ventilation, a diagnostic flexible bronchoscopy should be performed to assess the involved segment and decide on the best way to secure the airway. Once the trachea has been transected, the most popular option for intraoperative ventilation involves distal tracheal intubation and cross-field ventilation. For lesions involving the upper and middle trachea, the tracheal tube is pulled back above the segment to be resected while still kept in the tracheal lumen. The surgeon inserts a second, sterile, flexible wire-reinforced tube through the surgical field into the distal trachea. This tube is connected to the anesthesia circuit to continue intermittent positive pressure ventilation. After resection of the diseased tracheal segment, the tube is removed during short apneic periods to allow completion of an end-to-end tracheal anastomosis. The main advantage of this technique is simplicity and safety. The drawback is the presence of a tube inside the trachea interfering with the completion of the tracheal anastomosis.

If concern exists that a tracheal tube may interfere with delicate surgical exposure, manual low-frequency jet ventilation may occasionally be needed.[71] After the trachea is transected, a long jet ventilation catheter inserted through the lumen of the tracheal tube and positioned in the distal trachea is attached to an oxygen source with outlet pressure of 50 psi. Ventilation is achieved by manual triggering. The oxygen concentration is diluted by entrained air following the Venturi principle. The most important advantage of jet ventilation is to allow ample room around a small catheter for the surgeon to perform tracheal anastomosis. Potential drawbacks include whipping motion of the catheter tip, inadequate ventilation and oxygenation, and entrainment of blood and tissue debris into the distal tracheobronchial system. High-frequency jet ventilation and high-frequency positive pressure ventilation[72] are generally not needed for tracheal resection performed by

head and neck surgeons. At the conclusion of surgery, emergence and extubation constitute the most critical steps of the entire anesthetic. It requires meticulous planning and execution through collaborative efforts between surgeon and anesthesiologist. Long-acting narcotics should be avoided. Neuromuscular blockade effects should be fully reversed. Every effort should be made to extubate the trachea to avoid trauma to the tracheal anastomosis by the tracheal tube and its cuff during mechanical ventilation. A guardian stitch placed between the chin and the chest helps keep the neck flexed and prevents traction on the tracheal anastomosis.

ANESTHETIC AGENTS OR TECHNIQUES AND TUMOR RECURRENCE

Cancer recurrence and metastases constitute major concerns in the treatment and survival of cancer patients. Recently, investigative reports suggest that certain perioperative factors including anesthesia techniques and analgesic drugs may have direct effects on cancer cells and patient cell-mediated immunity, contributing to recurrence and metastases.[73] Consequently, there is a strong stimulus to identify these factors and develop better modalities of anesthesia care with the aim of lowering rates of recurrence. The basic process of recurrence involves the complex interaction between the propensity of cancer cells to grow and the host defenses against cancer cell proliferation. The mechanisms by which perioperative factors may influence cancer cell growth and the host immune response are multifactorial, complex, and not yet completely understood. Surgery itself, the use of blood products, postoperative pain, and inadequate pain relief have been known to promote tumor growth by stimulating the cytokine stress response and suppressing cell-mediated immunity. For these reasons, adequate relief of pain is essential. The drugs most commonly used to relieve acute pain following surgery are opioids. Unfortunately, opioids have also been shown to exert deleterious effects by inhibiting host humoral and cell-mediated immunity.[74,75] Morphine has also been shown to stimulate tumor cell migration and proliferation in human endothelial cells in vitro. Avoiding opioids by using alternative pain management strategies may positively

impact cancer recurrence. However, although single-dose or low-dose opioids can promote tumor growth, extended exposure to high concentrations may suppress tumor growth.[76] In contrast, in addition to the relief of pain, local anesthetics may also exert cytotoxic effects on cancer cells. Lidocaine and bupivacaine have been shown to inhibit stem cell division and growth in vitro.[77] Regional anesthesia techniques such as epidural and spinal anesthesia have been widely used for various types of cancer surgery because they provide excellent analgesia, attenuate the stress response, and preserve the integrity of the host immune system. These techniques have been reported to be associated with a decrease in recurrence in certain types of cancers.[78] For the same reasons, paravertebral blocks have become very popular for breast surgery. For head and neck cancer surgery, superficial cervical plexus blocks have been performed for analgesia for thyroidectomy. In a recent report, cervical epidural anesthesia was associated with increased cancer-free survival in laryngeal and hypopharyngeal cancer patients.[79] Owing to their effects on COX2 and PGE2, which are major mediators in cancer progression, nonsteroidal anti-inflammatory drugs have a strong potential anticancer effect.[80]

Intravenous induction agents such as thiopental and ketamine have been shown to suppress NK cell activity in an inoculation animal model of breast cancer, which resulted in an increase in metastases.[81] In contrast, propofol may exert an antineoplastic effect by decreasing the production of PGE2 by monocytes in vitro.[82] Potent inhalational agents such as isoflurane, desflurane, and sevoflurane have been associated with immune modulation and potentially increased tumor metastasis in vitro and in experimental animal models.[83] Finally, perioperative allogeneic blood transfusion has been linked to immunosuppression, inflammatory response, and cancer recurrence.[84] Most of these reports come from laboratory experiments and retrospective clinical studies. Until randomized clinical trials are able to support a causal link between a particular anesthetic agent or technique to cancer recurrence, it is premature to introduce changes to the current standards of anesthetic care.[85] For the time being, the traditional high standards of anesthesia practice should focus on minimizing preoperative anxiety, achieving optimal anesthetic depth to blunt the surgical stress response, and providing excellent relief of pain in the postoperative period.

Patients undergoing extensive surgical procedures are susceptible to

major intraoperative blood loss requiring transfusion of blood and blood products. Unfortunately, in cancer patients, blood transfusions may be associated with transfusion-related immunosuppression, inducing tumor growth and causing recurrence. Findings of studies investigating the association between blood transfusion and cancer recurrence differ widely depending on the type of cancer studied. On one hand, perioperative blood transfusions have been linked to cancer recurrence and cancer-related mortality in colorectal carcinoma,[86] hepatocellular carcinoma,[87] pancreatic carcinoma,[88] and lung cancers.[89] On the other hand, studies investigating ovarian, renal, and bladder cancer surgeries show conflicting and inconclusive results regarding blood transfusion as an independent risk factor for recurrence.[90] Finally, patients who received allogeneic blood transfusion for prostate cancer surgery did not have a higher risk for cancer-related deaths as compared to nontransfused patients.[91] With regard to patients with cancers of the head and neck necessitating complex reconstruction after resection, transfusion of blood is often required to maintain perfusion of microvascular free tissue flaps. At the present time, there are no published studies that specifically focus on head and neck cancer surgeries and cancer recurrence after blood transfusion. Studies in this area are definitely warranted.

Emergence and Tracheal Extubation

At the end of surgery, anesthetic goals include a smooth emergence and timely extubation to avoid gagging and bucking on the tube. Even when the surgery procedure does not involve the airway, extubation carries more risks than intubation.[92] The main risk factors for problems at extubation are preexisting difficult airway, residual effects from muscle relaxants and narcotic analgesics, and airway edema. The incidence of reintubation is higher for laryngoscopy and panendoscopy.[93] In surgery involving the oropharyngeal cavity or the larynx causing airway edema or vocal cords paralysis, the risk of reintubation is 1% to 3%, a 10 fold increase compared to surgery not involving the airway.[94] Furthermore, reintubation under these circumstances can be very challenging or even impossible. In case of failed extubation, devices to assist ventilation such as extraglottic devices may not function adequately due to edematous and distorted airway anatomy. Extubation of the difficult airway should be given as much attention as

intubation. The following criteria are sought for extubation: patient awake, comfortable, following verbal commands, and demonstrating adequate tidal volume, respiratory rate, peak inspiratory force, and sustained head lift. In cases of high-risk extubation, it is important to discuss extubation plans with the surgeon. If laryngeal edema is suspected, it is essential to ensure airway patency before extubation by performing the cuff leak test.[95] After deflating the tracheal tube cuff, the ETT lumen is occluded and the patient is asked to breathe in and out deeply. An audible air leak around the tube indicates that there is adequate flow of air around the tube and the airway is patent. If there is any doubt, especially in cases of potential vocal cord paralysis secondary to recurrent nerve injury,[96] a trial extubation can be performed. A hollow jet ventilating tube changer (Cook Airway Exchange Catheter Cook Critical Care) is inserted through the tracheal tube, the cuff of the ETT deflated, and the ETT withdrawn while the exchanger remains inside the tracheal lumen. The lumen of these hollow tubes can be used to insufflate or ventilate the patient with oxygen. If necessary, the exchanger can be used as a guide to reintubate the patient.

AIRWAY MANAGEMENT IN DEEP NECK INFECTIONS AND POSTOPERATIVE NECK HEMATOMA

The management of these life-threatening airway emergencies follows the same general principles. An enlarging neck mass compresses and distorts the airway and may progress rapidly to complete airway obstruction. In retropharyngeal abscess, there is the added risk of rupturing the abscess and pulmonary aspiration of purulent material during manipulation of the airway.[97] The techniques used to secure the airway must be carefully individualized, based on the anticipated difficulties and the expertise of the attending anesthesiologist and head and neck surgeon. Minor neck bleeding can be treated expectantly. Early deep neck infections can be treated with antibiotics and close observation. Even when surgery is indicated, an intravenous induction, laryngoscopy, and intubation may be considered in the following circumstances: early diagnosis, minimal neck swelling, no stridor, no trismus, and a normal airway without anticipated risk for difficult

ventilation and intubation.

In contrast, increasing stridor may signal impending complete airway obstruction. In the case of postoperative hematoma, because of the large mass under the mandible and severe edema of the epiglottis and vocal cords, airway anatomy becomes distorted, displaced, and narrowed. Ventilation and intubation, which were easy earlier during the initial induction of anesthesia, may become very challenging. Bag-mask ventilation and transtracheal surgical airway can be extremely difficult or even impossible.[98] The patient should be brought to the operating room as expeditiously as possible. A coordinated effort should be made to assemble equipment needed: anesthesia emergency airway cart and surgical airway equipment including cricothyrotomy, jet ventilation, and tracheostomy sets. Anesthesiologists and surgeons with special expertise in emergency airway management should be called for assistance. The decision to proceed with awake FOI versus awake tracheostomy should be made carefully taking into consideration the urgency of the situation and the expertise and skills of the attending physicians involved.[99] Under these circumstances, only operators with special expertise in dealing with critical airway emergency should attempt awake FOI after topical anesthesia of the airway. It is important to reassure the patient and explain the successive steps of the procedure and their rationale. To ensure adequate spontaneous breathing, the patient should be kept awake by avoiding sedatives, hypnotics, and muscle relaxants. It is imperative to avoid airway trauma from rigid laryngoscopy, which can precipitate complete airway obstruction. Even without intravenous sedation, complete airway obstruction during application of topical airway anesthesia may occur.[100] Consequently, the surgeon and surgical team should be scrubbed, gowned, and ready to perform emergent cricothyrotomy or tracheostomy. Because of copious secretions, pretreatment with anticholinergic agents may be needed, and it may take longer to achieve optimal conditions for intubation. Localization of the glottic opening may be facilitated by delivering high flows of oxygen through the fiberoptic bronchoscope to disperse secretions. A reasonable time limit and number of intubation attempts should be set. It is advisable to proceed immediately to awake tracheostomy under local anesthesia before complete airway obstruction occurs. Success in these difficult conditions requires the expertise of an experienced and skillful head and neck surgeon. In case of loss of airway during tracheostomy, an

extraglottic device should be placed for rescue ventilation to allow the surgeon to successfully complete the procedure.[101]

SUMMARY

Anesthesia for head and neck cancer surgery presents unique challenges in all aspects of anesthetic care and during all stages of the perioperative period. Thorough preoperative evaluation and expert consultation for assessment of serious comorbidities are crucial to optimize the patient’s clinical status before surgery. The major intraoperative concern is control of the airway not only during induction, intubation and throughout the entire surgical procedure but also at emergence and extubation. A difficult airway related to invasion of the airway by malignant tumors is unquestionably the most challenging airway encountered in anesthetic practice. A complete airway assessment should focus not only on the well-recognized causes of difficulties but also on the implications of the cancer, previous resections, and radiotherapy. Potential airway problems should be anticipated not only when the patient is awake but also after induction of GA. The surgeon should be involved through communication and discussion to formulate a comprehensive collaborative plan of action. In case of failed intubation, the first priority is to preserve the ability to ventilate. It is imperative to refrain from repeated traumatic intubation attempts because the ensuing airway edema and bleeding will lead to sudden and catastrophic loss of airway. Expert help should be summoned early to successfully manage potentially lethal “cannot intubate–cannot ventilate” scenarios. Improvement of professional competence through continuing education, practice, and learning new techniques ensures proficiency in managing the most challenging airways.

Anesthesia practice devoted mainly to surgery for head and neck cancers yields many important benefits. First, the expertise acquired through routinely managing difficult airways confers competence in the most vital area of anesthesia practice. Head and neck anesthesiologists are often called upon to assist with difficult airways encountered in other surgical specialties. Furthermore, in case of an unanticipated airway crisis, the best assistance an anesthesiologist can receive is from the head and neck surgeon who is

already present in the same operating room. There is no need to call for outside help and no precious time is wasted. Compared with surgeons from other specialties, head and neck surgeons are highly skillful in the procedures anesthesiologists perform to secure the airway, especially rigid laryngoscopy and flexible bronchoscopy. The timely establishment of a surgical airway through urgent cricothyrotomy or tracheostomy may mean the difference between life and death. Finally, as research findings concerning potential associations between anesthesia agents and cancer recurrence begin to emerge, these results should be taken into account and incorporated into daily anesthesia practice. Hopefully, high standards and up-to-date anesthetic care will contribute to favorable outcomes, not only during the perioperative period but also to the long-term survival of head and neck cancer patients.

7 Head and Neck Cancer Care: Quality Guidelines

Carol M. Lewis, Amy C. Hessel, Stephen Y. Lai, and Randal S. Weber

The quality and appropriateness of cancer care are of paramount importance and can critically impact outcome. Deviation from evidence-based care will result in higher treatment costs and may jeopardize patients' outcomes. Providing evidence-based care should provide the patient the best opportunity for cure. Failure of initial treatment is associated with diminished tumor control and survival regardless of salvage treatment.[1,2] Quality of care has been defined as delivering efficient evidence-based care by experienced clinicians in an accessible setting or as doing the right thing, for the right patient, at the right time, and achieving the best possible result.[3]

The 2001 report by the Institute of Medicine (IOM) entitled "Crossing the Quality Chasm: A New Health System for the 21st Century" highlighted the gap that exists between what we know to be effective, beneficial care, and the care that is often delivered to an individual patient.[4] In the report, the IOM stated, "Between the health care we have and the care we could have lies not just a gap, but a chasm." The report, signifying a national initiative to improve the quality of care in the United States, articulated the following 6 aims for a new health care system: (1) enhance the safety of health care by avoiding injuries to patients; (2) provide effective services based on scientific knowledge (evidence-based care) and avoid services of no proven benefit; (3) deliver patient-centric care; (4) deliver timely care by reducing wait times and harmful delays; (5) increase efficiency and decrease waste; and (6) deliver care that is equitable regardless of gender, ethnicity, and social economic status. The IOM also recognized a need to optimize quality cancer care in the United States and recommended funding research into factors

influencing care and the quality of cancer care delivered.[5]

The United States spends the most money per capita for health care delivery of any country in the world, yet our outcomes are not outstanding. It is estimated that patients receive evidence-based care only 50% of the time, leading to increased cost of care.[5] In the United States, health care costs continue to rise but at a less rapid rate. In 2013, hospitals received an increase of 4.3% to $936.9 billion compared to 5.7% growth in 2012.[6] Payments to physicians and clinical services provided increased 3.8% in 2013 to $586.7 billion, from 4.5% growth in 2012. Medicare outlays accounted for 20% of national health spending in 2013 and grew 3.4% to $585.7 billion, down from a growth rate of 4.0% in 2012. Cancer care costs will continue to increase for the foreseeable future due, in large part, to aging “baby boomers” who are in their cancer-prone years and the introduction of new technologies and molecularly targeted therapies.[7] The Affordable Care Act (ACA) is an attempt by the federal government to diminish the rate of increase while at the same time improving the quality of care provided to patients.

An example of methodologies within the ACA designed to decrease the cost of care includes alternative payment strategies; principal among these is value-based reimbursement.[8,9] Value in health care is defined as the outcome achieved (quality) divided by the cost of care to achieve that outcome.[10] Health care reimbursement is currently tied to the quantity and volume of care delivered rather than outcomes. Payers, the largest of which is the Centers for Medicare and Medicaid Services (CMS), are moving toward value-based reimbursement as a way of rewarding providers (hospitals and health care professionals) that achieve better outcomes. It is estimated that one-third or more of health care dollars expended caring for cancer patients are wasted on inappropriate or futile care.[5] Examples include inappropriate or poorly performed surgical procedures, care not consistent with current cancer therapeutic guidelines, or continuing to administer chemotherapy in the terminal phase of cancer illness when end of life and supportive care is more appropriate.

One of the difficulties in improving the quality of care for patients with cancer of the head and neck is a lack of available benchmark or comparator data; capturing outcome data is difficult and costly. Current electronic health records (EHR) do not facilitate capturing important data elements related to a

specific patient that can be easily retrieved for reporting and analysis. As the EHR evolves, patient information such as demographics, tumor-specific details, comorbidity, the treatment provided, and functional outcomes will be captured as discrete data elements in the workflow, thus facilitating reporting outcomes. As these databases become robust, risk-adjusted outcomes along with the cost of care will be reportable. At that point, value analysis based on high-quality data will be reportable allowing for benchmarking outcomes and the ability to compare individual providers and institutions.

Although the promise of the EHR to support these goals remains in the future, there are tools available now to improve the quality head and neck cancer care and to potentially diminish costs of care. Diminishing variability through the use of cancer care pathways is one readily available resource. The National Cancer Center Network (NCCN) has developed and refined treatment guidelines for patients with cancer of the head and neck based on the highest level of evidence available with input from a panel of cancer care specialists who are leaders in their respective fields of surgical, radiation, and medical oncology.[11] The American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) and the American Head and Neck Society (AHNS) continue to develop clinical practice guidelines (CPGs) and quality measures to aid in the treatment of diseases of the head and neck and also provide tools for assessing the quality of care delivered. Currently, payers use cancer care guidelines as a resource for approving diagnostic studies and proposed therapy. Treatment falling outside of these guidelines may be denied reimbursement. In the future, it is anticipated that payers will direct patients with complex diseases to providers and institutions that can demonstrate value-based care.[12]

This chapter reviews current methodologies for capturing treatment outcomes and systems-based approaches for improving cancer treatment that include organization and structure of the multidisciplinary team, the use of evidence-based guidelines, coordination of care among the disciplines, process metrics supporting efficiency, and quality improvement tools.

Evidence-Based Clinical Practice Guidelines

As medical science and technology advance at a rapid pace, it has been a challenge for hospitals and medical providers to consistently provide high-

quality care to all patients. Difficulties in achieving this goal stem from our inability to clearly define quality metrics. To improve the quality of care patients receive, the IOM has challenged the health care community to incorporate evidence-based treatment guidelines as a way of consistently providing the best care possible for patients with complex or chronic disease. Patient care should be based on a continuous healing relationship customized to the patient's needs and values and oriented toward a common goal. The patient should have access to all relevant medical information in order to make informed decisions. All medical decision making should be evidence based, cooperative, and transparent. In addition, the health system should be safe, continually trying both to decrease variation and waste and to anticipate the needs of the patients.[4]

Meeting these goals is a great challenge, for all providers at all levels of the health care system. One way of improving the consistency and reducing the variation of health care delivered is through the development of structured treatment pathways that provide evidence-based evaluations and interventions to optimize the use of resources and deliver the best outcome.[4] CPGs are an important and powerful tool for assisting individual practitioners in using the most current evidence and consistent methodology available.[13] As many organizations attempt to incorporate guidelines as a strategy to reach the goals articulated by the IOM, an important tool has been the development of CPGs that are specific to a patient and disease population. This section will define the role of CPGs as a means to improve current quality standards of medical care. In addition, it will discuss the necessary rigor critical to creating clinically relevant evidence-based guidelines and how they contribute to improved cancer care.

Definition of Clinical Practice Guidelines

The IOM has defined CPGs as statements that include recommendations intended to optimize patient care that are informed by a systematic review of the evidence and assessment of the benefits and harms of alternative care options.[14] It has defined best practice standards for the CPG development. These include the following:

1. *Establishing transparency*: The fundi ld be publicly detailed.
2. *Management of conflict of interest*: Conflicts of interest should be limited,

and avoided, with group members divesting themselves of such conflicts when possible. When not possible, these conflicts should be fully disclosed.

3. *Guideline development group composition*: The group should be multidisciplinary with public and patient involvement.
4. *Clinical practice guideline–systematic review intersection*: Those performing systematic reviews and those in the guideline group should agree on the scope, method, and anticipated output of each group's work.
5. *Establishing evidence foundations for and rating strength of recommendations*: Each recommendation should be accompanied by an explanation with summary of the evidence, a confidence rating, and a strength rating.
6. *Articulation of recommendations*: Recommendations should be clear, provide direction, and be worded appropriately.
7. *External review*: External reviewers should comprehensively represent relevant stakeholders, and all reviews should be kept confidential.
8. *Updating*: CPGs should be regularly reviewed and updated.

Once developed, a CPG is rigorously evaluated for inclusion in the National Guideline Clearinghouse (NGC) database.[15] The NGC is an initiative of the Agency for Healthcare Research and Quality (AHRQ), an organization within the U.S. Department of Health and Human Services. Its mission is to provide physicians and other health professionals, health care providers, health plans, integrated delivery systems, and purchasers an accessible mechanism for obtaining objective, detailed information on CPGs and to further their dissemination, implementation, and use.[15] The NCG is an extensive collection of CPGs for a broad variety of medical conditions.

CPGs should contain systematically developed statements that include recommendations, strategies, or information that assists health care professionals to make decisions about health care in specific circumstances. All of these guidelines are evidence based, providing corroborating documentation from a systematic literature review.[16] It is important to recognize that guidelines are not to be used for reimbursement, health care rationing, legal precedents, and measures for licensing or certification or for cookbook medicine.

Within oncology, the NCCN establishes CPGs for cancer management. NCCN guidelines are compiled by an expert panel of radiation, medical, and

surgical oncologists who review current literature and make management recommendations based upon the best available evidence. Where evidence is lacking, expert consensus, with multidisciplinary representation from leaders in each field, is rendered.

Why Use Clinical Practice Guidelines?

There is currently a strong initiative to identify metrics that demonstrate quality care; more efficient care will reduce health care costs. The CMS has defined health care efficiency as the absence of waste, overuse, misuse, and errors through the limitation of unexplainable practice utilization variation.[17] CPGs are tools that can be used to improve patient care and clinical outcomes with the goal of providing safe, consistent health care that can be tailored to each patient’s clinical and personal situation.

Opponents to CPGs express concerns that these remove the individual decision making of the medical professional. However, CPGs are not intended to dictate care but are created to serve providers; in the setting of an ever-increasing body of literature, CPGs outline best practices based upon the best available evidence. Put another way, CPGs are systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific individual circumstances.[17] They are not intended to supersede professional judgment and should allow for treatment options based on the variation in patients’ specific needs and interests.[18] The primary goals for CPGs are to minimize harm, reduce inappropriate provider variations in clinical care, and optimize health outcomes. Although the use of CPGs may result in reduction of costs, the financial benefit is not the main objective of an evidence-based guideline but merely a reflection of more efficient care.[16]

Process for Developing Clinical Practice Guidelines

CPG development has been refined over the years to be more standardized, thereby producing more reliable CPGs. When created with high methodologic rigor, a well-designed CPG can demonstrate the capacity of an organization or society to influence both patient health and public policy.[16] In general, the overall process needs to involve a systematic method of identifying evidence and ranking the relative strengths and quality of the

literature, which is then critically evaluated by a panel of experts to reach an agreement on the strength of a recommendation.

Because not every clinical question can be effectively answered by strong published evidence, there are three different approaches to constructing a CPG. The first is an informal consensus in which a panel of experts convenes to consider clinical questions and render a statement on best practices; this is done when strong evidence is lacking. The second is a formal consensus guideline for which a panel of experts considers clinical questions and renders a statement on best practices; this type does include a full formal review of the literature. However, due to gaps in the evidence, it may not be possible to link each individual recommendation to the evidence. In this situation, it may be necessary to produce a summary statement globally supported by the literature. The third method includes evidence-linked construction in which a comprehensive and systematic evidence search is performed. There is a formal ranking of the strength of the evidence through grade assignment. Each clinical recommendation is then linked to the supporting evidence and the strength for which the recommendation is supported by the evidence is defined. The latter is the most rigorous approach to developing CPGs, which represent the most complete evidence-based best practices; however, the process is often complex, time-consuming, and even inefficient.[16]

Within the surgical specialties, the AAO-HNS has been at the forefront of CPG development. This association has been interested in identifying high utilization and multidisciplinary clinical situations for which there needs to be clarification and standardization in otolaryngology practice. With the desire to produce high-quality CPGs, the AAO-HNS created a manual for guideline development[16] and assigned a task force to oversee the processes. This Guideline Development Task Force (GDTF) is made up of representatives from each sister society (e.g., AHNS) and receives input from all areas within otolaryngology. Through the GDTF and AAO-HNS leadership, otolaryngology has produced 13 CPGs and has more than 10 under development.

There are five basic steps for successfully creating a valid evidence-based guideline. First, the subject area must be identified and refined. Then, the guideline development group convenes and a systematic literature review is performed to assess the available evidence. The evidence is then translated

into recommendations. Lastly, the guidelines should be sent for external review.[19] The following steps outline the AAO-HNS process for producing a high-quality CPG.

Planning

The first step in guideline development is to define a topic that is timely for all of the stakeholders, including health care providers, patients and their families, society organizations, and even payers. The topic should be important and feasible. There should be multidisciplinary appeal, high utilization, or substantial burden of illness or cost due to the variation in care. A good topic also will have high-quality evidence available in the literature. It is also important to know if there are already existing published guidelines on a similar topic. During this phase of development, the guideline development group, including both the leaders and the outside stakeholders, should be identified. All conflicts of interest should be disclosed and addressed.

Evidence Collection

The initial topic may start out being very broad, but after an appropriate search of the literature, it may be refined to answer more specific questions. The target audience should be defined, as well as the types of practice settings in which the CPG would be applied. The group should discuss the clinical interventions as well as the outcomes that should be considered, including new technology and medications. With that information, it is possible to begin a literature search using identified keywords from such common sources as MEDLINE, Cochrane Community, etc.

Key Statements

Once the evidence has been defined, the key statements can be developed. These boldface statements are different from the global topics in that the latter often reflect controversy, practice variation, and areas for quality improvement. The key statements are more focused and describe when, who, what, and to whom each recommendation applies (i.e., under what conditions a provider would do a certain action to which patients). These statements use an action-type verb requesting the provider to perform a measureable action.

Examples would be “prescribe,” “perform,” “educate,” “test,” “dispose,” and “refer.” A key statement should avoid passive verbs such as “consider” when making a recommendation. There are times when a recommendation is vague, but the rationale for this, such as insufficient evidence, inability to reach a consensus, legal standard of care, economic prohibitions, and ethical constraints, must be included. After the key statements have been identified, each must be supported by text that summarizes the evidence. This text should describe the risks, harms, benefits, costs, and alternatives for the recommendation.

At this point, the evidence is reviewed to identify the strength of the recommendation. Using the evidence grading system described in GRADE,[19] the evidence can be ranked from A to D. A statement receiving Grade A evidence is strong enough that further research is very unlikely to change the confidence in the estimate of effect. The evidence supporting a Grade A is usually randomized controlled trials or diagnostic studies on specific or relevant populations. Grade B evidence indicates that further research is likely to have an important impact on the confidence in the estimate of effect and may even change the estimate. This type of evidence often comes from randomized controlled trials or diagnostic studies with minor limitations. A Grade C evidence recommendation is supported by evidence in which further research is very likely to have an important impact on the confidence in the estimate of effect; more studies are likely to change the recommendations. This is seen with statements based largely on observational studies. Lastly, a Grade D recommendation is one that is not supported by the evidence. In this setting, any estimate of effect is very uncertain and is usually based on expert opinion and case reports.[19]

The key statements, once completed, should contain a recommendation supported by graded evidence. In general, when a strong treatment recommendation can be made with Grade A evidence, it is also important to clearly state that the benefits of the recommended therapy exceed the potential harms. On the other end of the spectrum, providing an option within a Grade D recommendation indicates that the evidence did not describe a clear advantage to use one treatment over another, so other factors, such as patient preference and cost, must be considered. It is important to clarify that there is no evidence demonstrating that the benefits outweigh the harms when choosing one treatment over the others. When there is no recommendation

stated, there is a lack of evidence to guide a decision and to define the risk/benefit ratio. According to AAO-HNS guidelines, the recommendation is followed by supporting text, which discussed the level of evidence, benefits, harms, costs, values, and policies surrounding it.[16]

External Review

After the guideline is created, it must undergo an external review. This includes peer reviewers and relevant stakeholders. The reviewers scrutinize the CPG, focusing on the validity, the reliability, and the feasibility of the statements. In addition, the guideline should be reviewed by the board of any sponsoring organizations. Once the comments have been addressed and the guideline is edited, it can be submitted for publication. It is common that the guidelines are published in the journal of the organization or society. CPGs can also be made available on the society Web sites and submitted into clearinghouses such as NGC.[15]

Algorithm Development

Once a CPG has been developed, it sometimes becomes clear that the recommendations should also be outlined in a process map or clinical algorithm. These types of process pathways can be used to graphically demonstrate the decision-making logic and sequence. Algorithms are helpful when a CPG will be impacting a practice community where there are multiple health care providers involved in caring for the same patient population. In addition to creating easy visual organization of the practice process, an algorithm allows for “yes” and “no” decision points, which can easily be defined as a data point for measurement. It is often these crossroads in clinical decision making that can be identified as the basic for metrics, which can then be measured for assessment of compliance with best practices. These metrics can then be used to support appropriate and rapid changes in a practice process to continually improve the quality of health care.

There are increasing initiatives to improve the quality of health care. One of the ways for health care providers and medical societies to achieve this is through the development of evidence-based CPGs. CPGs have the ability to improve individual patient care and clinical outcomes by disseminating best practices while maintaining provider autonomy.

QUALITY METRICS

Assessing the quality of care focuses on three dimensions of care defined by Donabedian: structure, process, and outcome.[20] Structure is defined by the characteristics of a health system, such as a community hospital or a tertiary academic center. Process encompasses the activities performed by a health care provider. Outcome refers to results of the treatment affecting the patient, ranging from effects on quality of life to overall survival. In considering these aspects of care, it is frequently easier to measure process than outcome for assessing quality of cancer care, because a large number of factors, including comorbidities and patient preference, may influence patient outcome and may not be completely defined or measured.

The National Quality Forum (NQF) was established in 1999 as an expert panel and clearinghouse to distribute quality measures. There are currently 70 measures endorsed by the NQF relating to cancer.[21] For example, one measure documents the percentage of final procedure reports using fluoroscopy that document radiation exposure or exposure time. Another measure relates to overutilization of imaging studies in melanoma patients. None of these measures are directly related to cancer of the head and neck.

Measuring the quality of care for patients with cancer serves a number of important functions. Stakeholders, including patients, payers, and physicians, use the results to make informed decisions regarding treatment. Patients may decide among care centers or hospitals depending upon available quality measures or “grades.” Additionally, measuring quality of care can improve patient care. A cancer center or a specific department can evaluate its processes of care and determine rates of compliance with established standards (CPGs or NCCN head and neck cancer treatment guidelines). For example, patients with cancer of the head and neck with advanced cancer (T) stage or metastatic lymph nodes should be referred to radiation oncology for consideration of postoperative radiation therapy. Understanding levels of adherence to these guidelines and working to improve compliance should serve to improve patient care overall. Finally, measuring the quality of cancer care is critical for policy formulation. For example, routine preoperative imaging with a specific imaging modality may or may not affect treatment or improve outcome. Assessing the specific value of a preoperative imaging tool allows for decisions to be made at a system-wide level for such studies.

Establishing metrics that define quality care enables changes in the quality improvement process. The Shewhart cycle (Fig. 7.1), named for the quality engineer Walter Shewhart, has been used for several decades for industrial quality improvement and has more recently been used in the health care sector.[22] The premise of the cycle is continuous quality improvement, with the final step being ongoing monitoring to ensure the gains are held, and the ultimate goal of optimization of care is achieved.

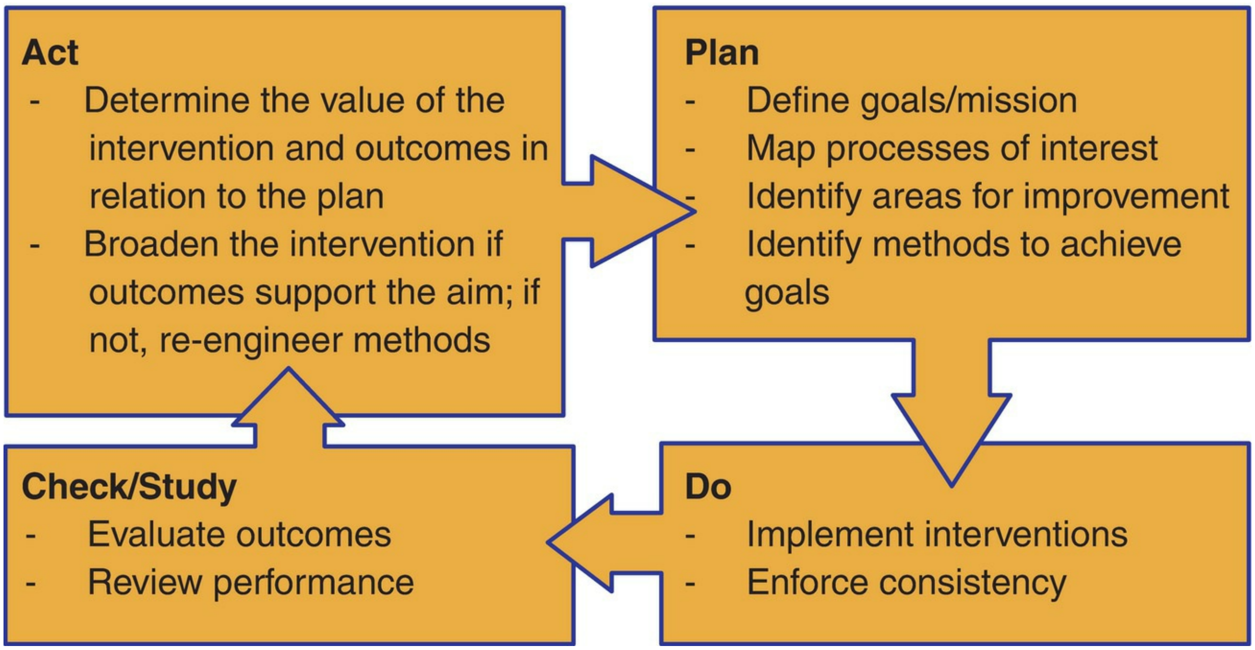

Figure 7.1. The Shewhart cycle.

Development of Quality Metrics

The establishment of quality measures typically evolves from the consensus of an expert multidisciplinary panel convened to review the literature and provide commentary; strong expert consensus is essential. A thorough and comprehensive review of the literature is performed to identify the available evidence regarding a particular process of care. This evidence is vetted to determine the level of evidence of the available clinical research (Table 7.1). The best process measure comes from research that a specific practice results in improved outcome(s). For example, patients treated surgically for squamous cell carcinoma of the head and neck with extracapsular extension of cancer detected in their cervical lymph nodes have improved locoregional control from the administration of postoperative adjuvant chemoradiotherapy

rather than radiation therapy alone.[23] In accounting for patient preferences, a quality measure may assess whether a treatment was offered or recommended rather than whether the treatment was actually performed. Once a quality measure is accepted, performance of physicians and/or institutions can be evaluated by adherence to this measure.

Table 7.1 Definitions of Levels of Evidence for Clinical Studies

Level	Study Type
1	a. Systematic reviews of randomized controlled trials
	b. Individual randomized controlled trials
	c. All or none studies
2	a. Systematic reviews of cohort studies
	b. Individual cohort studies
	c. Outcomes research/ecologic studies
3	a. Systematic review of case–control studies
	b. Individual case–control studies
4	Case series
5	Expert opinion

Assessing outcomes of care is also essential in measuring quality of care. The IOM defines three general categories of outcomes: clinical status, functional status, and patient satisfaction. Clinical status relates to the biologic outcome of the disease, such as 5-year survival after cancer diagnosis. Other clinical outcomes include postoperative events, such as 7-day return to operating room, 30-day readmission rate, postoperative wound infections, or 30-day mortality rates. The assessment of functional status includes disease effects on the patient in the physical, emotional, and cognitive domains. Karnofsky performance status is a well-validated measure of patient functional status that also correlates with quality of life and predicts survival.[24] Patient satisfaction measures emotional attitudes of a patient toward his/her treatment. Although patients who are more satisfied are more likely to complete and follow through with treatment regimens, no correlation

exists between patient satisfaction and the quality of the care process.[25,27] Although important in understanding consumer attitudes, patient satisfaction may not be a useful measure of quality of care. Finally, a robust outcomes measure must account for factors that are not directly influenced by the health system. These variables include age, socioeconomic status, insurance status, race, cultural beliefs, and comorbidities. While measuring outcomes may seem most relevant to patient care, assessing quality of care requires outcome measures that can be directly attributed to a specific process of care.

Assessment of a health care provider focuses on adherence to quality measures. Administrative records can be examined, although they typically lack sufficient clinical detail; tumor staging is typically not part of the diagnosis code for insurance records. Medical records may be filled with clinical detail, but systematic reviews are labor intensive and not feasible at a national scale to evaluate patterns of care. Cancer registries were established by the National Cancer Act and may include information regarding tumor stage, first course of treatment, and overall survival. However, the level of detail can be quite variable and thus be inadequate as a data source to monitor cancer care quality. For example, although a cancer registry may capture pathologic assessment, postoperative chemotherapy and/or radiation therapy details may be lacking. Furthermore, the actual completion of recommended therapy is typically not present. The various limitations of these data sources clearly signal the need for a better reporting system.

Measuring Quality of Care in Head and Neck Surgery

The IOM recommended the development of a set of core quality measures to evaluate and monitor the quality of cancer care.[28] Treatment guidelines or CPGs are formulated from reviews of the existing literature and resultant multidisciplinary consensus recommendations. These guidelines enable individual physicians to deliver optimal evidence-based care for their patients. Adherence to some or all of these guidelines serves as the basis for measuring quality of care.

The AAO-HNS established the GDTF to write treatment guidelines. These guidelines serve to standardize care and decrease variation in care that can lead to poor quality of care. These guidelines are not in themselves quality performance measures and were not formulated for that purpose. Currently, available treatment guidelines cover general issues of

otolaryngology such as cerumen impaction and acute sinusitis.[29,30] To date, the AAO-HNS has not established guidelines for cancer of the head and neck.

As previously described, no cancer of the head and neck for specific performance measures are available in the NQF database. There are general performance measures that may be applied to care of patients with cancer of the head and neck. For example, there are metrics for systematic and complete pathology reporting that include tumor staging and histologic grade. The NCCN has developed treatment guidelines for cancer of the head and neck in a multidisciplinary format.[31]

AHNS established its Quality of Care Committee in 2007. The mission of this committee was to formulate evidence-based quality of care measures for patients with cancer of the head and neck. The committee was also charged to promote compliance with these standards as a framework to measure quality of care in head and neck surgery. A multidisciplinary committee was formed and began to develop quality measures in 2006. Working groups focused on metrics related to pretreatment, treatment, and posttreatment care. From the group recommendations, the entire committee approved two to four measures for each phase of care. The initial set of quality measures, which focused on cancer of the oral cavity, were approved by the Executive Council of the AHNS[32] (Table 7.2). The committee subsequently developed quality measures for cancer of the larynx, which were also then approved by the Executive Council of the AHNS[33] (Table 7.3). Assessment of adherence to these measures for the two most common head and neck cancers may serve as an important beginning for performance metrics in head and neck surgery.

Table 7.2 AHNS Quality Measures for Oral Cavity Cancer

Pretreatment measures:

1. All oral tongue cancer patients require documentation of pathology using College of American Pathologists criteria with histopathologic confirmation of disease.
2. All oral tongue cancer patients require documentation of the appropriate TNM staging (as defined by the American Joint Committee on Cancer).
   a. Assessment of primary tumor size (T)
   b. Assessment of regional nodal basins for metastatic lymphadenopathy (N)
   c. Assessment for systemic disease (M)
   This should include documentation of a complete head and neck examination, appropriate radiologic imaging of the head and neck, and chest x-ray.
3. Tobacco cessation counseling

Treatment-related measures:

1. All oral cavity cancer patients with advanced T stage or metastatic lymph nodes should be referred to radiation oncology for consideration of postoperative radiotherapy.
2. All oral cavity cancer patients with positive pathologic margins or metastatic lymph nodes showing extracapsular extension should be referred to a medical oncologist and radiation oncologist for consideration for adjuvant chemotherapy and radiation.

Posttreatment measures:

1. All patients treated for oral cavity cancer should have follow-up visits for symptom management and surveillance for recurrence and second primary tumors.
2. Patients treated with radiation therapy to the neck should have assessment of serum thyroid-stimulating hormone level to detect hypothyroidism. Posttreatment serum thyroid-stimulating hormone levels should be checked within 12 mo of completing radiotherapy.

National Comprehensive Cancer Network. Clinical Practice Guidelines in Oncology: Head and Neck Cancers. *Guidelines for Treatment of Cancer by Site*. 2009, Reference 31.

Table 7.3 AHNS Quality Measures for Laryngeal Cancer

Pretreatment measures:

1. All laryngeal cancer patients require documentation of pathology using College of American Pathologists criteria with histopathologic confirmation of disease.
2. All laryngeal cancer patients require documentation of the appropriate TNM staging (as defined by the American Joint Committee on Cancer).
   a. Assessment of primary tumor size (T)
   b. Assessment of regional nodal basins for metastatic lymphadenopathy (N)
   c. Assessment for systemic disease (M)
3. Tobacco cessation counseling
4. Prelaryngectomy counseling for patients undergoing laryngectomy

Treatment-related measures:

1. All laryngeal cancer patients with advanced T stage or metastatic lymph nodes should be referred to radiation oncology for consideration of postoperative radiotherapy.
2. All postoperative laryngeal cancer patients with more than one positive lymph node and/or advanced T stage should be referred to radiation oncology for consideration of radiation therapy.
3. All laryngeal cancer patients with positive pathologic margins or metastatic lymph nodes showing extracapsular extension should be referred to a medical oncologist and radiation oncologist for consideration for adjuvant chemotherapy and radiation.
4. All patients who undergo laryngeal surgery (partial or total) should be evaluated and followed by a speech pathologist.

Posttreatment measures:

1. All patients treated for laryngeal cancer should have follow-up visits for symptom management and surveillance for recurrence and second primary tumors.
2. Patients treated with radiation therapy to the neck should have assessment of serum thyroid-stimulating hormone level to detect hypothyroidism. Posttreatment serum thyroid-stimulating hormone levels should be checked within 12 mo of completing radiotherapy.

The development of quality of care measures for oral cavity cancer. *Arch Otolaryngol Head Neck Surg*. 2008;134(6):672, Reference 32.

Significant opportunities exist in cancer of the head and neck to improve quality of care. Two studies by Chen et al. report that treatment for cancer of the head and neck is more likely to reflect treatment guidelines at tertiary care centers.[34,35] Mortality rates are higher for patients with advanced cancer of the larynx receiving care outside teaching/research hospitals.[36] Patients with early-stage cancer of the larynx may also have a higher risk for death if treated at low-volume facilities.[37] Hessel et al. used 4 main quality measures and 26 clinical endpoints based upon institutional and NCCN guidelines to evaluate the care delivered to patients with cancer of the oral cavity in a tertiary academic department.[38] Lewis et al. employed NCCN guidelines as a quality standard to evaluate care for patients with cancer of the head and neck with recurrent or persistent disease referred to a tertiary care department.[39] These studies were able to use CPGs to define specific quality metrics and set a quality standard.

PERFORMANCE METRICS IN HEAD AND NECK CANCER CARE

The concept of measuring physician performance through outcomes reporting dates back to 1908, when Dr. Ernest Codman advocated that physicians review and try to improve their own patient outcomes.[40] He was later responsible for the development of the American College of Surgeons' (ACS) Hospital Standardization Program and the ACS Minimum Standards for Hospitals, published in 1917. In 1918, only 89 of 692 hospitals surveyed met these minimum standards.[40] The program continued to grow, eventually forming the basis for the Joint Commission on Accreditation of Healthcare Organizations (JCAHO).

Recent legislation has mandated institutional reporting of outcomes centered on specific medical conditions. Although the list of conditions does not currently include cancer of the head and neck, many outcomes are generalizable to our patients' care. There are currently multiple programs focusing on performance and outcome measurement at institutional, subspecialty, and even individual levels. We are currently positioned to develop standardized performance and quality metrics for head and neck cancer care, which may shape the future of our specialty.

Institutional Programs

There are currently many programs that serve to evaluate the quality of care delivered by a medical center as compared to national, risk-adjusted standards. The algorithms for risk adjustment, however, are unique to each program.[41] Many of these programs require an investment by the institution of both personnel and infrastructure, in addition to program-related expenses. One such example is the University Health System Consortium (UHC), which collects administrative data on inpatient hospitalizations and, based on hospital discharge coding, provides risk-adjusted institutional outcomes.

Specific to surgical performance, the AHRQ has developed patient safety indicators (PSIs) that can be evaluated using administrative data and specific software that produces risk-adjusted outcomes focused on in-hospital postoperative and postprocedure complications. Because it relies on administrative data, this program can be applied to administrative databases to set national performance benchmarks for specific surgeries and procedures against which an institution can then measure its own performance. Fargen et al. used the Nationwide Inpatient Sample (NIS) database to evaluate the PSIs associated with procedural management of unruptured cerebral aneurysms to establish an acceptable national benchmark of adverse events for these procedures.[42]

The ACS' National Surgical Quality Improvement Program (NSQIP) abstracts data from patients' actual medical records, including follow-up phone calls to patients, instead of relying entirely on administrative data. Data are collected by specifically trained Surgical Clinical Reviewers (SCRs), whose work is periodically assessed for interrater reliability. Not every surgery is reviewed; cases are selected to provide a random but representative sample of a hospital's surgical caseload. This program also includes a 30-day postoperative time frame during which data on adverse events are collected. These data are then risk-adjusted against the national database and each participating institution receives a biannual report revealing how it compares nationally. This program originally started in the Veterans Affairs hospital system, and over the course of 10 years, decreased postoperative morbidity by 45% and postoperative mortality by 27% through quality improvement spurred by this audit and feedback mechanism.[43]

Using these programs for measuring quality of performance does,

however, take significant institutional investment. Recognizing the costs associated with performance measurement programs, Keller et al. developed a scoring system to assess the quality of an institution's colorectal surgery performance based on administrative data. Using a national inpatient database, the authors were able to validate that their scoring system reflects an institution's colorectal surgery complication rate, thereby providing a low-cost alternative to existing programs.[44]

Surgical Specialty Programs

Although the list of medical conditions subjected to mandatory reporting of outcomes does not cover most surgical specialties, specialty efforts to develop performance metrics, such as those of Keller et al. for colorectal surgery,[44] have increased with widespread recognition of the need for performance improvement efforts. The Society of Thoracic Surgeons (STS) established a database in 1989 with the purpose of improving the quality of care in thoracic surgery. Participation is voluntary and participants must purchase the appropriate software and input their own data, but this database provides a mechanism for thoracic surgeons to receive quarterly reports of their own risk-adjusted outcomes in comparison to national data; data are risk-adjusted in three separate areas (adult cardiac, general thoracic, and congenital heart surgery) to account for variability in the field.[45]

Specific to cancer of the head and neck, Weber et al. created a program to evaluate the performance of head and neck surgeons, which was applied within their academic department. They found that performance metrics were affected not only by patient comorbidity and procedure acuity but the individual surgeon as well.[46] A follow-up study to evaluate the impact of structured feedback on surgeon performance found significant improvements in length of stay and the prevalence of negative performance indicators.[47]

Another approach to building a mechanism for evaluating specialty-specific performance is to modify an existing platform. The first criterion is to select a program that is clinically relevant. When compared to AHRQ-PSIs for a select patient population at one institution, NSQIP identified more clinically relevant adverse events and was found to be a better measure of quality performance.[48] NSQIP has inherent flexibility and has previously been evaluated for development of a surgical subspecialty (hepatobiliary)

option.[49]

Specific to surgical oncology, Merkow et al. utilized the National Cancer Data Base (NCDB) to include cancer-specific variables in NSQIP to evaluate the impact on risk-adjusted hospital rankings. They found no significant difference in hospital rankings with the addition of these variables, indicating that the existing NSQIP risk-adjustment variables were sufficient.[50] However, Borja-Cacho et al. evaluated NSQIP's predictive ability for complications after major thoracic, abdominal, or pelvic oncologic resections. They found that NSQIP had low predictive ability, suggesting the need for additional disease- and surgery-specific variables to accommodate complex oncologic surgeries.[51]

The Department of Head and Neck Surgery at the University of Texas MD Anderson Cancer Center recently undertook efforts to create a head and neck surgery–specific version of NSQIP. Realizing from previous departmental performance assessments that the highest acuity procedures (i.e., those requiring plastic surgical reconstruction) were associated with a significantly higher rate of negative performance indicators,[46] a panel of head and neck and plastic surgeons was assembled to identify variables that would tailor the NSQIP platform to provide clinically relevant data on head and neck surgery patients. Because head and neck oncologic surgeries represented only a fraction of the total number of the institutions surgeries, a dedicated SCR was hired to sample these high-acuity cases with 100% capture. Although in its infancy, this project is now being expanded on a national level to increase its power as a mechanism for assessing the risk-adjusted performance of head and neck surgeons.

Morbidity and Mortality Database

Morbidity and mortality (M&M) conferences are an integral part of the education surgeons and trainees and usually occur on a departmental level. There are clearly practical lessons to be learned from the surgical and medical complications discussed in such a forum. However, several studies have noted significant deficits in accurate reporting of complications and even mortality to this forum.[52,53] Improving reporting and data collection for M&M conferences not only allows department members to discuss the entire spectrum of challenges related to patient care but also develops an accurate

database for longitudinal analysis. The data can be analyzed to understand the patterns of errors and adverse events that may occur within the clinical practice. This baseline information is critical to understand the current level of function for a given surgical department and serves as a basis for comparison to institutional and national metrics as they are developed. Even without extensive adjustments for patient factors, especially comorbidities, the pattern and rate of complications for an entire service and individual surgeons are valuable.

In an effort to improve M&M case reporting in our department, we began recording events at the time of recognition or occurrence rather than in a retrospective fashion. The primary reporting responsibility was shifted to the residents and fellows, rather than resting with the faculty, on a database located on a secure institutional network server. The determination of a true complication event was made by the department quality officer or through discussion in conference if any questions arose. The accuracy of the data could be compared to available institutional data, such as in-hospital mortality, return to the operating room within 7 days of primary surgery, and hospital readmission within 30 days of discharge.

At our institution, we noted that a 2-year reporting period had 330 events involving 258 patients over 4,659 surgical procedures.[54] The overall complication rate was 7.1%. We were able to categorize the various events that occurred, including hematologic/vascular (e.g., hemorrhage), wound related (e.g., infection/abscess), technical (e.g., chyle leak), and respiratory (e.g., pneumonia). We were able to compare our numbers for hospital readmission and return to the operating room for intervention. Our data collection process was confirmed by the institutional data, which were identical with regard to mortality, return to the operating room, and hospital readmission.

Active tracking of M&M cases provides a valuable practice-based system for clinical education and internal auditing of the quality of patient care. The continued acquisition and longitudinal analysis of this data provide a crucial internal benchmark for complications in order to make comparison against available data in the literature and with institutional and national metrics of quality of care at the individual surgeon and institutional level.

Individual Assessment

The work done by Weber et al. specifically addressed the performance of individual surgeons.[46] In the authors' follow-up study, performance was reevaluated after individual surgeons received their data as compared to anonymized departmental data and significant improvements were found (manuscript in preparation). The head and neck surgery version of NSQIP has also built in individual surgeon identification to allow for individual risk-adjusted feedback, much as the STS has done over the past 25 years.[45]

Although legislation in the United States has focused on institutional-level reporting, physicians realize the importance of individual performance assessment. Because of this, many performance improvement programs have their success rooted in physician feedback. In an effort to standardize blood transfusion indications in cardiac surgery patients, Beaty et al. performed an initial review of provider practices and then presented their providers with aggregate data, which was followed by an improvement in adherence to blood transfusion protocols. After this second audit, individual providers were then given individual feedback, which was followed by an additional improvement in adherence.[54] The importance of evaluating individual performance is highlighted in a study by Foglia et al. in which 5 (7%) surgeons were found to be responsible for 29% of surgical delays and 4 (8%) anesthesiologists were found to be responsible for 45% of anesthesiology delays,[56] having individual assessment allowed for more targeted performance improvement that decreased operating room delays institutionally.

A recent observational study highlighted the many reservations that physicians have about more public reporting of individual performance metrics. Although most of the surgeons interviewed indicated that they believed such measures would lead to quality and performance improvement, they raised concerns about data validity based on small sample size and coding accuracy, as well as about outside consequences, including misinterpretation of data by others and surgeon refusal to treat high-risk patients in order to better their performance.[57] These sentiments echo concerns about the recent public reporting of individual surgeons' outcomes by the National Health Service in the United Kingdom.[58] Although physician performance is important to assess in order to effect improvement in the quality of the care we provide, consideration must be given to how these data are collected and risk-adjusted and with whom and in what context they are

shared; these are issues that remain to be addressed as we move forward with performance improvement and reporting in head and neck cancer care.

CONCLUSION

Quality improvement is integral to conserving resources and ensuring the best possible care. Knowledge of measurable outcomes and the impact of delivered care on these outcomes should serve as an impetus for improving care through the identification of best practices.

8 Nonmelanoma Skin Cancer

Malcolm A. Buchanan, Carsten E. Palme, Faruque Riffat, and Michael J. Veness
Michael J. Veness

Nonmelanoma skin cancer (NMSC) is the most common malignancy worldwide and is managed by a diverse group of clinicians, including primary care physicians, dermatologists, otolaryngology—head and neck surgeons, surgical oncologists, plastic and reconstructive surgeons, and radiation oncologists. It is important that treating clinicians have a clear understanding of the epidemiology, staging, management, and prognosis of this disease. NMSC is a heterogeneous group of malignancies encompassing many different histologic subtypes, requiring different management approaches, and with widely varying prognoses.[1] These malignancies range from ubiquitous lesions, such as basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), to relatively uncommon lesions, including Merkel cell carcinoma (MCC), adnexal carcinomas, and mesenchymal tumors, such as cutaneous angiosarcoma and Kaposi sarcoma (KS).

EPIDEMIOLOGY

The most common NMSC is BCC, which constitutes 70% to 75% of cases, followed by SCC (20% to 25%).[2] MCC constitutes <5% of NMSC, and other histologic subtypes make up the remainder.[3,4] In general, males are affected more often than females, and the incidence increases with age.

The prevalence of NMSC has reached epidemic rates in regions such as Australia, where the incidence of skin cancer is the highest in the world.[2] Worldwide, there are differing rates of NMSC in various populations, but in most regions, the incidence is increasing.[2,5,6]

In Australia, the incidence of NMSC has risen significantly from 1985 to 2002, with the annual incidence of BCC increasing from 657/100,000 to 884/100,000, and SCC more than doubling from 166/100,000 to 387/100,000.[2] This continued increase has occurred despite recent public health campaigns, such as “SunSmart,” which advocates protective clothing, sun protection factor in excess of 30+ sunscreen, and avoidance of excessive sunlight, especially during peak sunlight hours.[7] In 2002, the incidence of NMSC in Australia was more than 5 times that of all other cancers, combined with an annual rate of 1,170/100,000.[2] In the United States, over 1 million new cases of NMSC are diagnosed annually.[8]

Death from NMSC is low compared with other cancers. Between 1998 and 2005, there was an average of 382 deaths per year in Australia, ~1 to 3 per 100,000.[9] Overall, NMSC has a good prognosis, with a low recurrence rate and >90% 5-year disease-specific survival rates. Despite this, NMSC, and in particular a subset of patients with high-risk SCC, can still provide a challenge for both patient and clinician, due to the development of locally recurrent disease in ~10% and the propensity for metastasis to the neck in 3% to 5% of patients.[10–13] Patients diagnosed with either an SCC or an MCC are at risk of developing metastasis and dying of their disease. Death resulting from BCC is extremely rare.

ETIOLOGY

Ultraviolet Radiation

Environmental exposure to ultraviolet (UV) radiation is the major etiologic factor that damages DNA and leads to the development of NMSC. The pathogenesis of SCC strongly correlates with cumulative exposure of UV radiation, in particular, UVB (290 to 320 nm). The sun-exposed head and neck is the region of the body most frequently affected by NMSC.[3] Risk factors include increasing age (particularly age over 70 years[2]) male gender, Caucasian ethnicity, chronic sun exposure, outdoor occupation, acquired or inherited immunosuppression, and certain rare systemic diseases such as epidermolysis bullosa, oculocutaneous albinism, and xeroderma pigmentosum (XP).[1,14–16] Additional factors such as proximity to the equator, ozone layer depletion, and both occupational and recreational

exposure significantly increase this risk.[15] NMSC is rare in dark-skinned races due to the protective role of melanin in UV-induced damage of skin cells.[17]

Immunosuppression

Immunosuppression such as in solid organ transplantation, hematologic malignancies, including non-Hodgkin lymphoma and chronic lymphocytic leukemia (CLL) (Fig. 8.1) and human immunodeficiency virus (HIV) infection increases the risk of NMSC. Posttransplantation patients and those with autoimmune disorders, or on immunosuppressive agents, exhibit an increased risk, particularly of SCC, with increasing risk associated with increasing duration of immunosuppression.[18,19] Recipients of solid organ transplants exhibit approximately a 100-fold increase in the risk of developing SCC compared with a 10- to16-fold increase in risk of developing BCC.[20] The risk for developing cervical lymph node metastases lies between 10% and 18%,[21,22] and the risk of death is significantly increased in patients who develop SCC after a renal transplant.[23]

Figure 8.1. Elderly male suffering from chronic lymphocytic leukemia

(CLL) presenting with a rapidly enlarging scalp SCC with concomitant metastatic lymph nodes in his ipsilateral posterior neck, as well as nodes enlarged secondary to CLL. Such aggressive behavior is rarely witnessed in nonimmunosuppressed patients.

Treatment-related immunosuppression, which classically occurs in solid organ transplant recipients, results in an 18 to 250 times increased risk of SCC[24,25] and, to a lesser extent, BCC. Furthermore, there is a greater risk of developing metastasis involving both regional and distant sites.[26] In the Australian transplant population, at least 45% of patients developed an SCC within 10 years of transplantation, whereas patients from Europe had an incidence of 10% to 15% at 10 years following transplant.[27] In the renal transplant population in Queensland, Australia, the incidence of NMSC at 20 years was 81%, with 75% having invasive SCC.[28]

Immunosuppression secondary to HIV has a different effect on NMSC. Associated with this greater incidence is a propensity for aggressive SCC, and an increased rate of spread to regional lymph nodes. Unlike other forms of immunosuppression, there does not appear to be an alteration in the ratio of BCC to SCC. Currently, it is unclear if CD4 count or HIV viral load affects the development of NMSC in HIV patients.[29] There are current data to support a role for human papillomavirus (HPV) in the development of SCC. This association has been demonstrated in the immunocompromised population, where up to 90% of tumors contain HPV DNA.[30]

Gene Mutations and Inherited Conditions

As with all malignancies, acquired and inherited mutations are involved in the pathogenesis of NMSC. The p53 tumor suppressor gene has an important regulatory role in the cell cycle, as well as in DNA repair and apoptosis.[31] Mutations of this gene are implicated in the etiology of many cancers, including SCC and BCC. Alterations in pyrimidine dimers, induced by UV radiation, may inactivate this gene, causing dysregulation of the cell cycle, failure of apoptosis, and tumor formation.[32] Another gene relevant in the pathogenesis of BCC is patched (*PTCH1*), located on chromosome 9, which was first identified in individuals with the autosomal dominant BCC nevus (Gorlin) syndrome.[33] Patients with this syndrome have defects in the sonic

hedgehog signaling pathway and present with multiple BCCs, odontogenic cysts, skeletal defects, palmar and plantar pits, and calcification of the falx cerebri.[33]

Other inherited conditions, including the autosomal recessive XP, can predispose individuals to a 100-fold increase in the risk of NMSC. In this condition, cells have an impaired ability to repair UV-induced damage, leading to multiple SCC and other skin cancers. The mutation involved disrupts the nucleotide excision repair, which enzymatically repairs UV-induced DNA damage.[31] Epidermodysplasia verruciformis is another autosomal recessive condition, in which increased susceptibility to viral oncogenesis, secondary to HPV infection, results in widespread wart formation followed by the appearance of cutaneous SCC.[34]

Cigarette Smoking and Carcinogens

Cigarette smoking has been implicated in the development of many malignancies, although its role in the development of NMSC is controversial. A Dutch study showed a doubling of the risk of development of cutaneous SCC in smokers with an associated dose response.[35] Some studies have supported the association, quoting increased rates of 1.5 to 4 times, whereas other studies have found no association. In contrast to the Dutch study, a large prospective study involving over 300,000 construction workers in Sweden did not find any association between smoking and the development of SCC.[36]

Other risk factors include exposure to chemical carcinogens, such as arsenic.[37] Arsenic is associated strongly with the development of a variety of dermatologic manifestations and malignancies, including SCC and BCC. Areas of chronic irritation and scarring also predispose to SCC, which is known to arise in chronic “Marjolin” ulcers, sinus tracts, and scars.[33]

Precursor Lesions

Actinic keratosis (AK) is a dysplastic keratinocytic lesion arising within the epidermal layer of the skin, induced by UV radiation.[14,38] In Australia, up to 50% of people over 40 years of age have one or more AK.[14] Although a substantial proportion (25% to 75%) of AK regress over time, a number

eventually progress to invasive SCC. Estimates of the rate of progression of an individual AK to SCC have been reported at up to 20%. Despite this, two longitudinal studies have reported a considerably lower annual rate of transformation—0.096% per year[14]; and 0.60% at 1 year and 2.57% at 4 years.[38] These studies reported that 60% to 65% of SCC arose from preexisting AK. Although the chance of an individual AK transforming into invasive SCC is low, individuals at risk usually have multiple AK, with one study documenting an average of 46.

BASAL CELL CARCINOMA

Clinical Presentation

Unlike SCC, BCC arises *de novo*, with no obvious precursor lesions. The nodular subtype is the most common and accounts for ~60% of BCC. Other variants are superficial or infiltrative. Nodular and morpheaform are the most common subtypes in the head and neck region; superficial BCCs commonly occur on the trunk.[39]

Nodular BCC typically presents as a “pearly” telangiectatic nodule with rolled borders. Central ulceration, crusting, and bleeding may occur. Superficial BCC may present as an asymptomatic plaque or papule and is pink/red in color. Most are asymptomatic, with ulceration, itching, and bleeding being uncommon. Morphoeic lesions are smooth, flesh-colored plaques or papules resembling scars with ill-defined borders.[40] They are often long-standing asymptomatic lesions and may be deeply invasive by the time of diagnosis. Perineural invasion (PNI) is frequently present. In the head and neck, the nose is the site most commonly affected, followed by other sun-exposed areas, such as the scalp and ear.[41,42] Prospectively acquired data in Australia have shown that 57% (379 out of 663) of BCCs were located in the head and neck, with the nose, cheek, forehead, and ears most commonly affected.[43] BCC rarely spreads to involve regional lymph nodes.

Histology

BCC is typified by collections of cells resembling the basal layer of the epithelium. Retraction between the stroma and tumor may be present as an

artifact and helps to differentiate BCC from appendageal tumors of similar appearance.[44] Morphoeic BCC differs histologically from the other subtypes of BCC as the stroma contains little mucin and retraction artifact is rare. PNI does occur but is uncommon.

Management

A punch or incisional biopsy of the lesion is required for initial diagnosis. As BCCs rarely metastasize, staging investigations are unnecessary, but computed tomography (CT) scans of the head and/or neck are performed in cases of locally advanced cancer to assess depth of invasion and involvement of functionally important soft tissue and bony structures (i.e., parotid gland (PG), external auditory canal, petrous temporal bone).

Surgical

Lesions are excised, typically with a margin of 3 to 5 mm. The majority of lesions can be excised and closed primarily. In patients in whom primary closure is not feasible, local flaps and skin grafts are used (Fig. 8.2). A positive margin has been reported to be associated with a 30% to 40% local recurrence rate,[45] and in these cases, patients should be considered for further surgery or adjuvant radiotherapy (RT). Positive margins underlying local flaps should rarely be left untreated because of the risk of undetected and delayed deep recurrence. Selected patients, such as those with morphoeic or recurrent BCC, can be referred for Mohs micrographic surgery, a technique in which serial sections of skin are excised and the peripheral and deep margins examined, so that 100% of the surgical margins are evaluated. Patients with morphoeic and large BCCs require wider surgical margins to maximize the chance of complete resection. For primary morphoeic lesions, the rate of complete excision with increasing peripheral surgical margins is 3-mm margin, 66%; 5-mm margin, 82%; 13- to 15-mm margin >95%.[46]

Figure 8.2. A 65-year-old female having undergone excision and grafting of a lower dorsum BCC. Midface lesions that require reconstruction, especially of the nose, may not always achieve an optimal cosmetic outcome.

Nonsurgical

A variety of nonsurgical options are also available to the clinician, including RT, cryosurgery, photodynamic therapy, curettage and cautery, topical

treatment, and intralesional injection.

Only a few randomized controlled trials have reported on the outcome of RT on patients with BCC. A Cochrane review suggested that either RT or surgery results in the lowest recurrence rates.[47] A trial of 347 patients examining RT versus excision of facial BCCs of <40 mm in diameter demonstrated fewer recurrences in the surgical cohort at 4 years (RR 0.09), and that cosmetic outcome was enhanced postsurgery (87% rated as “good”) at 4 years compared with RT (69%).[48] Conversely, in a separate trial of 374 patients, no significant difference was seen in recurrence rates between patients receiving RT or Mohs surgery, and overall cosmetic outcome did not differ between treatment groups.[49] RT is an effective option if surgery is declined or the outcome (form and/or function) is likely to be better nonsurgically.

Adjuvant RT is an option in the setting of close or positive excision margins, especially if a flap has been used for reconstruction, as detecting deep recurrence, especially in the midface, can be difficult. Up to 30% of incompletely excised BCCs will recur locally,[50] making RT a useful modality, especially if reexcision is not an option. In a trial of adjuvant RT versus surgery alone, RT improved the 5-year local control rate from 61% to 91%.[51] Ten-year local control rates were similar between the two groups (92% vs. 90%), indicating that most local recurrences can be salvaged surgically, although some patients require reconstruction after wide local excision. Patients with infiltrative BCC, particularly those with PNI, should be considered for adjuvant RT, given the propensity of these tumors to recur locally or spread to the skull base through perineural pathways.

Patients with XP should not undergo RT especially at a younger age because of the risk of inducing skin cancers. Similarly, lower limb lesions, especially in older patients suffering from diabetes and peripheral vascular disease, should not be irradiated if possible, because of the risk of delayed wound healing.[52]

SQUAMOUS CELL CARCINOMA

Clinical Presentation

Morphologically, the appearance of SCC exhibits a range of phenotypic variation. Classically, the appearance is of a shallow ulcer with raised, indistinct borders. A plaque often covers the lesion. Similar to BCC, sun-exposed areas of the head and neck are most commonly affected, with involvement of the lip or ear associated with a poorer prognosis and increased risk of metastases. Local symptoms and signs, such as numbness, pain, trismus, tumor immobility, paresthesias, dysesthesias, and cranial nerve palsy, are signs of advanced disease and may indicate deep tissue invasion and/or underlying perineural spread, which are poor prognostic factors.[16]

Patients with SCC may have a history of premalignant lesions, most commonly AK. Invasive SCC may also occur in the absence of a history of premalignant lesions. Bowen disease (intraepithelial SCC) presents as well-demarcated, erythematous, scaly keratotic papules and plaques.[53] The presence of nodal metastases has a potential adverse impact on prognosis in terms of morbidity, mortality, and quality of life.[54] Distant spread is rare but may occur in more advanced, neglected, and/or recurrent cancers. Lung and bone are reported to be the most common sites of distant metastasis,[55,56] with the liver and brain also potentially affected.[16] In a study of 122 patients treated for metastatic SCC, 7% developed distant metastatic disease, with the lung the most common site.[56]

Histology

SCC and its precursor lesions (AK and Bowen disease) are characterized by sheets and ridges of squamous cells. AK involves only part of the epidermis, Bowen disease involves the full thickness of the epidermis, and invasive SCC spreads beyond the basement membrane. SCC arises from the keratinocytes of the spinous layer of the epidermis. There is infiltration of the dermis by atypical squamous cells surrounded by an inflammatory infiltrate. The degree of cellular differentiation is categorized as mild, moderate, or severe and is of prognostic value. The degree of differentiation correlates with the extent of keratinization, nuclear hyperchromasia, and increased mitotic activity.[44] The more poorly differentiated the tumor, the fewer keratin pearls are present. The depth of anatomic invasion is indicated by Clark's level staging system[57]:

- Level 1: SCC confined to the epidermis (SCC *in situ*)

- Level 2: Invasion into the papillary dermis
- Level 3: Invasion to the junction of the papillary and reticular dermis
- Level 4: Invasion into the reticular dermis
- Level 5: Invasion into the subcutaneous adipose tissue

Metastasis to the Neck

The risk of developing lymph node metastasis in patients with SCC is uncommon, and ~3% to 5%, but increases in patients with unfavorable primary tumor features, that is, high-risk SCC.[11–13] Patients developing local recurrence are at higher risk of lymph node metastasis.[10,12,58] The parotid gland (PG) is the most frequent site for metastasis in patients with head and neck primaries. Patient factors that predict the development of metastasis include male gender, immunosuppression, and delayed presentation.[11,59] Tumor factors include histologic grade (poorly differentiated or undifferentiated), size (>2 cm), depth/thickness (>4 mm), invasion of adjacent tissue, anatomic location (ear, lower lip, and cheek), presence of perineural and/or lymphovascular invasion (LVI), and growth rate. Over 70% of lymph node metastasis presents within 1 year of treatment of the primary lesion, whereas few patients present with lymph node metastasis after 5 years.[12]

Regional nodes can be separated broadly into two groups, namely, parotid (preauricular and parotid tail) and cervical nodes (levels I to V). The location of a primary cutaneous SCC is an important determinant of the site of potential lymph node metastasis. The most frequent location for such a lesion is the lateral aspect of the head (Fig. 8.3). Metastasis is most commonly identified in parotid, level II (i.e., jugulodigastric), and external jugular chain nodes. Parotid nodes represent the first echelon of lymphatic drainage from the face, forehead, anterior scalp, temple, and ear. In Australia, metastatic cutaneous SCC is the most common malignant neoplasm of the parotid.[60] Facial lesions tend to metastasize to level I and II cervical nodes, whereas anterior lesions of the scalp, ear, temple, and forehead usually metastasize to parotid +/− level II cervical lymph nodes.[61] Drainage to multiple first echelon nodes is common. Drainage to contralateral nodes occurs in 10% of patients, predominantly in those with midline cancers.[62] Cancers posterior to the tragus usually metastasize to level V or the occipital nodes.

Figure 8.3. A 62-year-old bedbound, poor performance patient with a 3-cm thick poorly differentiated SCC located in his left preauricular region. Clinically, he was node negative but considered at risk of harboring occult nodal metastases. Being medically inoperable, he proceeded to wide-field high-dose radiotherapy (50 Gy in 20 fractions). Note the generous radiotherapy field (as marked) to treat potential subclinical spread.

High-Risk Tumor Features

Tumor size, using a cutoff of 2 cm (Fig. 8.4), is associated with a significant difference in the rate of lymph node metastasis.[10,11,63] There is, however, a limitation in applying two-dimensional tumor size as a sole prognostic factor. In a study of 266 patients with metastatic lymph node metastasis, where 70% of lesions were <2 cm in size, tumor thickness was >4 mm in the majority of patients with T1 lesions, all of whom had metastasis.[58] There was a significant correlation between increasing thickness of the cancer and size of the lesion, suggesting that these cancers had a propensity for both vertical and

horizontal growth. It was noted that not all large SCC metastasized, inferring that lesions that are horizontally large (2 to 3 cm), but not thick (i.e., 2 to 3 mm), may lack the tendency to metastasize.

Figure 8.4. An 82-year-old male who 9 months previously underwent excision of a 12-mm SCC. He now presents with biopsy-proven metastatic nodal SCC to his ipsilateral preauricular lymph nodes. The lateral forehead and temple should be considered as high-risk anatomic locations as the lymphatic vessels drain to the nearby parotid and upper neck.

Thickness of the cancer is also of prognostic importance.[12] Thickness of the cancer >6 mm was a highly significant independent predictor for the development of metastases in a large German prospective study.[12] Fourteen of 90 patients with cancers thicker than 6 mm developed regional metastasis, whereas no patients with cancers thinner than 2 mm developed regional metastasis. Another study demonstrated that although only one-third of patients with SCC have lesions >4 mm thick, these accounted for >80% of cancers developing metastatic nodal disease.[22] In a study involving more than 500 patients, no patients with an SCC of thickness <2 mm developed metastasis, whereas approximately 20% of patients with a lesion >5 mm developed regional nodal metastases.[64] In keeping with thickness, Clark levels have also been investigated and reported to be predictive. SCC measuring <4 mm thick or Clark level I to III had a metastatic rate of 6.7%, whereas the rate for SCC > 4 mm thick or Clark level IV or V was 45.7%.[10]

Desmoplastic SCC is an aggressive histologic variant, most frequently found on the ears, nose, and forehead. It is characterized by the presence of PNI, an invasive clinical course, and poor prognosis.[65] Patients with desmoplastic SCC have 10 times the risk of local recurrence and 6 times the risk of metastasis compared with other SCC subtypes.[64] Desmoplasia is reported to be the most important histologic feature for local recurrence, with 24% of 51 patients with desmoplasia versus 1% of 564 patients without desmoplasia developing local recurrence.[12]

Recurrent cancers are associated with a marked increase in the risk of developing metastases to the neck. Patients with inadequately excised SCC are at risk of both local recurrence and the development of nodal metastasis. The risk of nodal metastasis has been shown to be 15% in patients with recurrent lip SCC, compared with 2% in those with *de novo* lesions.[10] The incidence of lymph node metastasis was 32% and 45% in the setting of recurrent lip and ear SCC, respectively.[58] In one study, 18% of 78 patients had metastatic cancer following tumor recurrence (HR 2.81).[66] In a review of 122 patients with metastatic SCC, 11% of patients had lesions that were recurrent.[56]

Poorly differentiated SCC is more likely to be associated with the development of regional metastases. A significant difference in the rate of nodal metastasis between high- and low-grade SCCs (17% vs. 4%) has been

reported.[67] Other studies have demonstrated a difference in tumor behavior, based on histologic grade, with the rate of poorly differentiated SCC increased in patients developing metastasis (44% vs. 5%).[63] An Australian study also supported this finding, with 46% of patients with nodal metastasis displaying moderate or poor differentiation of their primary SCC, compared with 12% with a well-differentiated grade.[58]

Perineural invasion (PNI) refers to tumor growth in or around a nerve[68] and occurs by the contiguous spread of malignant cells along the potential space between a nerve and its surrounding sheath. PNI occurs in <5% of all cutaneous malignancies and is more common among SCC, involving 2.5% to 14% of cases, compared with 0.18% to 10% of BCC.[69] The presence of PNI is significant in that it confers an increased risk of recurrence in both BCC and SCC and the development of metastasis in SCC, and a poorer prognosis due to more aggressive tumor behavior.[69] The risk of death from PNI is much less likely with BCC.

PNI can be broadly classified as either "incidental" or "clinical." Incidental PNI is identified only at histopathology in clinically asymptomatic patients with negative imaging. Other terms used in the literature to describe incidental PNI include "minimal" or "microscopic" PNI. PNI is classified as "clinical" when the patient exhibits sensory or motor changes or there is radiographic evidence of perineural spread within a named nerve. It may also be referred to as "extensive" or "macroscopic" PNI.

The distinction between incidental and clinical PNI is prognostic. One study reported a 5-year local control rate of 80% for cutaneous malignancies with incidental PNI, compared with 54% for clinical PNI, despite aggressive treatment with RT +/− surgery and/or chemotherapy.[70]

A study on PNI in SCC demonstrated that the presence of additional tumor-related high-risk factors was associated with poorer outcomes, and concluded that these patients should also be considered for adjuvant RT.[71] Factors identified included poor differentiation, tumor diameter ≥2 cm, and invasion beyond subcutaneous adipose tissue. Significantly, patients with involvement of large nerves (≥0.1 mm) were also found to be more likely to have such concomitant adverse features.

The main challenge in managing patients with clinical PNI is achieving durable control of their disease. Appropriate resection with margin control

plus adjuvant RT is likely to offer select SCC patients with clinical PNI the best chance of cure. Even tumors previously considered potentially unresectable, such as those with extensive intracranial PNI involving cranial nerves up to the gasserian ganglion (zone 2), may be operable, and this treatment potentially offers improved survival with acceptable morbidity.[72]

High-dose definitive RT alone can also offer the chance of cure in ~50% to 60% of suitable patients, but with associated acute and late side effects. Intensity-modulated (IM) RT offers the ability to treat accurately defined volumes considered at risk, or involved, and at the same time limit the RT delivered to important structures at risk, such as the visual pathways and brain. The fusing of diagnostic magnetic resonance imaging (MRI) scans with RT simulation scans allows improved determination of the target volume.[73]

Lymphovascular invasion (LVI) denotes invasion of tumor cells into the microvasculature of the dermis and lodgment within a vessel lumen and has been demonstrated to be an independent risk factor for nodal disease (40% node positive vs. 8% node negative).[74] In a large study of 4,740 patients treated for SCC, multivariate analysis identified LVI as a significant risk factor for metastatic disease in patients with a lesion in the cheek or periauricular region (HR 3.18 and HR 3.31, respectively), but not at other sites of the head and neck.[75]

Anatomic subsites have been identified as being at increased risk for the development of nodal metastases. The most common primary sites leading to parotid and/or neck metastases, in descending order of frequency are the lip, cheek, ear, temple, forehead, scalp, and nose.[56,76,77] The most common primary sites leading to parotid metastases are temple/lateral forehead and preauricular area and cheek.

Positive excision margins are associated with recurrent SCC in up to 50% of patients (Fig. 8.5).[78] An excision margin of 6 mm in patients with high-risk SCC is recommended. In two studies, an excision margin of 4 to 5 mm for low-risk SCC resulted in tumor clearance in 95% to 97% of cases compared with 78% clearance when a 2-mm excision margin was applied.[79,80]

Figure 8.5. Recurrent SCC in a 92-year-old female. She previously underwent three excisions in the same site without being considered for adjuvant local radiotherapy, despite close and positive excision margins and recurrence. The extent of her recurrence precluded salvage surgery and has recommended wild-field radiotherapy (40 Gy in 10 fractions using orthovoltage photons) with protection of her globe. Her parotid and cervical lymph nodes will be clinically observed.

Staging

The 7th edition of the American Joint Committee on Cancer (7th AJCC) tumor, node, metastasis (TNM) staging system is widely used in staging the primary SCC and neck.[1] Previous editions of the AJCC TNM classification did not differentiate between subtypes of NMSC and were criticized for this. Previously, only the horizontal extent of the primary lesion was considered important when differentiating T stage, with nodal metastasis classified as either N0 or N1, to indicate presence or absence of regional involvement.[1]

The 7th AJCC staging system now incorporates multiple high-risk features when determining the T stage of an SCC and differentiates early lesions (T1 or T2) based on size (2 cm threshold) and the absence or presence of other tumor-related features such as thickness >2 mm, PNI, poor differentiation, and location on the ear or non–hair-bearing lip (Table 8.1). Advanced lesions (T3 and T4) are uncommon and based on the degree of local invasion into surrounding tissues. Of note, an obvious index lesion is not present in a minority of patients (20% to 30%) who present clinically with metastatic SCC of the head and neck, although most will have a past history of NMSC.[58]

Table 8.1 Staging for Cutaneous SCC (7th Edition of AJCC Staging Manual)

Tumor		Node		Metastasis	
Tx	Primary tumor cannot be assessed.	Nx	Regional lymph nodes cannot be assessed.	M0	No distant metastases
T0	No evidence of primary tumor	N0	No regional lymph node metastases	M1	Distant metastases
Tis	Carcinoma *in situ*	N1	Metastases in a single ipsilateral lymph node, 3 cm or less in greatest dimension		
T1	Tumor <2 cm in greatest dimension with <2 high-risk features	N2a	Metastases in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension		
T2	Tumor >2 cm in greatest dimension or any tumor with 2 or more high-risk features	N2b	Metastases in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension		
T3	Tumor with invasion of maxilla, mandible, orbit, or temporal bone	N2c	Metastases in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension		
T4	Tumor with invasion of skeleton (axial or appendicular) or perineural invasion of skull base	N3	Metastases in a lymph node more than 6 cm in greatest dimension		

High-risk features: >2 cm in size, >2 mm thickness, or Clark level ≥ IV, presence of perineural invasion, located on the ear or non–hair-bearing lip, poorly differentiated, or undifferentiated.Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springer.com.

O’Brien et al. (Table 8.2) recognized the significant limitation of the TNM system when proposing a new staging system, based on extent of metastatic regional disease involving the parotid and/or cervical neck nodes.[81] Eighty-seven patients who had been treated with curative intent for metastatic SCC of the head and neck were restaged according to this new

system, which separated nodal metastasis (size, number, and site) in the parotid (P) and neck (N). Multivariate analysis demonstrated that although increasing P stage, positive margins, and failure to have multimodality therapy were associated with increased risk of recurrence in the parotid, neither increased P stage nor type of therapy were significant for survival. However, both increasing N stage and positive margins were found to be predictive of worse disease-specific survival.

Table 8.2 O'Brien et al. System for Clinical Staging of Metastatic Cutaneous SCC Involving the Parotid Gland +/− Neck

Parotid		Neck	
P1	Metastatic node up to 3 cm diameter	N0	No clinical neck disease
P2	Metastatic node more than 3 cm up to 6 cm in diameter or multiple parotid nodes	N1	Single ipsilateral neck node up to 3 cm diameter
P3	Metastatic node more than 6 cm in diameter or cancer involving VII or contralateral nodes	N2	Single node more than 3 cm diameter or multiple neck nodes or contralateral nodes

Palme et al. subsequently tested this new P and N staging system on a separate group of patients from the Head and Neck Service, Westmead Hospital, Sydney.[82] One hundred and twenty-six patients with SCC metastasizing to the parotid and/or neck were retrospectively restaged. The results demonstrated that increasing P stage was associated with a reduction in local control and increased treatment failure within the parotid bed. Immunosuppression, single modality therapy, and increasing P stage were all found on multivariate analysis to be significantly associated with decreased survival. However, unlike the study of O'Brien et al., increasing N stage was

not found to be significant.[82]

A modification of the O'Brien staging system, including the parotid and remaining neck nodes, was introduced to include well-accepted nodal factors, such as size, location, and number, in order to improve prognostication and simplify staging of patients with metastatic SCC of the head and neck.[83] This proposed system was tested against a cohort of patients from the authors' institution and externally validated against a separate group from Westmead Hospital, Sydney. In both instances, the stratifications were found to have prognostic significance. The nodal classification in the N1S3 system is similar to that of the current 7th edition of the AJCC, which was modified based on results from published studies.[81]–[85]

Investigations

Following a thorough history and clinical examination of the primary cancer and head and neck region to ascertain the presence of nodal metastasis, and assessment of any neurologic deficit (cranial nerve palsy or sensory deficit) from PNI, histologic diagnosis of the primary is confirmed with an excisional biopsy for small lesions and punch or incisional for larger lesions. A fine needle aspiration of any palpably enlarged nodes should be undertaken under ultrasound guidance.

The majority of low-risk patients without palpable lymph nodes do not require further radiologic evaluation. The presence of high-risk clinical or histologic features—large or neglected tumors, recurrent disease, or suspected cranial nerve involvement, including the facial and/or trigeminal nerves, the immunocompromised host, or extracutaneous involvement—may indicate a need for further radiologic evaluation of the primary and local and distant metastatic disease.[86] A contrast-enhanced CT scan will assess the depth of invasion of the primary and whether underlying bone is involved. Central hypoechogenicity, round shape, and enlarged size of a lymph node are suggestive of metastatic disease. Loss of adjacent nodal adipose tissue planes indicates extracapsular spread. An MRI scan will provide information regarding infiltration of critical soft tissues, including orbit, brain, and, in particular, cranial nerves.

In a prospective study of 48 patients with head and neck cancer undergoing neck dissection, the modalities of palpation, ultrasound, and CT

findings were compared with the gold standard of histopathologic examination of lymph nodes.[87] Palpation had a positive predictive value and negative predictive value of 78% and 74%, respectively. In comparison, the corresponding values for ultrasound were 94% and 80%, and for CT 90% and 85%. However, similar data specific to cutaneous SCC are lacking.

Management

The optimal approach to a high-risk patient is surgery, preferably Mohs micrographic surgery.[88] However, this option is not always available, and alternatives include wide excision +/− adjuvant RT or definitive RT (Fig. 8.6A and B). The aim of surgery for a patient with SCC (low or high risk) is to obtain negative excision margins, which typically range from 3 to 10 mm, depending on patient and tumor variables. It is unacceptable to observe patients with inadequately excised SCC because of the risk associated with recurrence. Re-excision or adjuvant RT should be offered in this situation.

planned excision margin is illustrated on the patient. **B:** Wide excision of the lesion down to the parotid fascia.

Definitive RT is an efficacious option for both low- and high-risk SCC,[89] and, as with BCC, attention needs to be paid to the cosmetic and functional outcomes of surgery versus RT. One benefit of RT is the ability to treat widely (and deeply), to encompass microscopic subclinical spread that, if surgically approached, would leave a large defect, necessitating reconstruction.

Metastatic Nodal SCC

A minority (<5%) of patients with head and neck SCC develop metastatic SCC to the PG nodes and/or cervical nodes. Patients invariably have a past history of treated NMSC of the head and neck, and most will have an identifiable index lesion from which the metastatic SCC arose. Best practice for patients with metastatic cutaneous nodal SCC is appropriate surgery and, in most cases, adjuvant RT.[56] Very few patients will not benefit from combined treatment, excluding those with a single involved node without extracapsular spread and who are not immunosuppressed.[90] The addition of adjuvant RT is well documented to improve locoregional control and survival.

Surgery

For patients with metastatic SCC to cervical lymph nodes, surgery has traditionally involved a modified radical neck dissection. However, more recently, there has been a trend toward selective neck dissection in patients with a low burden of metastatic cancer (N1 and N2), with the aim of reducing surgical morbidity.[91–95] A recent Australian study of patients with SCC reported no statistically significant difference in 5-year overall survival (61% vs. 57%) or 5-year disease-free survival (74% vs. 60%) for selective neck dissection or radical neck dissection, respectively.[96] Recent data have simplified the relationship between the site of the primary SCC (if identified) and nodal metastasis, allowing more selective treatment of the neck, both surgically and with adjuvant RT. In a study of patients with an anterior facial SCC, there were metastases to level I nodes in 17.9%, whereas only 5.4% of

patients were identified with metastatic SCC in level V lymph nodes.[61] When no metastases were identified in level II lymph nodes, only 6% of patients with an anterior facial primary SCC had metastatic SCC in level I. Involvement of level II lymph nodes is, therefore, a predictor of metastatic disease in level I cervical nodes. Furthermore, patients with metastases in levels II/III were significantly more likely to have metastatic cancer in levels IV/V than were patients without levels II/III lymph node involvement (33.3% vs. 6.7%, respectively; $p < 0.001$).[61] Examination of primary site subgroups of patients reported 15.8% of posterior facial, 2.7% of anterior facial, and 0% of external ear SCC, without level II/III metastases, but had levels IV/V lymph node involvement.[61]

In that study, 21% of patients who underwent parotidectomy and elective neck dissection for a clinically N0 neck had pathologically proven metastatic cancer in cervical lymph nodes.[61] Importantly, in the same study, patients with metastatic SCC to the parotid region and a clinically N0 neck had no metastases in levels IV/V in the absence of pathologic metastatic disease in levels II/III. Therefore, selective neck dissection of cervical lymph node levels II and III is recommended for patients undergoing parotidectomy for metastatic SCC.

Parotid nodes are the most frequent site for metastasis from a primary SCC. Metastases travel via a rich lymphatic network from the primary site to 15 to 20 superficial periparotid lymph nodes and 4 to 5 lymph nodes within the deep parotid lobe. Involvement of parotid lymph nodes has implications with regard to prognosis and management. All patients with metastatic SCC to the parotid region and a clinically node-negative neck should undergo parotidectomy and ipsilateral selective neck dissection.[61,97,98]

Parotidectomy usually involves superficial lobectomy with preservation of the facial nerve (FN). Less commonly, an extended parotidectomy is required, with sacrifice of either the main trunk or at least one of the main branches of the FN. If the FN is sacrificed, facial reanimation is recommended either immediately or as a delayed procedure. As resection rarely achieves margins >5 mm, the FN should be sacrificed only in the presence of preoperative FN palsy or gross involvement at the time of operation. Consideration should be given preoperatively to both the extent of the resection of involved skin overlying the parotid and reconstructive options, including local and free flap reconstruction.

One study examined outcomes for patients with involved margins, in whom the tumor had been dissected from the FN.[99] Data on 15 patients treated with nerve-sparing surgery plus adjuvant RT from a database of 176 patients were analyzed. Two patients had residual FN palsy despite nerve-sparing surgery. Three patients developed recurrent cancer in the parotid bed, which was salvaged successfully with radical surgery and FN sacrifice. It was concluded that 10 of 15 patients had normal FN function posttreatment with no difference in disease-specific survival when compared with patients who had clear or close margins. Therefore, patients without macroscopic involvement of the FN, but with close margins, can still undergo nerve-sparing surgery provided adjuvant regional RT is delivered.

Reconstruction

Primary SCC should be excised with a macroscopically clear margin of 1 cm. If there is sufficient skin laxity, and the defect is not too large, primary closure can be performed, ideally parallel to the skin's natural relaxed skin tension lines. For larger defects, primary closure will not be possible, and the wound may be left to granulate by secondary intention. Concave areas, including the conchal bowl, perialar, and medial canthal regions, are amenable to healing by secondary intention. Reconstruction of the defect, to restore form and function, is a more viable alternative. The reconstructive ladder of healing by secondary intention, primary closure, skin grafting (Fig. 8.7), local flap, distant flap, free flap (Fig. 8.8) (including composite graft), and prosthesis should be followed. Local flap reconstruction follows the principle of replacing like with like, ideally from the same esthetic subunit of the face, and is the workhorse technique for repair of facial defects. Donor site morbidity should be kept to a minimum.

Figure 8.7. *A split-thickness* skin graft covering a large defect following wide local excision of an SCC. Note that as long as healing has been achieved, most skin grafts tolerate adjuvant radiotherapy well with a minimal risk of graft loss. Radiotherapy, if required, usually commences 4 to 6 weeks post excision allowing adequate time for healing.

Figure 8.8. Free flap reconstruction in a patient undergoing excision of a large deeply invasive right preauricular SCC.

Small defects of the nose can be reconstructed with a skin graft, or bilobed or paramedian forehead flap, whereas a rhomboid or V–Y flap can be used to reconstruct cheek defects. Larger defects of the cheek or tail of parotid can be repaired with a cervicofacial rotational flap (Fig. 8.9A–G). An Abbe-Estlander flap can be used to reconstruct small defects of the lip, whereas larger ones may require a Karapandzic flap.

Figure 8.9. A: A 77-year-old male with an SCC metastatic to the tail of his right parotid gland. No primary cutaneous SCC could be identified in the head and neck region. **B:** Preoperative surgical markings, demonstrating the approach for a parotidectomy. The tumor will be removed with a margin of skin, leaving behind a defect in the skin, which will be replaced by a rotational cervicofacial skin flap. **C:** Intraoperative view of the tumor having already been dissected from the parotid gland (PG), including an appropriate parotidectomy, exposing the underlying branches of the facial nerve (FN). A level II to III neck dissection was also performed (subsequently pN0). Anatomic structures displayed include the posterior belly of digastric (PBD), sternocleidomastoid (SCM), accessory (AN) and vagus (VN) nerves, superior belly of omohyoid (SBO) (marking the lower limit of the neck dissection), and internal jugular (IJV) and common facial (CFV) veins. **D:** Cervicofacial skin flap prior to its rotation anteriorly to fill the skin defect removed with the tumor. **E:** The mobilized and tension-free cervicofacial skin flap placed into the defect prior to being sutured in place. **F:** The wound and defect are closed with a cervicofacial rotation skin flap as the skin posterior to the original

tumor is rotated anteriorly. **G:** Wound appearance at 3 weeks postoperatively.

Restoration of function is important, for instance, when the FN is invaded by metastatic cutaneous intraparotid cancer, necessitating radical parotidectomy. Complete rehabilitation addresses adequate eye closure, facial symmetry, oral competence, nasal valve support, normal facial contour, appropriate skin color match, and eventual facial muscle tone. The anterolateral thigh free flap can be used to approach some of the above, with a fasciocutaneous flap to restore the contour of the cheek. Facial function can be reconstructed using static or dynamic means. Static techniques include brow lift, tarsorrhaphy, and gold weight to the tarsal plate of the upper eyelid. Dynamic techniques encompass cable grafting of the FN and muscle transposition. Cable grafting can use the great auricular, sural, or vastus lateralis nerves. Fascia lata slings, with transposition of the temporalis tendon, can help to maintain the oral commissure, whereas anterior belly of digastric transposition enables lower lip eversion.

Provided principles of reconstruction, with regard to esthetic facial subunits and knowledge of the various rotational and free flaps, are followed, adequate and acceptable restoration of both cosmesis and function can be achieved.

Radiotherapy of the Primary Site

RT to a primary SCC avoids an operation and the associated surgical morbidity, scarring, and requirement for reconstruction and has the advantage of treating tissue extensively and deeply (5 to 30+ mm margins) that may otherwise require excision (+/− reconstruction). An obvious benefit is improved cosmesis and preservation of function, especially in situations in which a flap or graft is required.[100] RT is particularly beneficial in areas of the midface where excision and reconstruction could have a greater impact on form and function [e.g., the periorbital region (especially the medial canthus), lower eyelid, nose (in particular the ala and tip), nasolabial fold, lip, and chin].[101] Elderly patients with significant comorbid conditions are also often better treated with RT (Fig. 8.10). A typical course of fractionated RT ranges from 10 to 25 minutes once per day (minus weekends) with 10-minute outpatient treatments (or fractions). However, in older, sicker patients, fewer (3 to 5) fractions can be used. Younger patients (<50 years) can still receive

RT, but the late (>5 years) in-field cosmetic outcome (i.e., hypopigmentation, telangiectasia, epidermal atrophy), especially with continued unprotected sun exposure, may not be ideal. The risk of an in-field radiation-induced malignancy many years after small-field cutaneous RT is theoretically possible, but rare, and should not be a reason to avoid RT in younger patients.

Figure 8.10. Patient from Figure 3, now 5 months post completion of definitive radiotherapy. He has achieved an excellent cosmetic outcome with acceptable acute and self-limiting toxicity from his treatment.

Patients with locally advanced (T4) primary skin cancers involving bone and cartilage, muscle, or nerves can still be treated and cured with definitive RT. In a study of 21 patients with T4 NMSC treated with megavoltage RT, almost 60% achieved disease control, with many treated by IMRT.[102] The use of newer technology such as IMRT, in select patients with advanced NMSC, may allow the delivery of higher doses of RT, yet minimizing the side effects of treatment. Similarly, in 25 patients with an advanced NMSC and treated with helical tomotherapy (a form of IMRT) delivering doses between 50 and 70 Gray (Gy), the authors documented complete clinical remission in 88%.[103]

In a study of 28 patients with advanced NMSC (5 cm median size) treated palliatively, 24 Gy were delivered over 3 weeks. The authors reported an alleviation of symptoms in 83% of assessable sites and a complete response in 36% of patients.[104] Alternatively, large single fractions of 10 to 15 Gy may also be appropriate in debilitated patients in a nursing home with large neglected lesions that are often painful, bleeding, and infected.

The sun-exposed lower lip is a site ideally suited to treatment with definitive RT where extensive surgery could result in significant morbidity from microstomia (reduction in size of oral commissure). RT can achieve excellent preservation of oral function and achieve an outcome comparable to surgery. Treatment with either RT or surgery has been documented to have similar efficacy in retrospective studies. Surgical series report disease control in 85% to 90% of cases, with local recurrence rates of 5% to 10% and regional relapse rates of ~5%.[105] The Westmead hospital group analyzed data on patients treated with surgery, RT, or surgery + adjuvant RT and documented a 5-year relapse-free survival (RFS) of 51%, 87%, and 92%, respectively, noting that the lower RFS for surgical patients was often secondary to a higher local relapse when there was incomplete resection. Most patients, however, were successfully salvaged, and consequently, the 5-year overall survival for RT versus that for surgery was similar (79% vs. 83%).[106]

Most clinicians accept excision as an excellent option, particularly in

younger patients, as wedge resection with primary closure is often curative. In patients with more extensive cancer, where wedge excision and primary closure may result in microstomia, local flaps may be required to achieve oral competency. RT is often considered an excellent option for elderly patients, many of whom suffer from comorbidities, as it obviates the need for a general anesthetic, surgery, and hospitalization and offers the advantage of preservation of lip function and cosmesis, making it also an option for younger patients, particularly if complex reconstruction is anticipated.

Regional Radiotherapy

In a study of 74 Australian patients with metastatic SCC to cervical lymph nodes, those treated with surgery and adjuvant RT had a lower recurrence rate (15% vs. 77%) and better 3-year disease-free survival (70% vs. 45%) compared with patients treated with surgery alone.[84] In a review of 122 Australian patients, there was a 5-year overall survival of 66% with adjuvant RT compared with 27% with surgery alone.[56] Patients should receive 60 Gy in 2 Gy fractions to an operative bed and 50 Gy in 2 Gy fractions to undissected regions, including the lower neck. Patients with metastatic SCC to the parotid region, with a clinically N0 neck, who undergo parotidectomy and selective neck dissection, and who are found to have pathologically evident metastasis in the neck require adjuvant RT to both the parotid bed and ipsilateral neck. Selective RT only to the parotid bed may be considered in patients with a pathologic N0 neck.[78,89] Despite best practice, 10% to 15% of patients will develop recurrence, most often regional, with only a minority (20% to 30%) successfully salvaged.

Prognostic Factors

The Westmead Hospital Group published a 4-factor prognostic scoring system, the ITEM score, which considers immunosuppression, treatment, extracapsular spread, and margins.[107] In this study, a cohort of 250 patients was analyzed to identify relevant patient, tumor, and treatment factors to examine prognosis in patients with metastatic SCC of the head and neck. Twenty-eight percent of patients developed recurrence. Those treated with combined modality had a lower recurrence rate than those treated with either surgery or RT alone (17% vs. 48%, respectively). Regional recurrence occurred in 73% of patients, whereas distant metastasis as the first

presentation of recurrence was uncommon and occurred in only 9 (13%) cases. Patients failing treatment did so within a median time of 8 months, and 73% died of their disease. This demonstrates the importance of achieving control of nodal metastasis.[107] Using coefficients of the ITEM variables as weights, risk scores were calculated for each patient. This allowed the development of risk groups based on cutoff scores. Patients with a score ≤2.6, >2.6 to ≤3, or >3 were, respectively, classed as low, medium, or high risk for dying of disease. Scores demonstrated that the chance of dying of disease according to this novel prognostic classification at 5 years was 6%, 24%, and 56%, respectively. This is a simple and easy system that can be used clinically to prognosticate and allows identification of patients at risk of a poor outcome.

Sentinel Node Biopsy

Sentinel lymph node biopsy (SLNB) offers the potential to identify occult (or subclinical) metastases and possibly influence outcome. The lower incidence of cutaneous metastatic nodal SCC and the need to identify high-risk patients better remain issues. Schmitt et al.,[108] in a meta-analysis, documented 12.3% of microscopic nodal metastases detected by SLNB in high-risk cutaneous SCC, with a false-negative rate of 2.6%. They highlighted the ambiguity of the term “high risk” and undertook a comparative analysis—one with the TNM from the AJCC-7 and another with an “alternative TNM System” proposed by Jambusaria-Pahlajani et al.[109] This “alternative tumor staging system” used risk factors identified to predict more than one outcome in a multivariate analysis, that is, tumor thickness >2 mm, Clark level of IV or higher, location on ear or non–hair-bearing (vermillion) lip, poor differentiation, and tumor diameter of 2 cm or greater. Utilizing the AJCC-7 criteria, 11.2% (13/116 patients) with a T2 cutaneous SCC had positive sentinel lymph nodes (SLNs), rising to 60% (3/5 patients) in patients with T4 tumors. All patients with a positive SLN had cutaneous SCC > 2 cm in diameter. Using the alternative TNM System, no cases (0/9 patients) of a positive SLN were documented in the T1 primary (0 risk factors), 7.1% (6/85 patients) in T2a lesions (1 risk factor), and 29.4% (5/17 patients) in T2b lesions (2 to 3 risk factors). The authors reported a statistically significant difference between the proportions of T2a and T2b ($p = 0.02$).[108] In view of these data, it would be reasonable to consider the 2-cm cutoff as an

independent risk factor for considering SLN biopsy, and patients with *more than* two risk factors (definition of T2b for the Alternative TNM system) may also warrant SLN biopsy. These results suggest that select high-risk patients may benefit from SLN biopsy, but further research is required (Fig. 8.11).

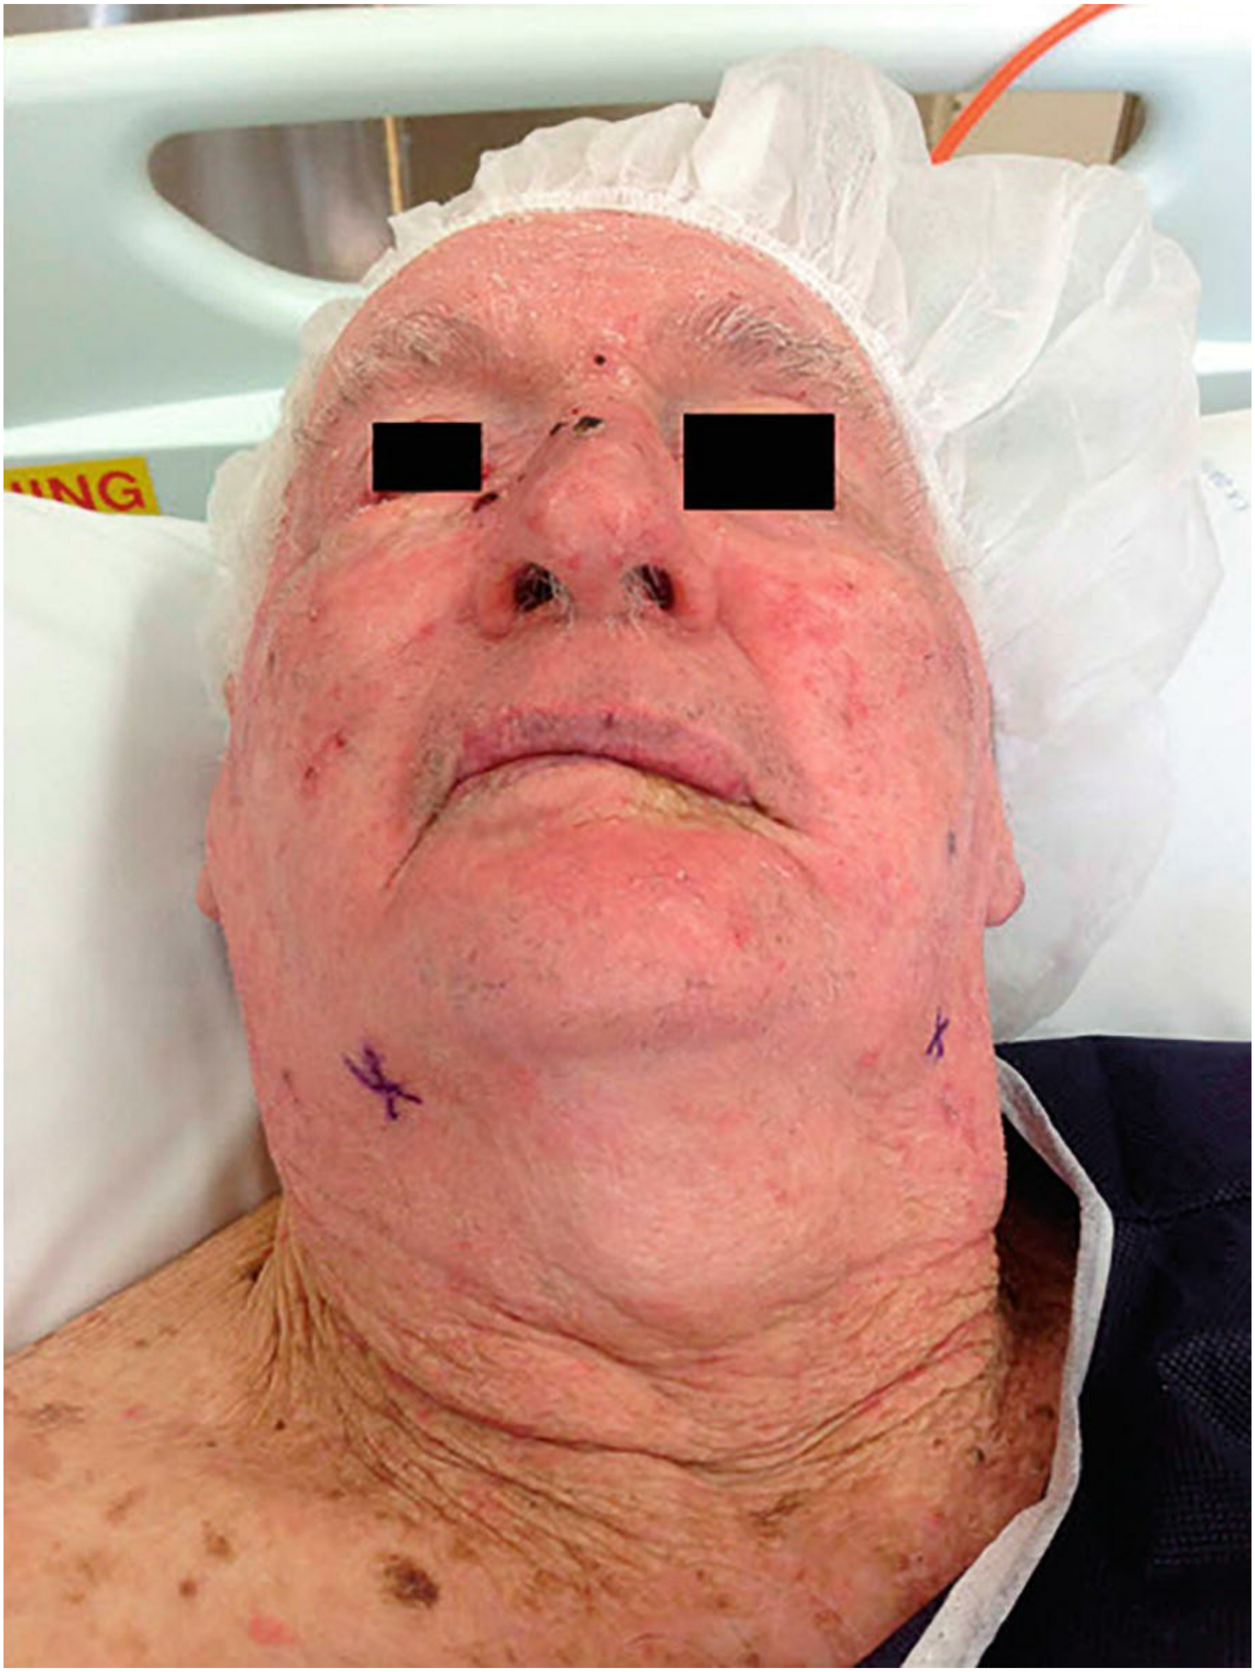

Figure 8.11. A 90-year-old male undergoing sentinel lymph node (SLN)

biopsy for a nasal 8-mm MCC. The patient had two SLNs located in his bilateral upper neck in his level Ib nodes (as marked). Both SLNs were positive for microscopic deposits of MCC, and he proceeded to radiotherapy to these sites and his nose.

Adjuvant Chemotherapy

Despite surgery and RT, a minority of patients will develop recurrence, most often regional in the treated parotid and/or neck. Any means to improve regional control is therefore likely to improve survival. A randomized controlled trial undertaken in Australia and New Zealand, and close to accrual in 2014, evaluated concurrent low-dose weekly carboplatin chemotherapy and RT as an adjuvant therapy in high-risk patients [Postoperative Concurrent Chemoradiotherapy Versus Postoperative Radiotherapy for Cancer of the Head and Neck (POST) trial]. The addition of concurrent platinum-based chemotherapy as a radiosensitizer is well documented in mucosal SCC, and the mature results of the POST trial may influence future management in these patients.

Targeted Treatment

Many cutaneous SCCs overexpress epidermal growth factor receptor (EGFR), and targeted treatment using monoclonal antibodies is an emerging option in certain patients with advanced (inoperable/incurable) disease. In some cases, dramatic results have been obtained using this relatively nontoxic treatment, although responses may be short-lived. In a study of 16 patients treated with single-agent panitumumab, the overall response rate was 31% with a 6-week disease control rate of 69%. Adverse events were recorded in all patients, most experiencing fatigue, cutaneous reaction, and nausea.[110] Analogous data in patients with mucosal SCC has suggested a beneficial outcome in combining RT and cetuximab. In a series of 16 patients with unresectable cutaneous SCC receiving combined RT and cetuximab, the authors documented an overall response rate of 64%, including complete response in 36%. Median progression-free and overall survival were 6.4 and 8 months, respectively, and most patients experienced a grade 3/4 reaction.[111]

Hedgehog pathway inhibitors have been used to exploit up-regulation of the hedgehog signaling pathway, seen recently in BCC patients with genetic

alterations. A new oral drug, vismodegib, inhibits this pathway and may offer a potentially new treatment for patients with advanced (inoperable and/or previously treated) and metastatic BCC and for those with Gorlin syndrome (basal cell nevus syndrome). A recent study reported a complete response of 21% in eligible patients, although the median duration of response was short (7.6 months) and serious adverse effects, even death, were reported.[112] With further research, it is likely that the outcome for these patients will improve with molecular inhibition of the hedgehog signaling and other pathways.

Merkel Cell Carcinoma

MCC is an aggressive neuroendocrine cutaneous malignancy that often manifests as a rapidly enlarging firm, painless, pink-red, dermal-based nodule, frequently on the head and neck (50% to 60%) or extremities/trunk in older (>60 to 70 years old) Caucasians.[113] In contrast to other types of NMSC, MCCs frequently arise in women (Fig. 8.12). It is often misdiagnosed, as it may resemble BCC or amelanotic melanoma. The median size of the primary lesion at diagnosis is ~2 cm, and the incidence of clinical nodal involvement at presentation is ~20% to 25%, although the risk of harboring occult nodal disease is high (30% to 40%). A minority of patients (10% to 15%) will have node metastases but without an identifiable primary (index) lesion and have a better prognosis compared to patients presenting with a concomitant primary and nodal metastases.[114] MCC has a high propensity to spread to regional lymph nodes and distant sites (usually in the relapse setting) and has a cause-specific mortality of 25% to 50%, despite treatment.

Figure 8.12. A 72-year-old female having undergone recent wide local excision of a 15-mm left cheek MCC presenting now with 2-cm nodal metastases in her left parotid. The patient proceeded to urgent radiotherapy to encompass her excision site and involved parotid and upper neck using high-dose electrons (50 Gy in 20 fractions). She achieved in-field locoregional control but died 5 months later from metastases to the liver.

Etiology is secondary to chronic ultraviolet B (UVB) sun exposure, and more recently, the identification of the Merkel cell polyomavirus (MCV or MCPyP),[115] first identified in 2008, with some studies identifying MCV integrated into the host's genome in 80% of cases, but reported to be much less (20%) in other studies. It is postulated that MCV in certain populations (e.g., Australians) may play less of a role in the development of MCC compared to the mutagenic consequences of chronic UVB exposure. The virus is considered part of normal human flora and is also present in healthy tissue from the general population. The role of MCV in the etiology and prognosis is under investigation. The increased risk of developing MCC in patients immunosuppressed due to CLL may possibly be explained secondary to MCV infection. MCC is highly immunogenic, with a higher incidence in immunosuppressed patients (e.g., transplant recipients and hematologic malignancy), who subsequently have a worse outcome.[116]

Prognostic Factors in MCC

The presence of clinical lymph node metastases (stage III) is the most important prognostic factor. Patients identified as having pathologically proven occult (or microscopic) metastases also have a worse prognosis compared with patients with MCC confined to the primary site. Increasing size of the primary cancer is moderately predictive of outcome, although other tumor variables such as thickness and Clark level are less helpful. Recently, the identification of LVI[117] has been reported as predictive for the development of metastases.

TNM Staging and Prognostic Risk Grouping

Stage at diagnosis is prognostic (AJCC 7th edition staging manual, Table 8.3). Patients with stage I (T1N0) and II (T2-4N0) with pathologically evaluated negative lymph nodes have a better survival compared with clinically node-negative patients.[118] Of the 3 stages documenting nondistant spread, stages I and II are classified by tumor size (T1 ≤ 2 cm, T2 > 2 to 5 cm, T3 > 5 cm) and within each stage further categorized (A, B) depending on whether draining nodes have been evaluated pathologically or clinically. Due to the high false-negative rate (30% to 40%) for detecting occult metastatic nodal metastases clinically, patients with the same stage, but with clinically staged nodes, have a documented worse prognosis compared to

patients who undergo pathologic staging of nodes (e.g., SLN biopsy). Patients with stage III disease have pathologically confirmed nodal metastases and are further divided into those with micrometastases (i.e., occult) or macrometastases (clinically detectable).

Table 8.3 Staging for Merkel Cell Carcinoma (7th Edition of AJCC Staging Manual)

Tumor		Node		Metastasis	
TX	Primary tumor cannot be assessed	NX	Regional lymph nodes cannot be assessed	M0	No distant metastasis
T0	No evidence of primary tumor (e.g., nodal/metastatic presentation without associated primary)	N0	No regional lymph nodes metastasis	M1	Metastasis beyond regional lymph nodes
Tis	*In situ* primary tumor	cN0	Nodes negative by clinical examination (no pathologic node examination performed)	M1a	Metastasis to skin, subcutaneous tissues, or distant lymph nodes
T1	≤2 cm maximum tumor dimension	pN0	Nodes negative by pathologic exam	M1b	Metastasis to lung
T2	>2 cm but ≤5 cm maximum tumor dimension	N1	Metastasis in regional lymph node(s)	M1c	Metastasis to all other visceral sites
T3	>5 cm maximum tumor dimension	N1a	Micrometastasis		
T4	Primary tumor invades bone, muscle, fascia, or cartilage	N1b	Macrometastasis		
		N2	In-transit metastasis

Role of RT in Patients with Early-Stage MCC

The propensity for MCC to recur after local excision and the excellent response to RT have meant that many publications have reported a statistical and clinical benefit in reduced locoregional recurrence, with the addition of wide-field (2- to 3-cm field margins) adjuvant RT.[119] Locations such as the head and neck often result in close or positive margins of resection in an attempt to maintain acceptable cosmetic outcome and/or function. There are no randomized studies addressing the benefit of RT versus surgery. Some clinicians may omit adjuvant RT for patients who have had adequately excised (margins > 10 mm) small (<2 cm) cancers that do not have LVI present and are pathologically node negative. In many series, patients with these low-risk features make up only a minority, and therefore, the majority

of patients at these particular centers would undergo excision and adjuvant RT. Proponents of combined treatment advocate margin negative surgery, without the need for wide 5- to 10-mm margins, to be followed by RT.

Target Volume

The target volume for MCC consists of the excision site (with 3- to 4-cm margins), in-transit tissue, and at least the first echelon nodes (may consider next level as well). When a lesion is close to critical structures (e.g., orbit), narrower margins and appropriate shielding need to be considered.

Management of Lymph Nodes in Clinically Node-Negative Disease

Studies using SLN biopsy report positive occult nodes in 30% to 50% of cases.[120] No single clinicopathologic feature strongly predicts for the risk of harboring occult metastases, and clinical staging alone, including relevant investigations, will not detect small volume (<5 mm) or microscopic MCC nodal metastases. Studies clearly show that patients with a positive SLN biopsy have a worse outcome compared with a negative biopsy and will benefit from treatment to the nodal basin. Those not investigated pathologically have a lower survival compared to patients staged pathologically. Lesions located on the trunk or extremities may particularly benefit from SLN biopsy as treatment of a positive nodal basin may need to be discontinuous from the primary site, unlike the head and neck where often the primary site, in-transit tissue, and nodes can be approached with an en bloc RT field. Patients not undergoing SLN biopsy should be considered for elective nodal treatment (e.g., surgery or RT) or alternatively be monitored very closely.

Management of Lymph Nodes in Clinically Node-Positive Disease

Numerous studies reporting RT alone in the setting of macroscopic MCC have documented durable in-field control of 75% to 85% using doses of 50 to 60 Gy.[121] Most patients with metastases to the cervical lymph nodes will still be candidates for adjuvant nodal RT after lymph node dissection (multiple nodes, extracapsular spread, close soft tissue margins). A recommendation

for RT alone to patients with technically operable low volume (~3 cm maximum dimension) is not standard or routinely recommended, but avoids the need for hospitalization and the morbidity of surgery of the lymph nodes. The addition of adjuvant RT to axilla/groin following surgery also increases the risk of limb edema. Patients with medical comorbidity may also experience postoperative complications, delaying the commencement of adjuvant RT.

Role of Chemotherapy in the Definitive Setting

The benefit of systemic chemotherapy in the definitive setting remains unclear and unproven.[122] Similar to small cell carcinomas arising from other sites such as the lung, regimens using carboplatin and etoposide have been investigated. Numerous single-arm studies administering chemotherapy during (concomitantly) and after (adjuvantly) RT have documented the feasibility and efficacy of combined chemotherapy/RT. However, chemotherapy-associated mortality and morbidity are not inconsequential in this group of older patients, many suffering from multiple comorbidities.

OTHER RARE TUMORS

Malignant Adnexal Tumors

Malignant tumors of the adnexa arise from the pilosebaceous unit and eccrine and apocrine sweat glands. These tumors tend to be indolent and rarely metastasize. Microcystic adnexal carcinoma (MAC), malignant cylindroma, sebaceous carcinoma, primary cutaneous mucinous carcinoma, pilomatrix carcinoma, and adenoid cystic carcinoma show a predilection toward the head and neck region.[123]

They usually appear as a solitary, flesh-colored nodule. MAC can infiltrate nerves and has a 10-year survival rate approaching 97%.[124] Risk factors include previous irradiation and immunosuppression.[125] Sebaceous carcinomas usually arise from orbital sebaceous glands, typically the meibomian glands of the tarsal plate.[126] Apocrine carcinoma is more common in middle-aged females, occurring on the eyelid, scalp, and ear.[127] Primary cutaneous mucinous and adenoid cystic carcinomas are more

common in the elderly, the former occurring most often on the eyelid, cheek, and scalp[128] and the latter on the scalp.[129]

Once diagnosis is confirmed by biopsy, these tumors are excised with a 1-cm margin. RT can be given adjuvantly for positive margins or presence of PNI.[103,124]

Angiosarcoma

This tumor is a rare (<1% of all head and neck malignancies[130]), but aggressive, malignancy, most commonly arising on the scalp and upper forehead of elderly Caucasian males.[131] Previous RT and chronic lymphedema are risk factors.[132] It can be multifocal, presenting as bluish nodules, plaques, or flat infiltrating areas. It often presents too late for effective surgical excision. Only 7% of patients have nodal disease.[132] Surgery and wide-field RT are the mainstay of treatment, but recurrence at the margins of the RT field is common. It metastasizes hematogenously, in which case palliative chemotherapy is appropriate, enabling 1- to 5-month survival. Five-year survival is 10% to 30%.[131]

Kaposi Sarcoma

This rare cutaneous spindle cell tumor is considered to be derived from endothelial cells. It occurs more frequently in patients with acquired immune deficiency syndrome (AIDS), in whom the clinical course is more aggressive, but is up to 100 times more frequent in organ transplant patients.[133] Cutaneous lesions typically occur in the head and neck region as brown, pink, or red macules, papules, nodules, or plaques. There are often concurrent mucosal lesions.

Optimal control of AIDS is required, but treatment of the lesions includes RT,[134] cryotherapy,[135] excision by scalpel or laser,[136] intralesional or systemic vinca alkaloid,[137] or topical retinoids.[138]

CONCLUSION

Patients with BCC can expect to be cured of their disease. Patients who develop either high-risk SCC or MCC are at a risk of morbidity and,

potentially, mortality. Exposure to UV radiation is the most important risk factor for the development of NMSC, but there are other factors, including immunosuppression, which increase the likelihood of a poor outcome. A simple, accurate, and universally applied staging system is vital when managing these patients. Ongoing research is required to develop therapeutic strategies, such as adjuvant chemotherapy and targeted molecular therapy, for patients with high-risk disease. Contemporary best practice management of primary and metastatic cutaneous SCC of the head and neck includes a combination of surgery and/or external beam RT.

9 Melanoma of the Head and Neck

Cecelia E. Schmalbach, Alison B. Durham, Timothy M. Johnson, and Carol R. Bradford

Although melanoma accounts for only 5% of cutaneous cancers diagnosed each year, it is the most lethal form, accounting for over 75% of deaths attributed to skin cancer. Approximately 25% of all cutaneous melanomas arise in the head and neck (HN) region.[1] The dramatic increase in melanoma incidence and mortality over the past two decades has led to significant economic burden.[2] In 2010, the total direct cost of treating melanoma in the United States exceeded $2.3 billion.[3] The leading cause of melanoma remains intense sun exposure; consequently, it is a cancer of young as well as older adults. Melanoma ranks second only to testicular cancer in loss of average adult life-years per fatality and a loss of ~$3.5 billion in productivity.[4] These startling melanoma statistics underscore the importance of prevention, accurate staging, and clinical trials.

EPIDEMIOLOGY

The incidence of cutaneous melanoma in the United States continues to rise at epidemic proportions with 137,990 new cases of melanoma estimated in 2014 (61,300 noninvasive; 76,690 invasive).[2,5] This rate has consistently increased 2.8% per year since 1981. By 2015, it is estimated that 1 in 50 Americans will develop a melanoma in their lifetime.[6] A slight male predominance has been consistently reported throughout the literature.[7,8]

Although the mortality rate of various cancers has declined, mortality from melanoma has risen by 3% each year since 2004. 9,710 Americans will die from melanoma this year, an estimate that averages to approximately one

patient per hour.[2] Melanoma typically arises in the fifth and sixth decade.[7] However, this statistic is misleading because one in four new melanoma cases will present before the age of 40 years. The increasing incidence among younger patients, especially women, is attributed to sun worshiping tendencies and indoor tanning.[9] Melanoma is the most common cancer for young adults aged 25 to 29 years, the second most common cancer for women aged 30 to 34 years, and the second most common cancer in ages 15 to 14.[5] Patients in the pediatric age group account for ~1.66% of the HN melanoma cases, with patients being diagnosed as young as 4 years old.[10,11]

PATHOPHYSIOLOGY

Melanocytes are dendritic cells of neural crest origin, located at the epidermal–dermal junction.[12] They contain cytoplasmic organelles termed *melanosomes*, which synthesize *melanin*. The melanin is degraded and distributed to surrounding keratinocytes where the granules form supranuclear caps within the keratinocytes for protection from damaging ultraviolet radiation (UVR).[13] The photoprotective property of melanin results from the absorption of both UVR photons and the oxygen radical by-products of UVR.[14,15] This protective role of melanin is evident during tanning: UVR exposure increases melanogenesis, which leads to skin darkening. The protective layer of melanin serves as an endogenous sunscreen, persisting for ~3 weeks following exposure.[15]

All individuals, regardless of ethnicity, have approximately the same number of melanocytes. It is a difference in the number, distribution, and density of melanin granules within keratinocytes that account for racial variation in skin color.[12] Melanocyte density varies throughout the body. Within the HN region, the average number of melanocytes per mm^2 is 1,194 for the adult face, 1,060 for the scalp, and 926 for the neck.[12] This concentration is considerably higher compared to other anatomic sites such as the buttock and abdomen, which contain only 565 and 578 melanocytes/mm^2, respectively. The concentration of melanocytes within sun-exposed regions of the body further emphasizes the UVR-protective role of melanin.[16]

Whereas cutaneous squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) are associated with lifetime cumulative sun exposure,

melanoma is associated with intermittent and intense exposures common in sunburns.[17,18] It is most often diagnosed among individuals with indoor occupations, who have intermittent sun exposure only during weekends or vacations.[19] This correlation may explain the high melanoma incidence of melanoma in northern states known for long winters (Fig. 9.1). This contrast in cutaneous cancer etiology is attributed to an inherent difference in tumor cell origin. SCC and BCC both arise from keratinocytes, which undergo apoptosis in response to severe UVR damage. Throughout years of low-dose solar exposure, keratinocytes can accumulate a significant amount of unrepaired DNA damage to ultimately lead to SCC or BCC. Melanocytes, however, have not been found to undergo apoptosis, a quality that is deemed photoprotective.[20] However, this protective measure comes at the expense of increased risk for melanoma. The appearance of freckles after intense sun exposure supports this theory because freckles represent clones of mutated melanocytes and carry an increased risk for melanoma.

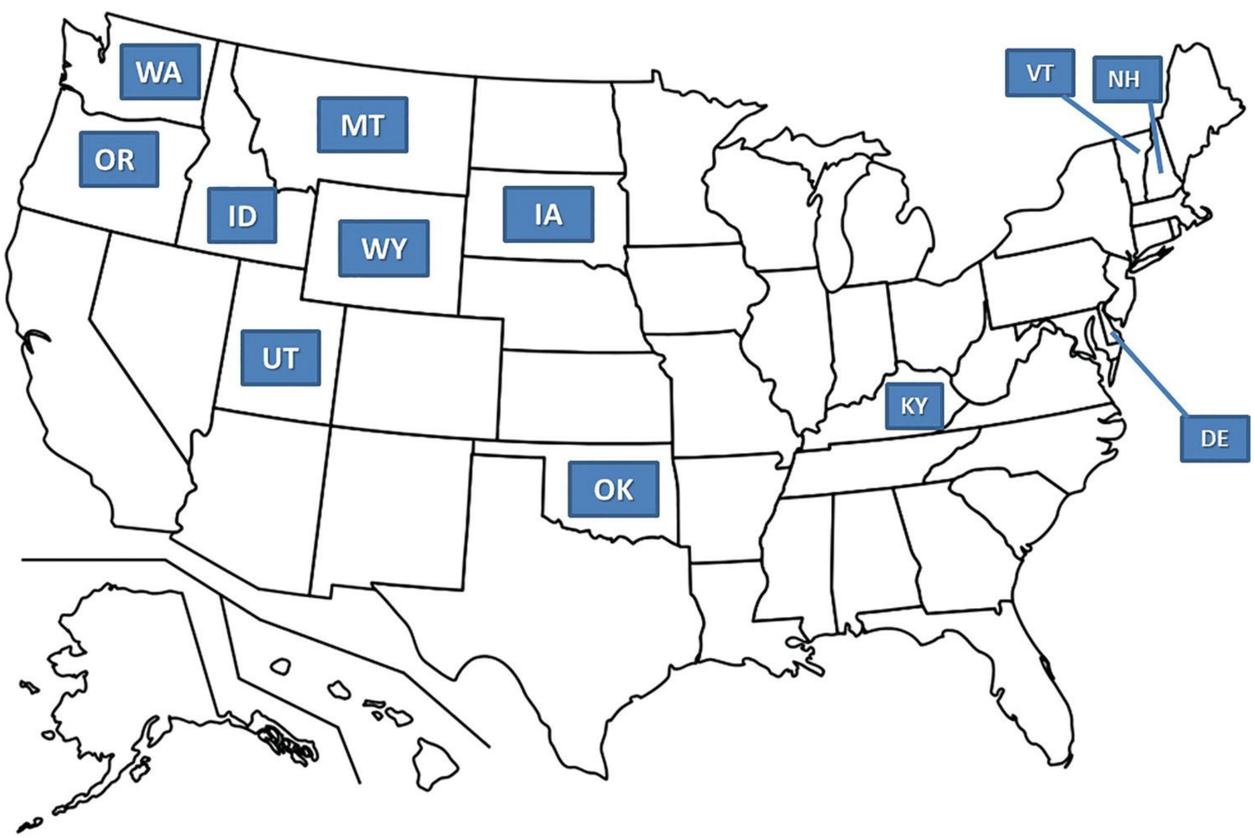

Figure 9.1. United States Center for Disease Control and Prevention (CDC) 2010 list of the highest melanoma incidence by state. Statistics include both genders and all races. Melanoma is attributed to intense, intermittent as

opposed to cumulative sun exposure, which may account for this high incidence in northern states.

ANATOMIC DISTRIBUTION

Approximately 25% of all cutaneous melanomas arise in the HN region.[1] The majority arise on the cheek, scalp, and neck.[7,8,21] Among 857 HN melanoma patients, Fisher et al.[7] found that the face and neck regions accounted for over 60% of primary tumors. An additional 26% arise from the scalp, with the ear and nose accounting for only 9% and 4% of primary tumors, respectively. This anatomic distribution was confirmed by O'Brien et al.[21] The forehead and cheek regions contain a two- to threefold higher melanocyte density compared to other anatomic sites. This difference, coupled with the increased sun exposure, likely accounts for the distribution of melanomas within the HN region.

RISK FACTORS

Table 9.1 summarizes the environmental and genetic risk factors implicated in the development of cutaneous melanoma.

Table 9.1 Cutaneous Melanoma: Environmental and Genetic Risk Factors

Environmental	Medical/Genetic
Inability to tan	*CDKN2A* (p16) mutation
Fair skin/freckling	Immunosuppression
Blue/green eyes	Xeroderma pigmentosa
Blonde/red hair	Dysplastic nevus
History of blistering sunburn	Giant congenital melanocytic nevus
Outdoor summer job	History of prior skin cancer
Tanning booth use (UV[a] radiation)	Family history of melanoma

[a]UV: ultraviolet-alpha rays (315 to 400 nm).

Adapted from Schmalbach CE, Johnson TM, Bradford CR. The management of head and neck melanoma. *Curr Probl Surg*. 2006;43:781–835. Ref.[22]

Sun Exposure

The leading cause of melanoma is sun exposure. Johnson et al. found that 81% of 1,515 patients with melanoma investigated recalled a history of at least one sunburn.[23] Recent epidemiologic trends further support the causal relationship of solar damage and melanoma. A "latitude gradient" has been reported in which the incidence of melanoma increases among similar ethnic populations as distance to the equator decreases.[17] A higher rate of melanoma has also been reported among immigrants to areas of increased solar radiation compared to native residents.[17,24]

Rigel[25] analyzed 43 melanoma risk factors among 200 patients. Two of the six key factors associated with increased melanoma risk directly related to sun exposure are three or more blistering sunburns before the age of 20 and three or more outdoor jobs during teenage years. Additional significant risk factors identified included red/blonde hair, family history of melanoma, actinic keratoses, and marked freckling of the upper back. Individuals

demonstrating one or two key factors carried a three- to fourfold increased risk for development of melanoma. The risk for melanoma increased 20-fold if a patient was found to have three or more key risk factors.

Genetics

A genetic etiology has also been implicated in the pathogenesis of melanoma.[26] Approximately 15% of patients with melanoma report a positive family history.[27] The most commonly inherited genomic abnormalities associated with melanoma is the *CDKN2A* locus, which encodes the *p16* tumor suppressor gene.[27,28] However, *p16* mutation is reported in only 0.2% of the melanoma cases diagnosed.[29] The hereditary nature of cutaneous melanoma was first described in the 1970s when Clark et al.[30] observed two families in which members acquired large dysplastic nevi, often in sun-protected regions of the body such as the scalp and trunk. They coined the term "*B-K mole syndrome*." During this same time period, Lynch et al.[31] independently reported a similar association, which they termed "*familial atypical multiple mole–melanoma syndrome*" or *FAMMM syndrome*. Today, the term "*atypical mole syndrome*" is applied to familial cases of melanoma. The syndrome is inherited in an autosomally dominant fashion. Family members carry a 10-year melanoma risk of 10.7%, which is significantly >0.62% risk reported in control patients. A 56% cumulative risk is estimated in these carriers from age 20 to 59 years. Nearly 100% of patients with atypical mole syndrome develop melanoma by age 76.[32]

Although a melanoma gene has been postulated, the genetic aspect of this disease is far more complex.[33] The first whole-genome melanoma sequence was published in 2010 and identified more than 33,000 mutations compared to the germline control.[34] Various tumor suppressors, transcription factors, and oncogene mutations have been associated with melanoma.[35] The majority of melanomas are found to harbor one or more mutations related to a kinase signaling pathway.[33] A point mutation in *BRAF*, a serine–threonine protein kinase, has been identified in 65% of melanoma cell lines and 42% of tumors.[36,37] Eighty-five percent of the BRAF mutations are associated with a single substitution (*V600*E).[37] Mutations in *NRAS*, a member of the RAS family of GTPases, have also been implicated in up to 25% of melanoma tumors.[33] The *c-KIT* gene encodes for a tyrosine kinase receptor within the

cellular membrane, and mutation of the *c-Kit* gene has been identified in 19% of melanomas arising in chronically sun-exposed regions of the body.[38] Although the genetic alterations are promising avenues for targeted therapy (see section below), it is important to realize that an estimated 30% of patients with melanoma lack a detectable genetic abnormality.[33]

In addition to the familial forms of melanoma described above, there is another syndrome associated with melanoma development termed *xeroderma pigmentosum (XP)*. XP is a rare, autosomally recessive disease associated with skin cancers including melanoma.[39] Fibroblasts in XP patients have an impaired ability to repair DNA damaged by UVR,[40] which leads to the development of multiple cutaneous malignancies including melanoma, BCC, and SCC. Patients are usually diagnosed with their first cancer before the age of 10. Despite UVR precautions, careful surveillance, and aggressive treatment, the development of skin cancers is relentless, with the majority of XP patients succumbing to cancer during their childhood years.

Immunosuppression

Numerous studies throughout the literature provide supporting evidence for a role of immunosuppression in the development of melanoma. A recent systematic review of the literature identified an association between melanoma and the following immunosuppression settings: solid organ transplant, lymphoproliferative disorders, iatrogenic immunosuppression, and human immunodeficiency virus infection/AIDS.[41] Higher rates of premalignant melanocytic nevi in the setting of transplantation, chemotherapy, and childhood leukemia lend further support of this association.[42,43] Ultimately, immunosuppressed patients warrant vigilant monitoring for skin cancer, and melanoma care must be coordinated carefully with all medical teams.

Melanotic Nevi

Although melanoma can arise de novo, ~50% of cases develop from a preexisting pigmented lesion[44] (Fig. 9.2). The vast majority of adults have at least one melanotic lesion. *Intradermal nevi* account for the majority of adult moles. *Junctional nevi* are common in childhood. This lesion appears as a flat, tan-brown papule, which is smooth and well defined. Overall, junctional

nevi are recognized as the most common premalignant nevi.[45]

Figure 9.2. Approximately 50% of melanomas develop from a preexisting pigmented lesion.

Atypical melanocytic nevi (AMN), also known as *atypical moles, dysplastic nevi, and Clark nevi*, are acquired pigmented lesions with both a clinical and histologic appearance different from that of the common mole.[46] AMN are recognized as a marker for increased risk for melanoma risk and as a melanoma precursor. They often display irregular or poorly demarcated borders. They differ from common benign nevi in that they are typically larger in size, measuring between 5 and 12 mm in diameter.

Congenital melanocytic nevi (CMN) are pigmented lesions present at birth or within the first 6 months of infancy.[47,48] Up to 6% of children are born with CMN. CMN size ultimately dictates the melanoma risk. Small CMN (<1.5 cm diameter) and medium CMN (1.5 to 1.99 cm diameter) carry

the same lifetime melanoma risk as do any other typical nevi. However, *large* CMN (≥2 cm diameter) carry an increased risk for development of melanoma, with development in an estimated 5% to 20% of individuals.[47] These melanomas are usually diagnosed in early childhood, with 70% of cancers being diagnosed before the age of 10.[49] For this reason, prophylactic excision is advocated for large CMN if the nevus is in an anatomic location amenable to surgery. Unfortunately, the large size can carry significant cosmetic, as well as psychosocial, implications.[48]

Lentigo maligna (LM) (see above) is a melanoma subtype in which the cancer is limited to the intraepidermal layer. Classified as melanoma in situ, it is deemed a precursor to invasive melanoma. The exact percentage of LMs that progress to invasive lentigo malignant melanoma (LMM), remains unknown.[50] However, the rate of progression is estimated to be between 5% and 33%.

MELANOMA CLASSIFICATION

Three histologic variants of melanoma are reported within the HN region and are outlined below. It is important to realize that melanoma subtype does not generally influence prognosis once tumor thickness and other prognostic variables such as ulceration are taken into account. For this reason, the melanoma subtype does not impact tumor staging.

Common HN Melanoma Subtypes

The majority of HN cutaneous melanomas are *superficial spreading melanoma (SSM)*, accounting for ~70% of all cases.[19] The characteristic SSM feature is color variation, which is often described as kaleidoscopic with areas of black, dark brown, tan, and blue-gray pigmentation. Areas of pink and white may be present and represent hypopigmentation secondary to tumor regression. Although SSM lesions are well circumscribed, the borders tend to be scalloped and asymmetric. Patients are usually diagnosed within their fourth to fifth decade and often report a preexisting nevus in the region of their newly diagnosed melanoma.

Nodular melanoma (NM) is the second most common melanoma variant, accounting for 15% to 30% of cases.[19] The majority of mucosal melanomas

are of the nodular variant. The lesion typically appears as a raised, blue-black or blue-red nodule. As hemangioma, blue nevus, pyogenic granuloma, and pigmented BCC can appear similarly, it is important to biopsy lesions with this appearance before treating them to avoid undertreatment.

As mentioned above, *LM* represents intraepidermal or melanoma in situ. Also known as “Hutchinson melanotic freckle,” it is often diagnosed in the background of chronic solar damage. The invasive counterpart to LM is *lentigo malignant melanoma (LMM)*. The exact percentage of LMs that progress to invasive LMM remains unknown.[50] It is speculated that if LM patients live long enough, all will progress to invasive melanoma. LM/LMM is commonly found within the H&N region. The subtype has been associated with older individuals, but the frequency in younger patients is increasing.[30] LM/LMM can display subepithelial extension as well as peripheral involvement with atypical junctional melanocytic hyperplasia (AJMH). These findings make achieving adequate surgical margins challenging from both an esthetic and a functional standpoint. Additional challenges associated with LMM are that both amelanotic and desmoplastic melanoma (DM) commonly arise in the setting of LM/LMM.

Desmoplastic Melanoma

DM is a rare subtype of melanoma composed of spindle cells with abundant collagen.[51] Although DMs are rare, accounting for only 1% of melanoma cases,[52] 75% are diagnosed in the HN region. They commonly arise in the setting of LMM. DMs are distinct from other melanoma subtypes in that they present in an older patient population; the median age of diagnosis is 61 years compared to 46 years.[52] Although amelanotic cases account for only 7% of cutaneous melanomas, up to 73% of DM and DNM have been found to be amelanotic.[52,53] This atypical appearance (Fig. 9.3), coupled with the spindle cell histology, makes DM somewhat of a diagnostic challenge. Immunohistochemistry (IHC) is helpful because the majority of tumors will stain positive for S100 and vimentin; HMB-45 is less reliable due to the amelanotic appearance. DM is highly infiltrative, has a propensity for neurotropic spread, and is considered locally aggressive. Spread along cranial nerves to the skull base and cavernous sinus is not uncommon. In addition, early local recurrences are reported as high as 49%, and this may be related to undetected perineural spread.[53]

Figure 9.3. Amelanotic melanoma of the nose mimicking basal cell carcinoma. Note the lack of traditional melanoma ABCD warning signs.

Primary treatment for DM remains surgical excision, with a minimum of 1 cm margins in order to prevent local recurrence. Pure DMs carry a low (<10%) rate of regional metastasis; therefore, sentinel lymph node biopsy (SLNB) is not recommended in this setting.[54] Despite the low rate of regional metastasis, patients with this diagnosis have a similar risk for the development of distant metastases as patients with NM of similar depth of invasion. More commonly, melanomas will be classified as "mixed" DM. These lesions carry the same rate of regional metastasis as do other melanoma subtypes, and SLNB should be offered to patients meeting the criteria outlined in Table 9.2. Evaluation of these lesions by an experienced dermatopathologist is critical in discerning between pure DM and mixed DM lesions.

Table 9.2 Indications for Cutaneous SLNB
Localized melanoma ≥1 mm depth of invasion (T1-T4N0)
Localized melanoma <1 mm depth of invasion (T1N0)
Demonstrating a poor prognostic feature include: Ulceration (T1bN0) Mitotic rate ≥1/mm^2 (T1bN0) Young age Angiolymphatic invasion Positive deep margin Tumor regression

Mucosal Melanoma

Mucosal melanoma (MM) represents a rare variant of melanoma, accounting for <2% of all cases.[55] Review of the Surveillance, Epidemiology, and End Results (SEER) database from 1987 to 2009 identified an increasing incidence of MM in the United States.[56] This increase was unique to the nasal cavity subsite, especially for women ages 55 to 84.

MM is regarded as a distinct and separate entity from its cutaneous counterpart. Unlike cutaneous melanoma, etiologic environmental factors have not been linked to the development of MM.[57] MM presents on average one decade later than cutaneous lesions.[58] In addition, women are diagnosed twice as often as men. Lastly, the BRAF oncogene mutation commonly identified in cutaneous melanoma is rarely found in the mucosal subtype. Instead, a relatively high incidence of KIT mutations has been reported.[59]

The majority of MMs arise in the nasal cavity. The anterior nasal septum is involved most often (33%), followed by the lateral nasal wall (28%), turbinates (15%), and nasal vestibule (10%).[60] The paranasal sinuses are another common site of origin, with the maxillary sinus involved most often. Given these anatomic locations, it is not uncommon for patients with sinonasal MM to present with nasal obstruction and epistaxis. These symptoms often lead to early diagnosis, with 75% of sinonasal patients presenting with localized disease only.[61]

Approximately 40% of HN MMs arise in the oral cavity (OC), with the upper alveolus and hard palate (Fig. 9.4) reported as the most common subsite (70%).[62] OC MM is often asymptomatic and can go undiagnosed until a neck mass develops from metastasis.[63] A review of five major MM series by Batsakis et al.[64] found laryngeal primary tumors to account for fewer than 4% of all cases. Within the larynx, the supraglottis was the most common site of origin.

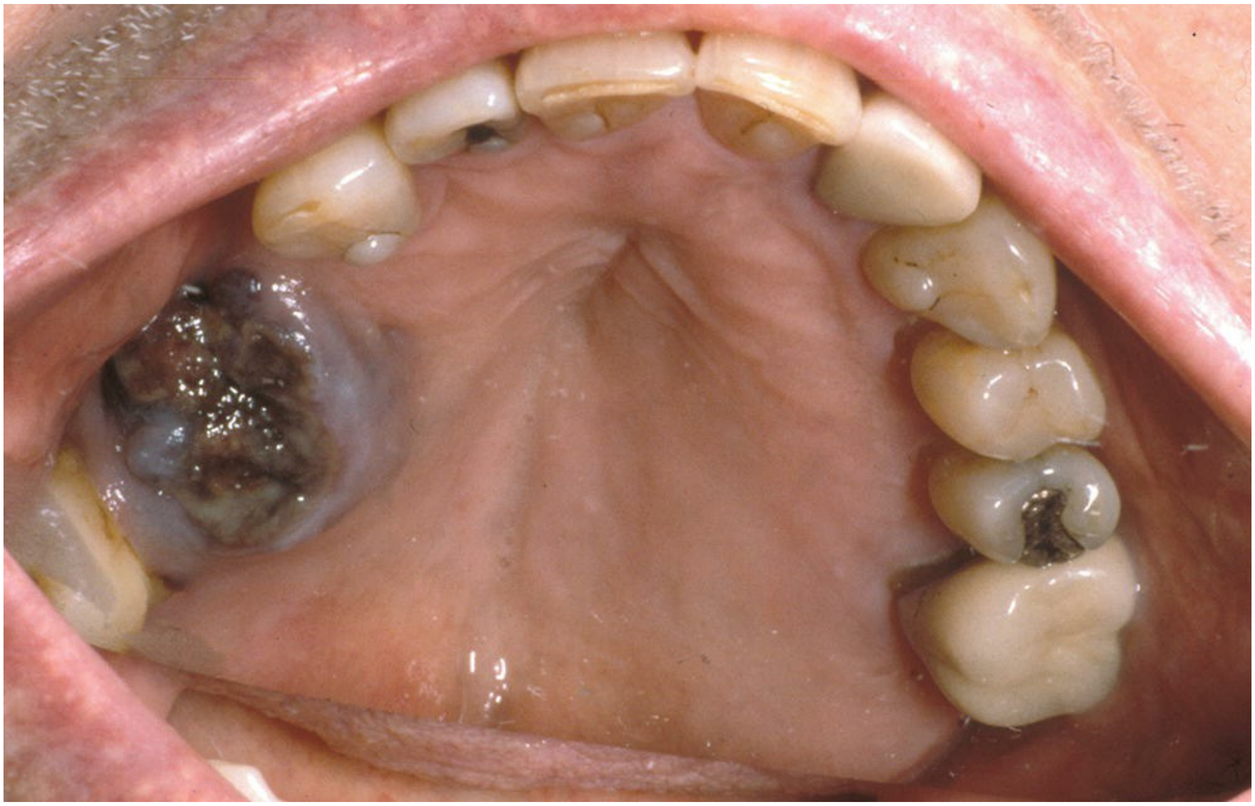

Figure 9.4. Mucosal melanoma of the hard palate. The oral cavity is the second most common site for mucosal melanoma, accounting for 40% of cases.

MM arises from respiratory stromal and mucosal melanocytes.[60] The diagnosis can be more challenging than that of cutaneous melanoma due to amelanotic nature of many tumors (Fig. 9.5). For this reason, IHC plays an important role in diagnosis. MM will often stain for S100, HMB-45, and Melan-A (MART1). Olfactory neuroblastoma may stain for S100 and HMB-45; however, the MAP-2, cytokeratin, and epithelial membrane antigen stains will facilitate the correct diagnosis.[65] Sinonasal undifferentiated carcinoma (SNUC) will stain for cytokeratin but not S100 or HMB-45. Lastly, plasmacytoma and lymphoma are routinely leukocyte common antigen positive in the absence of S100 staining.

Figure 9.5. Mucosal melanoma resected from the superior nasal cavity via a subfrontal craniotomy approach. Note the amelanotic nature of MM, which mimics a nasal polyp.

The recent 7th edition of the AJCC cancer staging system now incorporates a dedicated tumor–node–metastases (TNM) staging system for MM.[66] The staging system begins with stage III disease because of the overall poor prognosis of MM, even in the setting of limited primary tumor burden. Due to the overall aggressive nature of MM, T1 and T2 categories do not exist. T3 tumors are limited to the mucosa. T4a represents moderately advanced disease with invasion into the deep soft tissue, cartilage, bone, or overlying skin. T4b is reserved for very advanced disease, which includes the brain, dura, skull base, cranial nerve, masticator space, carotid artery, prevertebral space, and mediastinal structures. Regional disease and distant disease also impact patient outcome. Patients with nodal metastasis are classified as N1, which upstages them to stage IVA. Similarly, patients with distant metastasis are designated M1 and are classified as stage IVC.

Wide local excision (WLE) of the primary tumor remains the standard of care, and therapeutic neck dissection is recommended for known nodal metastasis.[57] Elective management of the N-zero neck is based upon the site of origin. Sinonasal MM is usually confined to the primary site at presentation.[67] For this reason, an elective neck dissection (END) is not typically recommended. However, OC MM carries an increased risk for

nodal metastasis and may warrant END.

Adjuvant radiation to the primary MM is recommended, regardless of depth of invasion. Extracapsular spread (ECS), two or more positive nodes, intraparotid nodal metastasis, any node >3 cm in diameter, and tumor recurrence are considered high-risk features warranting adjuvant radiation to the draining nodal basins.[57] Radiation planning is based on anatomic subsite and risk. The most common plan for high-risk MMs is conventional fractionation to 60 to 66 Gray (Gy) postoperatively or 70 Gy to gross disease.

Melanoma of the Auricle

Melanoma of the auricle was originally thought to carry a worse prognosis compared to other HN sites.[68] The increased risk was attributed to rich lymphatics, complex anatomic subdivisions of the auricle (6 hillock of His), and a paucity of subcutaneous tissue between the thin skin of the auricle and the underlying perichondrium.[69] For these reasons, total auriculectomy was historically considered standard of care. Retrospective reviews failed to demonstrate a difference in local recurrence based on the extent of auricular excision.[69] After accounting for known prognostic features such as tumor thickness, recent studies demonstrate similar survival rates between melanoma of the auricle compared to other anatomic sites.[70] It is now recognized that current prognostic indicators and surgical principles can be applied safely to the auricular region. Perichondrium is considered a barrier to the spread of melanoma.[71] For this reason, the underlying cartilage requires resection only in the setting of tumor involvement or if previous surgery/biopsy has violated the plane making it impossible for the surgeon to determine if there was direct tumor extension.

EVALUATION OF THE PATIENT

History

Approximately 25% of melanomas are diagnosed during routine office physical examination, whereas the vast majority of these cancers are first detected by the patient or his/her partner.[23,72] The earliest signs of melanoma include change in color, size, or shape of an existing lesion. The earliest

symptom is persistent pruritus. Bleeding, ulceration, and pain represent later changes concerning for more advanced disease. Patients should be questioned about a previous personal and family history of melanoma. Information elucidated during the history should include previous skin biopsies to include “mole” removal, sun exposure (history of blistering sunburns, tanning booth use, and occupation), and immunosuppression.

Physical Examination

Patients presenting with a suspicious lesion warrant a full body evaluation to include the skin as well as associated draining nodal basins. Ideally, this examination is performed by a physician who routinely treats patients with melanoma. A thorough physical examination is imperative because up to 8% of newly diagnosed patients have a synchronous cutaneous melanoma as well as a high risk of synchronous nonmelanoma skin cancers.[73]

In an effort to educate both physicians and patients on the warning signs of melanoma, the American Cancer Society (ACS) published the ABCD checklist.[74] Concerning signs include lesion Asymmetry, Border irregularity, Color variation within a lesion, or Diameter >6 mm. Although this ABCD checklist is helpful in identifying melanoma, it is not entirely comprehensive and will not detect every case of melanoma.[75] A subset of previously described cancers such as nodular, amelanotic (Fig. 9.3), and DMs lacks these common features of the ABCDs. For this reason, a seven-point checklist has been proposed in Europe, which focuses on the importance of *change* within an existing lesion.[76] In one series, 615 of 696 (88%) patients with melanoma recalled a change in their pigmented lesion prior to the diagnosis of melanoma.[77] This significance in a change with lesion led to the addition of “E”—evolving changes to the traditional ABCD warning signs.[78] Patients with melanoma will often present with significant solar damage and nevi. For this reason, a useful screening tool is also the “ugly duckling sign”[79,80] in which any pigmented lesion that appears significantly and individually different from surrounding lesions should be viewed with a high index of suspicion. This suspicion should remain high, even if the “ugly duckling” lesion lacks the traditional ABCDE warning signs.

Biopsy

Any pigmented lesion that demonstrates the ABCDE warning signs outlined above, has undergone change, or appears different from surrounding nevi warrants a biopsy with histologic evaluation. The differential diagnosis for cutaneous melanoma is quite broad, including seborrheic keratosis, hemangioma, blue nevus, Spitz nevus, pyogenic granuloma, pigmented BCC, and cutaneous SCC. It is important to view the biopsy of a melanotic lesion as a two-staged process: the first step involves histologic diagnosis including microstaging of tumor depth and evaluation of concerning features such as ulceration, mitotic rate, angiolymphatic invasion, and perineural spread. These results then serve as the guide for the second stage, which is definitive treatment with WLE and possible SLNB. Although combining the two steps by excising the lesion at the time of initial biopsy may seem both cost and time effective, clinical accuracy is uncertain. In addition, wide excision of the lesion may compromise the ability to accurately stage the melanoma with SLNB.[81]

If excisional biopsy is not feasible due to the large size or anatomic location of the concerning lesion, punch biopsy or incisional biopsy through the thickest portion of the neoplasm is recommended. Shave biopsy and fine needle aspiration of a pigmented lesion are discouraged because tumor thickness, which dictates further diagnostic workup as well as treatment, cannot be accurately determined. Both punch and incisional biopsies are subject to sampling error. If a diagnosis of melanoma is not rendered following either procedure, a repeat biopsy is suggested.

The American Academy of Dermatology (AAD)[82] and National Cancer Comprehensive Network (NCCN)[81] encourage standardization of reporting melanoma pathology. Dermatopathologists are encouraged to report tumor depth of invasion (measured in millimeters and often referred to as Breslow depth), mitotic rate, margin status (deep and peripheral), melanoma subtype to include pure desmoplasia if present, Clark histologic level of invasion for thin (≤1 mm) tumors, vertical growth pattern, tumor-infiltrating lymphocytes, tumor regression, and satellitosis.

Radiographic Imaging

Current NCCN staging guidelines[81] are outlined in Table 9.3. The majority of patients with melanoma present with localized lesions. They are usually

asymptomatic and lack clinical findings suggestive of regional or distant metastasis. Patients with melanoma in situ and stage IA disease (invasion up to 1 mm depth in the absence of ulceration, involvement beyond Clark level III, and high mitotic rate) are considered early stage, and imaging studies are not indicated.[83]

Table 9.3 National Comprehensive Cancer Network Workup Recommendations for Cutaneous Melanoma Based on American Joint Committee on Cancer Staging

Stage[66]	TNM	Recommendations
Stage 0	In situ melanoma	H&P only
Stage IA	T1aN0: depth ≤1 mm without ulceration or high MR	H&P only[a]
Stage IB	T1bN0: depth ≤1 mm with ulceration or high MR T2aN0: depth 1.01–2.0 mm without ulceration or MR	H&P SLNB
Stage II	T2bN0: depth 1.01–2.0 mm with ulceration or high MR T3aN0: depth 2.01–4 mm without ulceration or high MR T3bN0: depth 2.01–4.0 mm with ulceration or high MR T4aN0: depth >4.0 mm without ulceration or high MR T4bN0: depth >4.0 mm with ulceration or high MR	H&P SLNB
Stage III	Regional disease, satellite lesion, or in-transit metastasis	H&P FNA Baseline imaging
Stage IV	Distant metastasis	H&P FNA CT chest/abdomen/pelvis Brain MRI and/or PET

[a]SLNB can be considered in the setting of poor prognostic features outlined in Table 9.2.

TNM, tumor–nodal–metastasis staging description; H&P, history and physical examination; high MR, mitotic rate ≥1/mm^2; SLNB, sentinel lymph node biopsy; FNA, fine-needle aspiration of regional or distant disease; LDH, lactate dehydrogenase level; CT, computed tomography scan; MRI, magnetic resonance imaging; PET, positron emission tomography.

From National Cancer Comprehensive Network. NCCN clinical practice guidelines in oncology: melanoma. Available at http://www.nccn.org. Accessed April 14, 2014.

The most common site for distant metastasis is the lungs.[84] However, the incidence of occult pulmonary metastasis in an asymptomatic stage I and II disease is exceedingly low.[85] Routine chest radiograph (CXR) in this low-risk patient population carries a high false-positive rate of 7%,[86] necessitates additional evaluation, is not cost-effective, and is not suggested for stage I and II disease.[81,83] Evidence supporting the use of other screening modalities such as computed tomography (CT), liver–spleen scans, magnetic resonance

imaging (MRI), and bone scans for patients with limited stage I and II disease is lacking.[87] Site-specific imaging is only recommended in the event that a patient reports one of the symptoms listed in Table 9.4.[85] Routine blood tests are not recommended for stage I and II melanoma.[81] Screening lactate dehydrogenase (LDH) carries a 15% false-positive rate, does not correlate with SLN status, and has not been helpful in detecting occult disease in asymptomatic patients.[86] LDH is only recommended for stage I and II disease when the history or physical examination reveals jaundice, abdominal pain, or other specific findings raising concerns for distant metastasis.[85]

Table 9.4 Review of Systems to Guide Diagnostic Imaging Workup

Constitutional	Neurologic
Change in appetite/weight loss Fatigue and malaise Fever	Headache Memory loss Depression/mood changes Visual changes Seizures Loss of consciousness Numbness Weakness/paralysis
Respiratory	**Musculoskeletal**
Cough Hemoptysis Pleurisy/chest pain Dyspnea Recurrent pneumonia	Bone pain Joint pain
Hepatic	**Gastrointestinal**
Jaundice Abdominal pain Back pain	Abdominal pain Nausea/vomiting/anorexia Bleeding Constipation

Patients with stage III disease, who present with clinically or radiographically suspicious lymph nodes, satellite lesions, or in-transit lesions (defined by melanoma located >2 cm from the primary lesion), carry a significant risk of distant metastasis and warrant baseline imaging and FNA.[22,57] FNA is an accurate and cost-effective means to confirm metastatic melanoma.[88]

Patients with known stage IV disseminated melanoma required a comprehensive workup for systemic metastasis. Clinical trial protocols often dictate the evaluation in this setting.[22] The NCCN recommends FNA, if feasible, to confirm the distant metastasis disease as well as LDH testing.[81] A survival benefit has not been found between patients who are asymptomatic when diagnosed with distant stage IV disease compared to their counterparts who are diagnosed with symptomatic stage IV disease.[85] Although a thorough evaluation for systemic metastasis will not impact overall survival, it may lead to improvement in the patient's quality of life.

Sentinel Lymph Node Biopsy

Because multiple prospective, randomized trials failed to demonstrate an overall survival benefit for patients undergoing END,[89–93] the NCCN no longer suggests routine END for melanoma.[81] The procedure has been replaced by SLNB, which is a much less invasive, cost-effective, and efficient means of staging and screening patients for regional metastasis.[94] Cross-sectional imaging using traditional radiographic modalities only identifies 0.5% to 3.7% of occult stage III melanoma cases.[95–98] Given the often minute tumor volume in a positive sentinel node (+SLN), serial sectioning and evaluation with both H&E staining and IHC for melanoma markers confer greater sensitivity in the detection of micrometastasis disease and are recommended for all sentinel nodes found to be negative for melanoma on conventional H&E staining and microscopic examination.

Patients meeting the criteria outlined in Table 9.2 should be counseled on the utility of SLNB. Approximately 4 to 6 hours prior to surgery, patients undergo preoperative injection of a radioactive colloid into the lesion and lymphoscintigraphy to determine the number, location, and laterality of at-risk draining nodal basins (Fig. 9.6). This imaging serves as a road map for the surgeon and is particularly helpful for midline lesions, which have the

propensity to drain bilaterally. Recent studies demonstrate that fused single-photon emission computed tomography/computed tomography (SPECT/CT) is a superior imaging modality compared to traditional planar lymphoscintigraphy because of the increased anatomical three-dimensional detail and improved resolution (Fig. 9.7). The largest prospective study comparing SPECT/CT to planar lymphoscintigraphy included 403 melanoma patients.[99] SPECT/CT altered the surgical plan in 22% of cases. It yielded a higher number of + SLNs per patient (2.4 vs. 1.87; $p < 0.001$) as well as a higher metastatic rate (0.34 vs. 0.21; $p = 0.04$). At a mean follow-up of 28.8 months, patients undergoing SLNB utilizing SPECT/CT had a higher disease-free survival (DFS) compared to the lymphoscintigraphy group (94% vs. 79%; $p = 0.02$). Multivariate analysis identified use of SPECT/CT as a factor associated with DFS (HR = 4.11; $p = 0.02$).

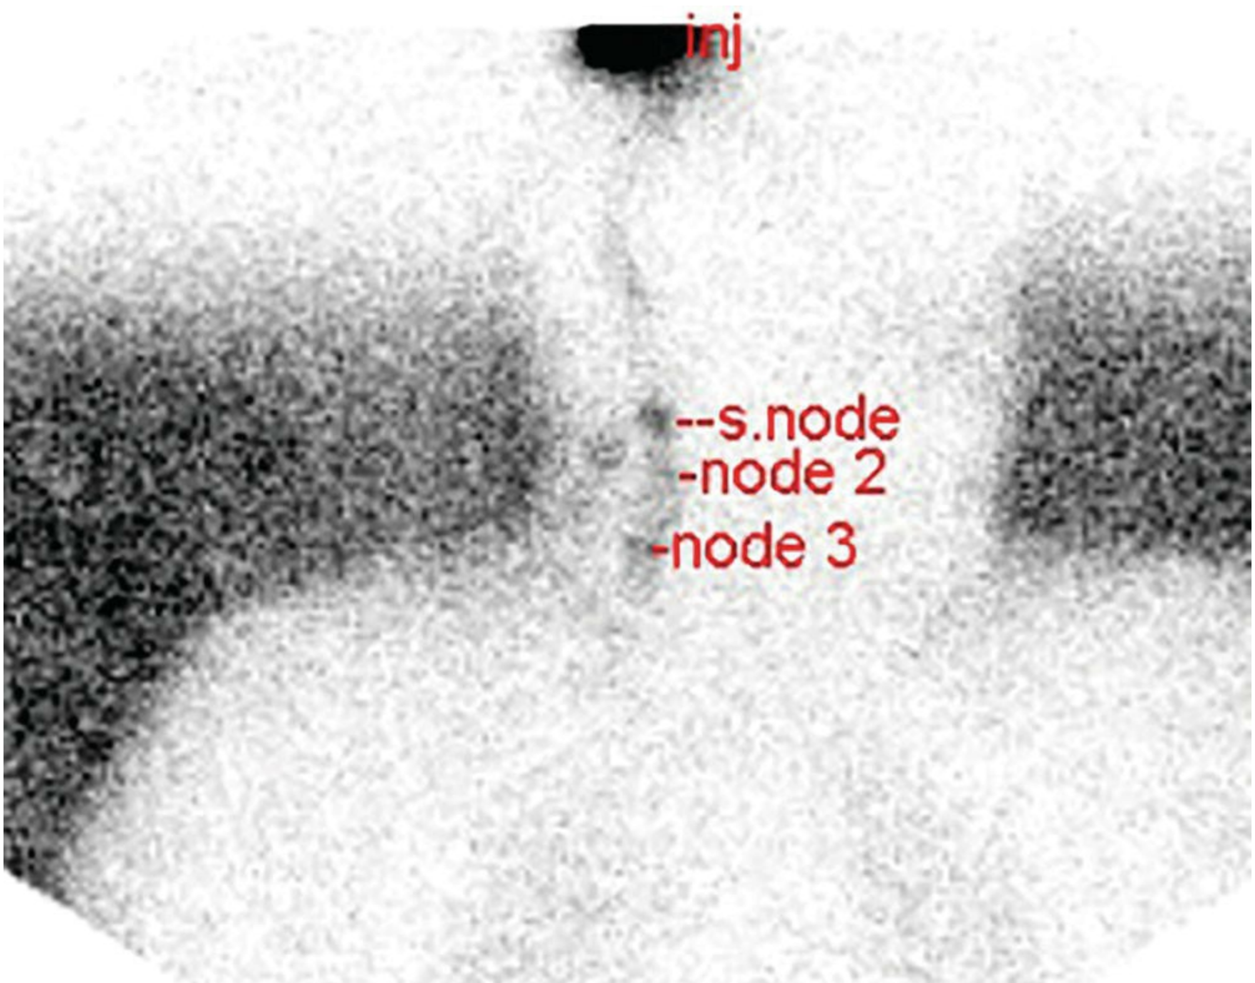

Figure 9.6. Sentinel lymph node biopsy traditional two-planar imaging

utilizing preoperative radioactive colloid and lymphoscintigraphy. The hottest region represents the primary right scalp melanoma where intradermal injections were performed (inj site). S. node, sentinel node.

Figure 9.7. Sentinel lymph node biopsy SPECT/CT fused coronal imaging of

a patient with a left scalp melanoma (*white circle*). A sentinel lymph node with radiolabel uptake is detected in the left parotid nodal basin. Note increased anatomic detail compared to lymphoscintigraphy in Figure 9.6.

Once under anesthesia, patients undergo intraoperative lymphatic mapping with vital blue dye.[100] Approximately 1 mL of dye is injected intradermally into the four quadrants surrounding the primary melanoma. Combining both the radioactive colloid and blue dye is highly recommended because studies consistently demonstrate increased SLNB sensitivity when using both techniques together.[101,102]

WLE of the HN primary is often performed first because the close proximity of the melanoma and draining lymphatics creates radioactive "shine-through" that can make the gamma probe readings difficult to interpret in certain basins underlying or very close to the primary melanoma. Following WLE, the nodal basins at risk based in part on the preoperative lymphoscintigraphy are evaluated for increased radioactivity using a handheld gamma probe (Fig. 9.8). The smallest incision possible to remove the SLN without risk to neurovascular structures is then made overlying the areas of increased radioactivity. Approximately 25% of HN cutaneous melanomas drain to the parotid nodal basin.[103,104] A preauricular incision is recommended in the parotid region in order to optimize cosmesis and minimize injury to the facial nerve (Fig. 9.9). The use of facial nerve monitoring can also decrease the risk of facial nerve injury. Numerous studies demonstrate that SLNB can be reliably and safely performed within the parotid nodal basin, especially when using continuous facial nerve monitoring.[104–106] It had previously been thought that inflammation from the biopsy would increase the risk of facial nerve injury when a therapeutic superficial parotidectomy was required for patients with a + SLN.[107] However, Erman et al.[108] reported preservation of facial nerve function in all patients undergoing therapeutic superficial parotidectomy following a positive SLNB.

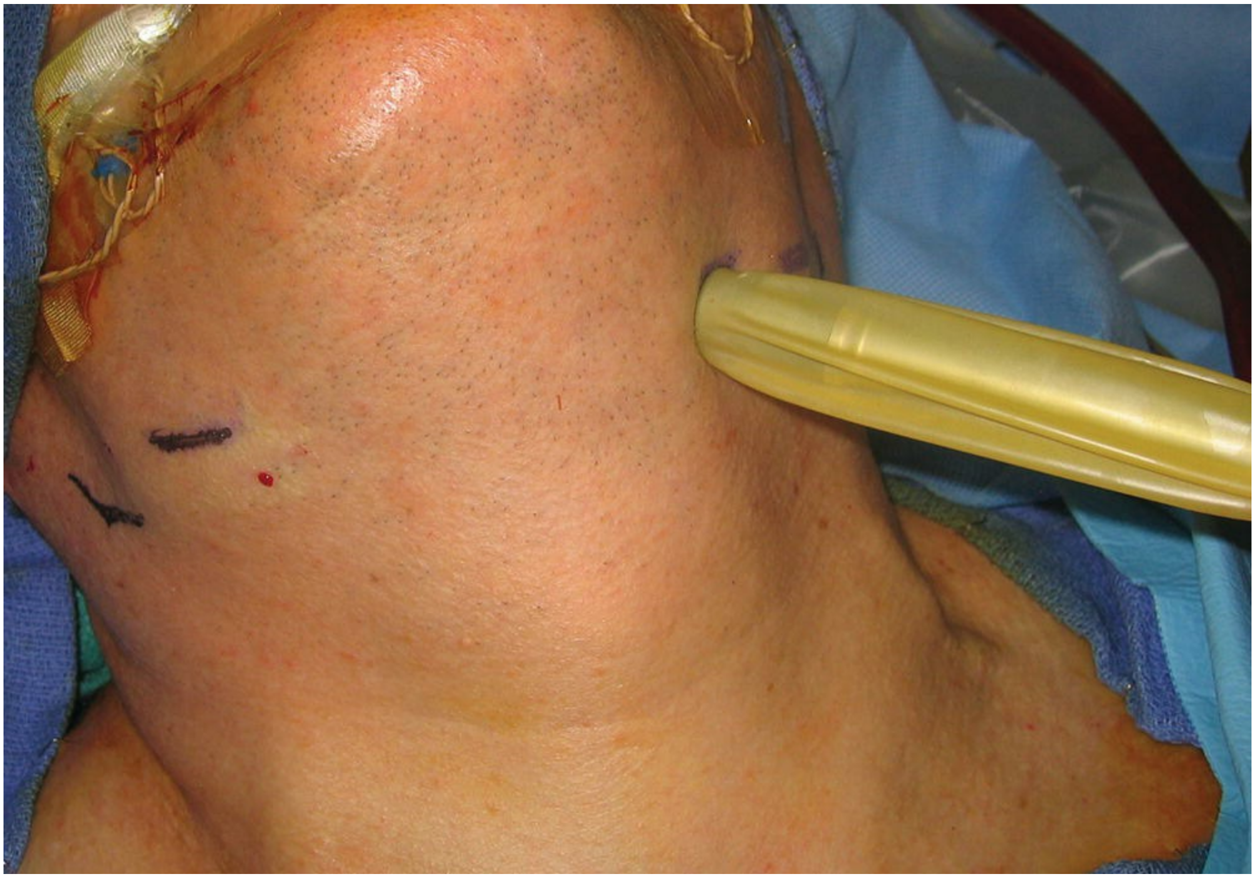

Figure 9.8. Following preoperative injection of radioactive colloid, intraoperative injection of blue dye, and wide local excision of the primary melanoma, the gamma probe is utilized to identify increased areas of radioactivity indicative of a sentinel node.

Figure 9.9. A preauricular incision and facial nerve monitor is sometimes recommended for SLNB within the parotid nodal basin to allow for optimal cosmetic healing and reduced risk to the facial nerve, respectively.

By definition, a lymph node demonstrating 10% or greater counters per minute compared to the hottest node ex vivo is considered “sentinel”[109] Using a combination of the gamma probe and visual cues from the blue dye, individual SLNs are identified (Fig. 9.10) and sent separately for permanent histologic evaluation because frozen section evaluation of melanoma specimens has a false-negative rate between 5% and 10%.[110] The evaluation includes serial microsectioning, hematoxylin and eosin (H&E) staining, and melanoma-specific immunohistochemistry to include S100, Melan-A (MART1), and HMB-45. On average, 2.4 SLNs are harvested per patient.[108] This small number allows for a more practical, thorough, and complete histologic evaluation compared to an entire lymphadenectomy specimen, which can yield too many lymph nodes to cost-effectively evaluate with more

than a single H&E section.[111] Patients with a + SLN should be returned to the operating room within 2 weeks of diagnosis for definitive therapeutic lymph node dissection (TLND); patients with a negative biopsy are followed clinically.

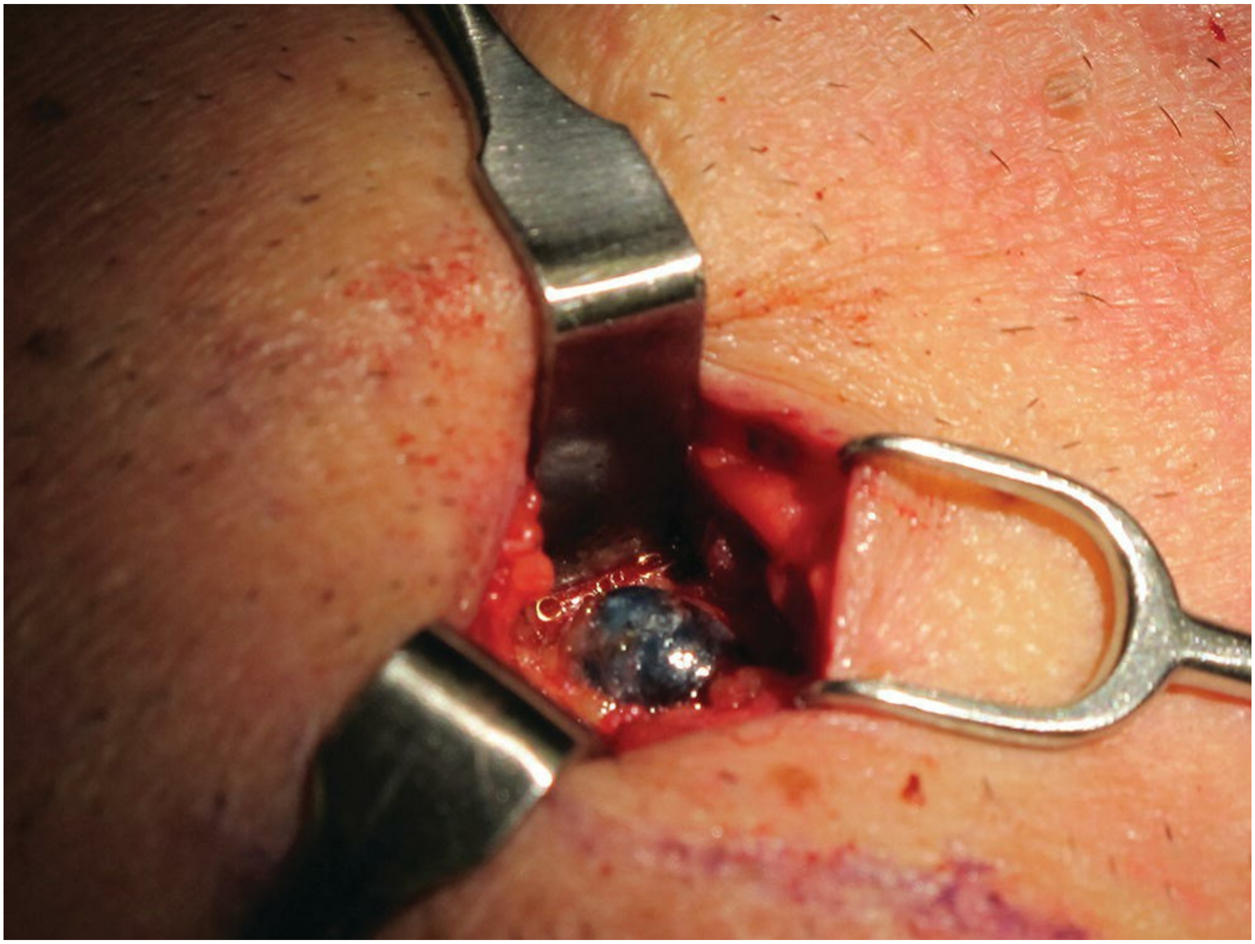

Figure 9.10. A sentinel lymph node identified by increased radioactivity and demonstrating the expected intense staining from the intradermal injection of the primary lesion with blue dye.

END no longer has a role in cutaneous melanoma,[57] and SLNB is now considered standard of care for the reasons outlined in Table 9.5.[119,120] Although damage to cranial nerves and unpredictable lymphatics were an original concern in applying SLNB within the HN region,[107] studies throughout the past two decades have consistently demonstrated that SLNB can be accurately performed in cervical nodal basins without significant risk to the cranial nerves and great vessels.[104,121–123] The largest single-institution

HN SLNB prospective study identified an SLN in 352 of 353 cases (99.7%) with no reported permanent facial nerve, cranial nerve, or vascular damage. Sixty-nine of 353 patients (19.6%) had a positive SLN biopsy.[108] This 19.6% positivity rate mirrors the results achieved in other anatomic sites such as the trunk and extremities.[92,124] At a mean follow-up of 48 months, 12 of 283 negative SLN patients were locally free of disease but developed regional recurrence within a previously mapped nodal basin, yielding a false-negative rate of 14.8% (12 false-negatives/12 false-negatives + 69 true positives). The negative predictive value of 95.8% and false rate of omission of 4.2% mirror that of trunk and extremity melanoma, thus demonstrating feasibility of SLNB in the HN region.

Table 9.5 Supporting Rationale for SLNB as Standard of Care for Cutaneous Melanoma

1. The pathologic status of the SLN is the most important prognostic factor for melanoma disease free survival (HR = 3.41; $p < 0.00001$) and overall survival (HR = 6.53; $p < 0.0001$).[112]
2. Lymph node tumor burden (microscopic/occult disease vs. macroscopic/clinically palpable disease) is the second most important prognostic factor following number of nodal metastasis for patient with stage III melanoma ($p < 0.0001$).[113]
3. The *American Joint Committee on Cancer (AJCC)* incorporated SLN status into the 2002 cancer staging system[114] and has validated the prognostic importance of the SLN status in the most recent edition.[115]
4. SLNB remains the most specific and sensitive means for regional staging.[81]
5. SLNB allows for accurate staging and identification of a homogeneous population of patients to enroll in clinical trials.[116]
6. SLNB is now incorporated into the current *National Comprehensive Cancer Network (NCCN)* guidelines.[81]
7. The *American Society of Clinical Oncology (ASCO)* and the *Society of Surgical Oncology (SSO)* have recently published updated clinical practice guidelines regarding use of SLNB for melanoma.[117]
8. *The World Health Organization (WHO)* issued a statement that SLNB is standard of care for melanoma.[118]
9. SLNB is incorporated into numerous national and international numerous oncology consensus statements.[82,119,120]

Communication and collaboration are imperative to SLNB success. An experienced nuclear medicine team is necessary to avoid inappropriate administration of the radioactive tracer causing "shine-through." The pathologist plays an extremely critical role given the tedious task of identifying micrometastasis, which can measure <1 mm in size.[125] The referring dermatology team is vital in working up and identifying appropriate SLNB candidates. Lastly, the surgeon requires experience in the SLNB technique. Morton et al.[110] prospectively identified a 55-case learning curve in order to achieve at least 95% accuracy with SLNB.

In 2014, SLNB remains a staging modality. The long-awaited multicenter selective lymphadenectomy trial-1 (MSLT-1) led by Donald Morton commenced in 1994 to determine if immediate completion lymphadenectomy improved survival over observation and delayed lymphadenectomy.[126] A total of 2001 patients with melanoma were randomized to WLE and delayed lymphadenectomy for nodal recurrence versus WLE with SLNB and immediate lymphadenectomy for micrometastatic disease. At 10-year follow-up, SLNB correctly determined the pathologic nodal stage in 96% of cases. Patients with a + SLN demonstrated worse outcomes compared to their SLN-negative counterparts (DFS 62% vs. 85%; $p < 0.001$). Intermediate and thick melanoma patients in the WLE/SLN group experienced an improved 10-year DFS compared to observation with delayed lymphadenectomy. Although an overall survival benefit was not reported for the entire 2001 cohort, only 20% were estimated to harbor occult nodal metastasis and benefit from early intervention. Subgroup analysis of patients with nodal disease identified an improved melanoma-specific survival in the WLE/SLN group (62% vs. 41.5%; $p = 0.006$). This treatment-related difference was unique to patients with intermediate-thickness melanomas (1.20 to 3.5 mm) but not thick melanomas >3.5 mm in depth. The final MSLT-1 results demonstrate that early lymphadenectomy following a + SLNB decreases nodal recurrence, distant metastasis, and death from melanoma for patients with intermediate-thickness melanomas and occult regional disease.

The benefit of SLNB in staging thin melanomas remains to be determined. Morton et al.[126] could not draw meaningful conclusions from the 340 patients with thin melanomas measuring <1.20 mm invasion. A meta-analysis of SLN positivity in thin melanomas ≤1 mm identifies a pooled occult nodal disease rate of only 5.6%.[127] Clinical and histopathologic

criteria to reliably detect this small at-risk population has not emerged. Future studies are required and will need to balance benefit with cost and associated morbidity. Table 9.2 lists situations in which SLNB can be considered in the setting of thin melanomas.

Future SLNB research endeavors hold exciting promise. Ongoing efforts investigate the *therapeutic potential* of SLNB. Studies have attempted to identify markers of both the primary melanoma and SLN predictive of cancer remaining in non-SLNs.[128–130] Such markers would allow for identification of the subset of + SLN patients who may not require further completion TLND. Unfortunately, a reliable marker has yet to emerge. The ongoing *MSLT-II trial* is designed to investigate the indications for TLND following a + SLNB.[110] It will determine if immediate TLND provides a survival benefit over postoperative, diligent, ultrasonographic monitoring of the draining nodal basins. Until the results of MSLT-II are available, it is important to realize that TLND following + SLNB remains the standard of care.[81] SLNB implementing *optical imaging* with near-infrared fluorescence utilizing indocyanine green (NIR-ICG) as a lymphatic tracer has been successfully applied in various cancers.[131] NIR fluorescence has outperformed traditional blue dye in several SLN clinical trials.[132–135] Tissue depth and large body mass index (BMI) remains the rate-limiting factor. A hybrid tracer combining ICG with ^{99m}Tc-radioactive colloid has been introduced in an attempt to increase depth of detection and length of time the tracer is retained within the lymph nodes.[136] The application of SLN optical imaging remains investigational at present but is promising.

STAGING AND PROGNOSIS

As a result of an increased understanding of the biology of cutaneous melanoma, the AJCC introduced a revised staging system in 2009.[115] The sample size was expanded to 17,600 patients, the prognostic significance of mitotic rate was analyzed, the stage IV category was expanded fivefold, LDH levels were formally evaluated for the first time, and the importance of SLN status as criterion for stage III disease was evaluated. This investigation marks the largest analysis of its kind to date.

The current AJCC staging system for cutaneous melanoma remains

founded upon the traditional TNM classification system.[115] Stages I and II represent localized disease, stage III is regional disease inclusive of satellite and in-transit metastasis, and stage IV is reserved for distant metastatic disease. The most important predictors for survival now serve as criteria for the definition of melanoma stage and are summarized in Table 9.6.

Table 9.6 AJCC Cutaneous Melanoma Staging Criteria Defining Tumor Stage

Stage I and II: Localized Disease 1. Tumor thickness (recorded in even integer increments) 2. Tumor ulceration 3. Mitotic rate for thin T1 melanomas (≤1 mm thickness)
Stage III: Regional Metastasis 1. Number of metastatic lymph nodes 2. Tumor burden (microscopic + SLN vs. macroscopic) 3. Primary tumor ulceration 4. In-transit or satellite metastasis
Stage IV: Distant Metastasis 1. Site of distant disease 2. LDH level

+ SLN, positive sentinel lymph node; LDH, serum lactate dehydrogenase level

The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springer.com.

Multivariate analysis of 13,500 patients with localized disease confirmed tumor thickness and ulcerations as the most important predictors of outcome.[115] Overall, *tumor thickness* remained the most important risk factor for stage I/II patients. It was previously incorporated into the 1997 staging system, but at that time, it was empirically based on the Breslow depth.

Recent analysis confirmed that even integer cut points (1.0, 2.0, 4.0 mm) represent the best statistical model correlating thickness and survival. Ten-year survival rates were reported as 92%, 80%, 63%, and 50% for T1 through T4 tumors, respectively.[115]

Primary tumor *ulceration* was identified as the second most important factor for localized stage I/II disease. It is a histologic diagnosis in which the epithelium overlying the primary tumor is absent. Patients with ulcerated melanomas carry a worse survival rate, mirroring that of patients with nonulcerated tumors in the next higher T-category.[114]

Primary tumor *mitotic rate* is now incorporated into the staging of the thinnest T1 melanomas. Mitotic rate is an indicator of tumor proliferation and is reported in features per mm^2. Increased mitotic rate is associated with a worse survival rate,[115] and it is recognized as an independent predictor of a positive SLN[137,138] as well as the second most powerful predictor of survival for patients with stage III + SLN disease. Multivariate analysis of 10,233 patients with localized stage I/II disease found mitotic rate to be the second most powerful predictor of overall survival following tumor thickness ($p < 0.0001$).[115] Mitotic rate has now replaced Clark level of invasion for thin T1 melanomas; when this is present, patients are staged as T1b.

Stage III melanoma is a heterogeneous group of patients with a 5-year survival rate ranging from 82% for patients with nonulcerated primaries with 1 + SLN to a dismal 29% for patients with ulcerated melanomas with ≥4 clinically palpable metastatic nodes.[115,139] The heterogenous survival rate for stage III melanoma highlights the importance of accurate tumor staging, which is particularly important in the context of clinical trials.[116] The *number of nodal metastasis* remains the most important prognostic factor for stage III disease, regardless of micrometastatic versus macrometastatic deposits. Other important prognostic factors include tumor burden (micrometastatic disease identified on SLNB vs. clinically palpable macroscopic disease); the majority of stage III melanoma patients now present with micrometastasis.[140] Ulceration remains the only prognostic factor of the primary lesion once patients develop regional disease; tumor thickness is no longer prognostic once patients develop regional metastasis. *In-transit metastases* and *satellite lesions* represent intralymphatic metastasis and are considered stage III disease, even in the absence of nodal metastasis.

Stage IV melanoma describes patients with distant metastasis. Analysis of 7,972 patients with disseminated melanoma confirmed anatomic site and elevated serum LDH levels as the most important prognostic factors.[115] Patients with distant metastasis to the skin, subcutaneous tissue, or distant lymph nodes with a normal LDH level (M1a) had a slightly higher survival rate as compared to other subsites. Patients with only lung metastasis have a better prognosis than those with involvement of other visceral distant metastasis and are denoted as having stage M1b disease. Patients with metastasis involving any other visceral organs and those with elevated LDH levels (regardless of the site of metastatic disease) have the worst prognosis and are categorized as M1c. The median survival time following the diagnosis of disseminated melanoma is only 6 to 8 months; the 5-year survival rate is 6%.[141,142] For this reason, stage IV melanoma is not subclassified under the AJCC staging system.

The AJCC has now incorporated staging guidelines for metastatic disease with unknown primary origin.[115] Patients with isolated nodal metastasis are considered stage III, provided that a comprehensive workup does not find evidence of distant disease. All other presentations of metastatic melanoma with unknown primary are deemed stage IV disease. Patients with unknown primary melanoma carry an equivalent to better outcome compared to those with a known primary in the same staging category.[143,144]

SURGICAL MANAGEMENT

Primary Melanoma

WLE remains the primary treatment for cutaneous melanoma. The extent of surgical margins remains an unanswered question despite numerous retrospective studies, meta-analyses, and clinical trials. Numerous prospective trials[145–148] investigating the optimal surgical margin for intermediate-thickness melanomas failed to demonstrate improved local control rates and overall survival in using margins >1 cm. Meta-analysis of such trials concluded that a surgical margin of at least 1 cm and no more than 2 cm was adequate for WLE.[149] Current surgical margins are dictated by melanoma depth of invasion (Table 9.7).[81] The depth of excision includes full-thickness skin and subcutaneous tissue. Resection of fascia,

perichondrium, and periosteum is required only in the setting of direct tumor invasion or if the surgical plane was violated during a previous biopsy.[150] These recommendations serve merely as a guideline; each patient must be treated on an individual basis, with surgeon experience and judgment playing an important role.

Table 9.7 Recommended Surgical Margins for Cutaneous Melanoma WLE

Tumor Depth	Surgical Margin
In situ	0.5–1.0 cm
≤1 mm (T1)	1.0 cm
1.01–2.0 mm (T2)	1.0–2.0 cm
2.01–4.0 mm (T3)	2.0 cm
>4.0 mm (T4)	2.0 cm

From National Cancer Comprehensive Network. NCCN clinical practice guidelines in oncology: melanoma. Available at http://www.nccn.org. Accessed April 14, 2014.

Wide undermining allows for the closure of the majority of HN melanoma defects. Larger defects may require reconstruction with a skin graft, advancement flap, regional flap, or free tissue transfer. A delay in closure may be required until the surgical margins are adequately cleared on permanent pathology. Rush permanent section analysis of margins is available in many centers enabling patients to have delayed reconstructions performed within 24 hours of the initial primary resection. The method of reconstruction ultimately depends on the anatomic location including skin color and texture, depth of the defect, and patient, as well as surgeon, preference. The method of closure has not been shown to hinder detection of melanoma recurrence or to negatively impact survival.[151]

LM/LMM can be a challenge to excise due to the propensity for unpredictable, subclinical spread involving AJMH.[152] Positive margins are not uncommon. Application of a Wood lamp or digital epiluminescence

microscopy has proven helpful in the accurate identification of tumor margins.[152] A prospective trial of 1,120 LM patients treated with MOHS microsurgery yielded removal of 99% of melanomas using a 9-mm margin and 86% with a 6-mm margin.[153] Alternatively, the “square” technique[154,155] is a staged procedure in which a double-bladed instrument is used to completely excise the peripheral margins. This technique allows permanent histologic evaluation of 100% of the peripheral margins surrounding the entire melanoma. On rare occasions, WLE of large LM/LMM is not feasible due to the associated comorbidities and psychosocial implications. Topical imiquimod[156] and primary radiation[157,158] are reasonable alternatives in these challenging cases.

Regional Lymph Nodes

The cervical and parotid nodal basins are the most common site of metastasis for HN cutaneous melanoma.[7,140,141] TLND is universally accepted as the standard of care for regional nodal disease.[81] The neck dissection must surgically address the draining nodal basins as well as the intervening lymphatics between the primary melanoma and the site of known regional disease. Every effort should be made to preserve the spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle.[142] These structures should only be sacrificed when there is guidance of gross tumor invasion.

The location of the primary melanoma dictates the type of TLND, as well as the need for a superficial parotidectomy (Fig. 9.11). An imaginary coronal plane through the external auditory canal (EAC) serves as a guide: melanomas located anterior to this plane (i.e., anterolateral scalp, temple, lateral forehead, lateral cheek, and ear) drain via the parotid nodal basin to the jugular lymph node chain.[142] Adequate management of the nodal basins for these melanomas located anteriorly and superiorly in the HN region requires both a superficial parotidectomy and a modified radical neck dissection (MRND). If the melanoma arises anterior to the imaginary coronal plane through the EAC, but in a more inferior location (i.e., chin or neck), a superficial parotidectomy is not warranted. Conversely, melanomas located on the scalp and occiput, posterior to the imaginary coronal plane through the EAC, can drain to postauricular, suboccipital, and posterior triangle lymph nodes. These nodal basins are not addressed during routine MRND. Instead, a posterolateral neck dissection, which extends to the midline of the superior,

posterior neck, is required.[143]

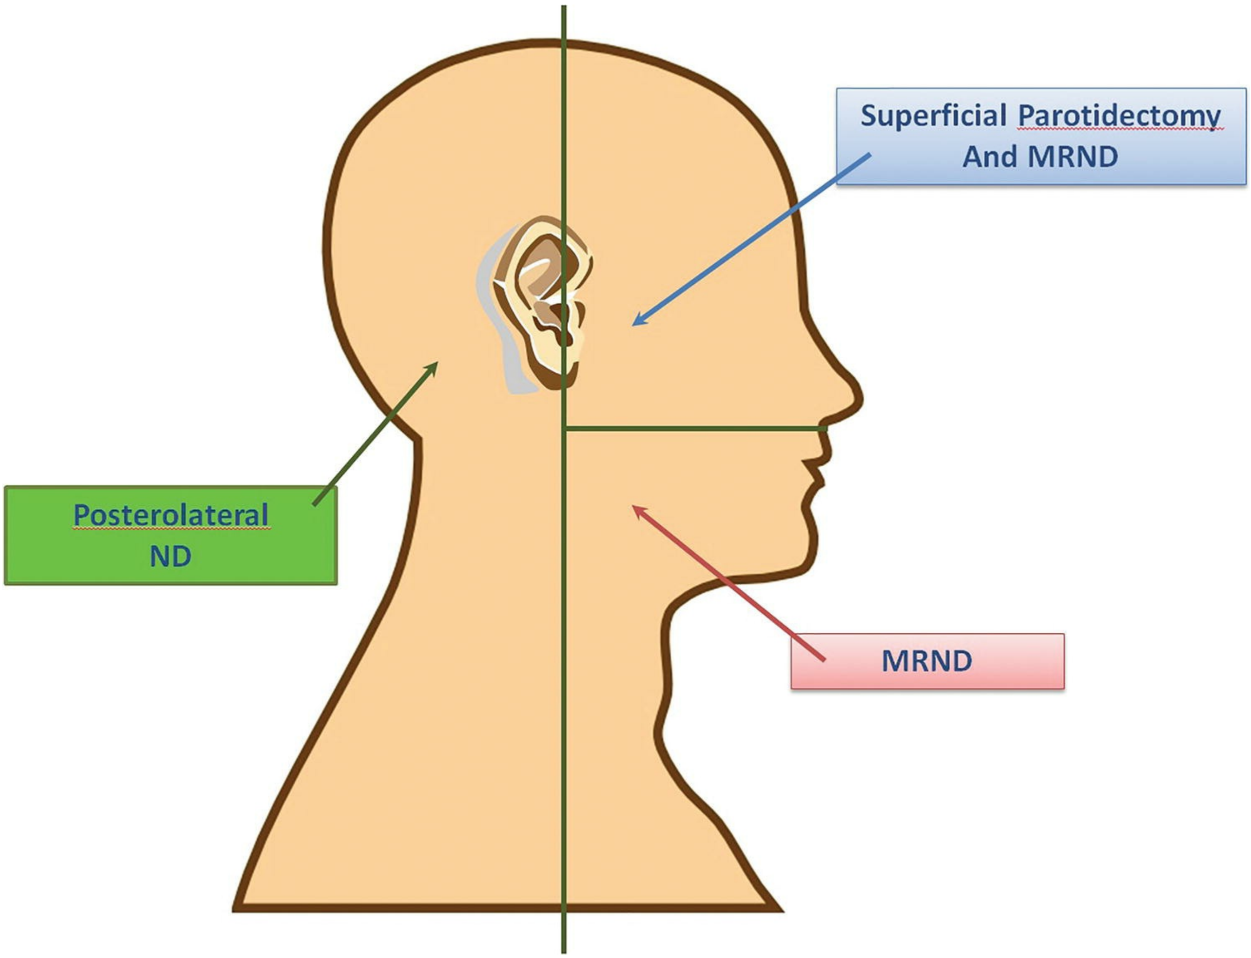

Figure 9.11. The type of neck dissection and need for superficial parotidectomy are dictated by the location of the primary melanoma.

In-Transit Metastasis

WLE of in-transit metastasis remains the standard of care when clear margins can be achieved.[81] Ultimately, the treatment will be based upon the size of the in-transit metastasis, anatomic location, number of metastatic lesions, and overall patient prognosis. Patients with in-transit stage III disease are at increased risk for occult regional metastasis, and a + SLNB in this setting portends a worse prognosis.[159] Nonsurgical options include intralesional injections with bacille Calmette-Guerin (BCG),[160] interleukin-2 (IL-2), interferon, laser ablation, and topical imiquimod.[161] Consensus has not been reached for the optimal nonsurgical treatment of in-transit melanoma

metastasis; enrollment into clinical trials is encouraged for this patient population.[81]

Distant Metastasis

Patients with stage IV melanoma metastasis to distant sites have an exceedingly grave prognosis with an overall survival rate measured in months as opposed to years. Surgical intervention is reserved for palliation in patients suffering from brain, lung, gastrointestinal, subcutaneous soft tissue, and distant lymph node metastasis.[162] Surgery should only be considered if clearly identifiable and specific symptoms are associated with the metastatic lesion. Consideration must be given to surgical morbidity, expected quality of life, anticipated survival, and, most importantly, patient's wishes.[22] The patient and family must understand that the goal of each surgery is palliative in nature.

RADIATION

Although surgery offers the highest rate of local control and cure, radiation can have a role as the primary treatment modality for elderly individuals who are deemed poor surgical candidates. Radiation may also be considered the primary treatment modality for patients with exceedingly large melanomas (usually of the LMM variant) in which WLE would be extremely morbid from a cosmetic and functional standpoint.[158]

Radiation is most often used in the setting of adjuvant treatment following WLE and/or regional lymphadenectomy. The rationale for adjuvant radiation is to improve local and regional control rates without adding toxicity. Preventing regional recurrence is important given the associated morbidity and negative impact on quality of life. Indications for adjuvant radiation to the primary surgical bed and regional nodal basis are outlined in Table 9.8. Hypofractionation (3 fractions of 7 Gy administered days 1, 7, and 21 or 5 to 6 Gy fractions) is the most common regimen.[81,163,164] Patients meeting the criteria listed in Table 9.8 are often eligible to receive adjuvant interferon-α2b (see below). Interferon is thought to act as a radiosensitizer; adjuvant radiation is usually delayed until the 4-week induction phase of interferon therapy is complete.[165]

Table 9.8 Indications for Adjuvant Cutaneous Melanoma Irradiation

Local Irradiation	Regional Irradiation
Desmoplastic melanoma	≥1 Parotid node
Positive margin	≥2 Cervical nodes
Recurrent disease	Cervical node ≥3 cm diameter
Breslow depth >4.0 mm with ulceration	Extracapsular spread
Satellitosis	+ SLN without completion lymphadenectomy
	Regional metastasis

and Burmeister BH, Henderson MA, Ainslie J, et al. Adjuvant radiotherapy versus observation alone for patients at risk of lymph-node field relapse after therapeutic lymphadenectomy for melanoma: a randomised trial. *Lancet Oncol.* 2012;13:589–597.

Guadagnolo et al. reported a statistically significant improvement in 5-year regional control rates for HN patients undergoing cervical TLND followed by adjuvant irradiation versus cervical TLND alone (43% vs. 93%; $p < 0.001$).[164] Burmeister et al.[166] conducted a prospective trial in which patients were randomized following lymphadenectomy to adjuvant radiation versus observation. At 40 months' follow-up, no difference in disease-specific and overall survival was reported. However, the improved regional control rate (HR = 0.56; $p = 0.041$) compelled the authors to conclude that radiation improves regional control in patients at high risk for nodal relapse following lymphadenectomy.

Radiation can also play a role in the palliative setting.[163] Hypofractionated dosing is suggested in order to limit toxicity as well as the

amount of time spent in treatment. Individual lesions are usually treated only after becoming symptomatic. The exception is brain metastases, which tend to be irradiated preemptively in order to prevent cerebral hemorrhage.[163] As with all palliative care, the focus ultimately is one of quality as opposed to quantity of life.

SYSTEMIC THERAPY

Chemotherapy and Biologic Agents

Melanoma is a relatively chemoresistant tumor, and a definite impact of treatment with conventional chemotherapy on overall survival has not emerged.[167] Consequently, the main role of chemotherapy remains in palliative treatment for metastatic stage IV disease.[81] *Dacarbazine (DTIC)* was the first chemotherapeutic agent to show significant activity against melanoma, and today, it remains the only agent approved for chemotherapeutic agent for treating stage IV melanoma. Unfortunately, chemotherapy response rates are between 10% and 20%, with <5% demonstrating a complete response.[168–170] This modest response has led to increased focus on targeted therapies outlined below.

IL-2 is a variant of immunotherapy used as the primary treatment for disseminated stage IV metastatic melanoma. IL-2 stimulates the immune host response by activating natural killer cells (NKCs), monocytes, cytotoxic T cells, and helper T cells. Initial trials involving high doses of IL-2 were promising with an overall response rate of 7% and partial response rate of 10%, both of which were long-standing between 8 and 10 years.[171] IL-2 toxicities are significant and can be life threatening. Only patients with outstanding performance and cardiopulmonary status are eligible for clinical trials.[22] Various randomized trials have combined IL-2 and other biologic agents with various chemotherapy drugs, including DTIC, cisplatin, and vinblastine.[172,173] Although these biochemotherapy regimes demonstrate overall response rates, a survival benefit for patients with metastatic melanoma has not been reported.[174]

Interferon-α2b

Despite myriad clinical trials involving adjuvant regimens, high-dose interferon-α2b (INF-α2b) remains the *only US Food and Drug Administration (FDA)-approved adjuvant treatment for stage III melanoma*. Three large clinical trials involving adjuvant INF-α2b have been conducted by the Eastern Cooperative Oncology Group (ECOG).[175–177] ECOG trial E1684 was the first study to demonstrate the efficacy of INF-α2b.[175] High-dose interferon was administered intravenously during a 1-month induction period (20 million units[MU]/m^2/d) followed by 11 months of subcutaneous maintenance treatment (10 MU/ m^2/d) administered 3 days a week. At 6.9 years' follow-up, the prolonged disease-free survival rate and overall survival rate in the INF-α2b arm of E1684 prompted US FDA approval of adjuvant high-dose INF-α2b.

The follow-up trial E1690 failed to confirm the efficacy of high-dose INF-α2b[176]; however, the study designs have been criticized for the following reasons[116]: (1) Unlike E1684, enrollment did not require pathologic staging with ELND or SLNB. (2) Patients were not stratified on the important prognostic feature of ulceration. (3) A disproportionate number of individuals from the observation arm crossed over into the INF-α2b arm in order to receive salvage therapy for recurrent disease. Any therapeutic benefit provided to this subgroup by INF-α2b went unrecognized given the intention to treat statistical analysis.

The most recent and largest of the three studies, ECOG 1694,[177] compared high-dose INF-α2b to an experimental vaccine (GM2-KLH21). This trail confirmed the efficacy of high-dose INF-α2b. The relapse-free and overall survival benefit observed in the high-dose INF-α2b control arm compared to the experimental vaccine arm was so compelling that the Data Safety Monitoring Committee terminated the trial early. More recently, the E1694 vaccine cohort has been found to have worse than expected survival rates compared to the interferon group, prompting concern about this form of therapy.[81]

Pooled analysis of E1684, E1690, and E1694 identified an improved relapse-free survival for high-risk melanoma patients undergoing adjuvant high-dose INF-α2b (p = 0.006).[178] An improvement in overall survival was not reported. A recent Cochrane review involving 18 randomized controlled trials with a total of 10,499 patients reported an improved DFS (HR = 0.83; p

< 0.00001) and overall survival (HR = 0.91; p = 0.003) for high-risk stage II and III patients receiving adjuvant INF-α2b.[179]

Although clinical trials continue to investigate alternative dosages and schedules,[180,181] only high-dose INF-α2b is FDA approved and used as routine adjuvant therapy within the United States. INF-α2b has significant toxicities to include flu-like symptoms, chronic fatigue (20% to 30%), neurologic side effects, depression and suicidal ideation, myelosuppression, thyroid dysfunction, and elevated liver enzymes.[176,177,182] Therefore, a thoughtful discussion with eligible at-risk patients about the risk/benefit ratio of adjuvant interferon treatment and their individual priorities with respect to quantity and quality of life is recommended.

Recent studies have focused on PEGylated interferon INF-α2b. The polyethylene glycol (PEG) covalently bonds to interferon, changing the pharmacokinetics to increase the drugs half-life. This change reduces the above toxicities and allows for a more convenient subcutaneous dosing schedule. EORTC 18991 was a phase III trial comparing PEGylated interferon to observation[183] for patients with completely resected stage III melanoma. At 7.6 years' follow-up, an improved recurrence-free but not overall survival rate was reported. Patients with microscopic nodal disease and ulcerated primary melanomas demonstrated greater benefit. In 2011, the FDA approved PEGylated interferon as adjuvant treatment for patients with stage III regional melanoma.

Targeted Agents

Given the significant toxicities associated with the above systemic therapies, research efforts have focused on targeted therapy. 2011 marked a landmark year for melanoma, with targeted agents receiving FDA approval for the treatment of advanced disease for the first time in over a decade.

In March 2011, the FDA approved *ipilimumab* for the treatment of stage IV melanoma. This monoclonal antibody targets cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4), which ultimately sustains T-cell activation.[184,185] It is administered intravenously (3 mg/kg) once a week for four doses. A randomized control trial of patients with stage IV metastatic melanoma randomized to ipilimumab versus ipilimumab plus gp100 peptide vaccine and gp100 peptide vaccine alone demonstrated an overall survival

benefit with combined therapy (10 months; $p < 0.001$) and ipilimumab alone (10.1 months; $p = 0.003$) compared to vaccine only (6.4 months).[186] This improved overall survival rate was confirmed in a phase III randomized trial comparing ipilimumab and DTIC to DTIC alone.[187] Tumor response can take months. Only 20% of patients with melanoma respond to ipilimumab, but the response when present is long term. As many as 60% of patients experience immune-related side effects, the most common being diarrhea secondary to colitis. Patients with underlying autoimmune disorders are especially susceptible.

BRAF mutation has been identified in 42% of cutaneous melanomas include arthralgias (21%), development of cutaneous SCCs and keratoacanthomas (18%), and photosensitivity (12%). Approximately 38% of patients required dose modification to accommodate these side effects. A rapid response in days to weeks is common, but unfortunately, this response is not long term with a median response rate of 5 to 6 months. Since FDA approval of vemurafenib in August of 2011, two additional BRAF mutation–targeted agents have been approved. *Dabrafenib* is associated with fewer cutaneous SCCs and keratoacanthomas (6%).[81,188] Photosensitivity was also reduced compared to vemurafenib (6%), but pyrexia was more common (11%).

Trametinib is an inhibitor of MEK1/MEK2, a signaling molecule, which is downstream from BRAF in the MAP kinase signaling pathway. This orally administered adjuvant drug was studied in an open-label phase III clinical trial in patients with advanced metastatic melanoma.[189] The trametinib group demonstrated an improved progression-free survival (4.8 vs. 1.5 months; $p < 0.001$) and a 6-month survival (81% vs. 67%; $p = 0.01$). Unlike BRAF inhibitors, there were no incident of secondary skin lesions, but rash, diarrhea, and peripheral edema were commonly reported. The NCCN now recommends ipilimumab, vemurafenib, dabrafenib, and dabrafenib with trametinib as the preferred regimen for advanced or metastatic melanoma.[81]

KIT (c-kit) mutations are common to MMs and melanomas in sun-damaged sites.[38] *Imatinib* is a tyrosine kinase inhibitor known to inhibit KIT. Similar to the above BRAF inhibitors, molecular screening is imperative for appropriate patient selection. A phase II trial demonstrated a 23% overall response rate with imatinib.[190] Patients with KIT mutations involving exons

11 and 13 are most likely to respond; however, these responses have typically not been durable.[38]

FOLLOW-UP

The primary goals in the follow-up of patients who have been treated for melanoma are (1) early detection of locoregional recurrence, (2) early detection of a second melanoma (as well as nonmelanoma skin cancer), (3) psychosocial support for the patient and family, (4) patient education, and (5) detection of distant metastasis. Five to ten percent of melanoma patients go on to develop a second primary cancer during their lifetime.[73] This risk is lifelong and can occur anywhere on the skin. Thus, long-term, annual follow-up with a thorough total body examination is critical. Photodocumentation has proven helpful in following nevi.[191] Each office visit affords an opportunity to educate both patient and family members on the ABCDE warning signs, the importance of the use of sunscreen, the avoidance of sun during peak hours (11 AM to 2 PM), and the risks associated with tanning booths. The exact timing of follow-up appointments remains a debate. The current NCCN guidelines recommend skin surveillance at least once a year.[81] Regional ultrasound can be considered in patients who declined SLNB or who did not undergo TLND following a + SLN.[115] Ultimately, patient follow-up should be individualized and based on patient risk factors, family history, and level of anxiety.

10 Cancer of the Nasal Cavity and the Paranasal Sinuses

Ehab Y. N. Hanna, Shirley Su, Michael E. Kupferman, Shaan M. Raza, and Franco DeMonte

INTRODUCTION

Over the last two decades, significant advances have been made in both the diagnosis and management of cancer of the nasal cavity and paranasal sinuses. The most significant advances in diagnosis are office endoscopy and high-resolution imaging. These diagnostic tools have allowed more accurate delineation of the extent of sinonasal tumors and, hence, improved treatment planning. Significant advances in treatment include progress made in cranial base surgery allowing for safe excision of tumors involving the cranial base. In addition, the development of microvascular free tissue transfer has made effective reconstruction of more extensive surgical defects possible. Advances have also been made in both planning and delivery of radiotherapy such as intensity-modulated radiation therapy (IMRT) and proton therapy. Both modalities allow optimal radiation dosimetry to the tumor while sparing normal surrounding tissue. Various new combinations of effective cytotoxic chemotherapeutic and targeted biologic agents are also being increasingly incorporated in the overall management of patients with sinonasal cancer.

Recent advances made in diagnosis and treatment of patients with sinonasal cancer have clearly impacted our ability to control the disease and improve survival. Over the last 40 years, survival rates have improved from 25% to 40% in the 1960s to 65% to 75% in the last decade (**Fig. 10.1**). Despite these improvements, a significant number of patients die of their disease. The rarity of these tumors and the similarity of their presenting

symptoms to more common benign conditions, coupled with the propensity for early spread and involvement of surrounding critical structures, are reflected in the fact that most patients still present with advanced stage disease. This has clearly hampered attempts to further improve prognosis. In this chapter, we present the current trends in diagnosis, classification, staging, and treatment of patients with cancers of the nasal cavity and paranasal sinuses. We also discuss some of the strategies to improve the outcome of these patients.

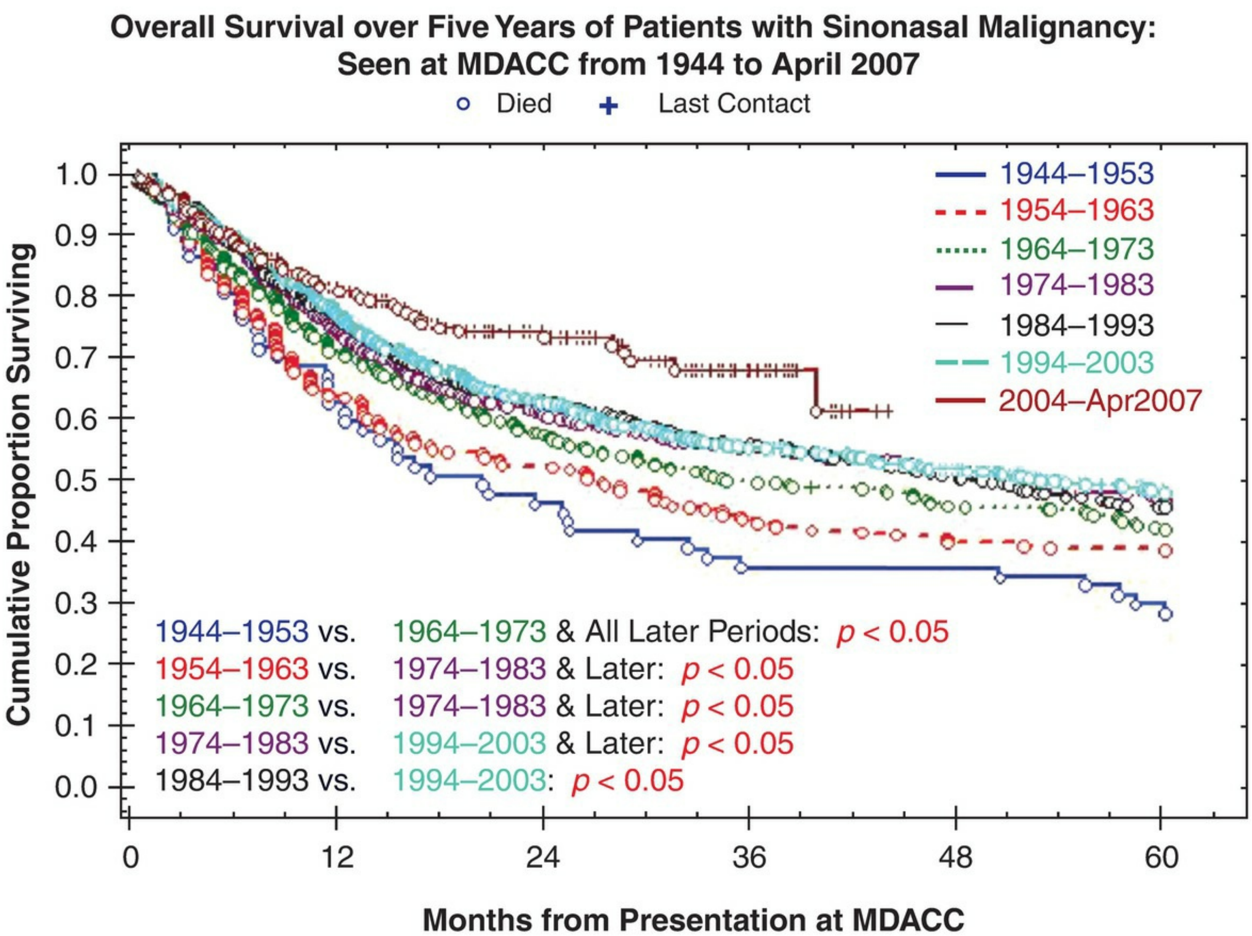

Figure 10.1. Improvement in 5-year OS of Patients with Sinonasal Malignancy. Data of 2,698 patients with sinonasal cancer seen at MD Anderson Cancer Center (MDACC) from 1944 to 2007.

ANATOMY

Nasal Cavity

The nasal cavity is bounded by the bony pyriform aperture and the external framework of the nose (**Fig.** 10.2**A**). The nasal cavity opens anteriorly through the skin-lined nasal vestibule into the nares and communicates posteriorly through the choanae with the nasopharynx (**Fig. 10.2B**). The nasal cavity is divided in the midline by the *nasal septum*, which includes both cartilaginous and bony components (**Fig. 10.2C**). The cartilage of the septum is somewhat quadrilateral in form and is thicker at its margins than at its center. Its anterior margin is connected with the nasal bones and is continuous with the anterior margins of the lateral cartilages; below, it is connected to the medial crura of the greater alar cartilages by fibrous tissue (Fig. 10.2A). Its posterior margin is connected with the perpendicular plate of the ethmoid, its inferior margin with the vomer and the palatine process of the maxilla.

On the *lateral nasal wall* are the superior, middle, and inferior nasal turbinates, and below and lateral to each turbinate (concha) is the corresponding nasal passage or meatus (**Fig.** 10.3**A and B**). Above the superior turbinate is a narrow recess, the sphenoethmoidal recess, into which the sphenoid sinus opens. The superior meatus is a short oblique passage extending about halfway along the upper border of the middle turbinate; the posterior ethmoid cells open into the front part of this meatus. The middle meatus is below and lateral to the middle turbinate. The anatomy of the middle meatus is fully displayed by removing the middle turbinate (Fig. 10.3A and B). The bulla ethmoidalis is the most prominent anterior ethmoid air cell. The hiatus semilunaris is a curved cleft lying below and in front of the bulla ethmoidalis. It is bounded inferiorly by the sharp concave margin of the uncinate process of the ethmoid bone and leads into a curved channel, the infundibulum, bounded above by the bulla ethmoidalis and below by the lateral surface of the uncinate process of the ethmoid. The anterior ethmoid air cells open into the front part of the infundibulum. The frontal sinus drains through the nasofrontal duct, which in ~50% of subjects will also drain into the infundibulum; but when the anterior end of the uncinate process fuses with the front part of the bulla, this continuity is interrupted and the frontonasal duct then opens directly into the anterior end of the middle meatus. Below the bulla ethmoidalis, and partly hidden by the inferior end of the uncinate process, is the ostium of the maxillary sinus. An accessory ostium from the maxillary sinus is frequently present below the posterior end of the middle nasal concha. The inferior meatus is below and lateral to the

inferior nasal turbinate. The nasolacrimal duct opens into the inferior meatus under cover of the anterior part of the inferior turbinate.

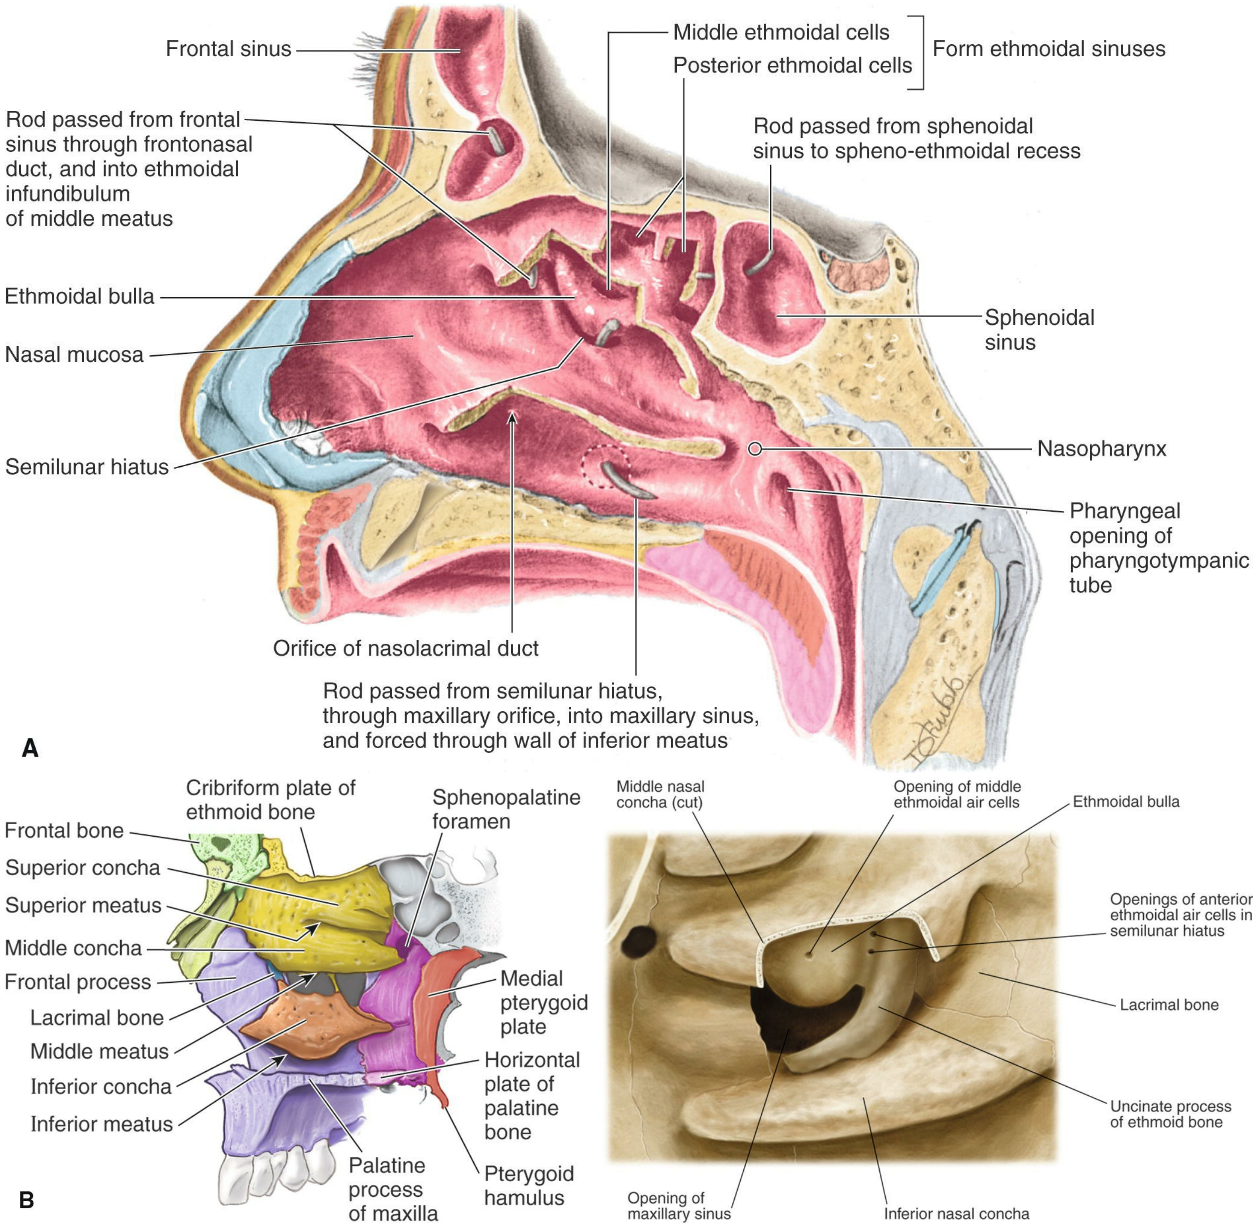

Figure 10.3. A: Anatomy of the lateral nasal wall. Removal of the middle turbinate demonstrates the anatomy of the middle meatus. (From Moore KL, Agur AMR, Dalley AF, eds. *Clinically Oriented Anatomy*. 7th ed. Philadelphia, PA: Wolters Kluwer Health; 2013.) **B:** Skeletal framework of the lateral nasal wall. Removal of the middle turbinate demonstrates the anatomy of the middle meatus. (Left image from Moore KL, Agur AMR, Dalley AF, eds. *Clinically Oriented Anatomy*. 7th ed. Philadelphia, PA:

Wolters Kluwer Health; 2013. Right image from Pansky B, Gest TR, eds. *Lippincott's Concise Illustrated Anatomy: Head and Neck* (vol. 3). Philadelphia, PA: Wolters Kluwer Health; 2014.)

The *roof* of the nasal cavity is narrow from side to side and slopes downward (at about a 30-degree angle) from front to back. The cribriform plate, which transmits the filaments of the olfactory nerve, forms the roof of the nasal cavity medial to the superior attachment of the middle turbinate. Lateral to the middle turbinate, the fovea ethmoidalis forms the roof of the ethmoid sinuses. Careful assessment of the anatomy of the nasal roof, especially the relationship of the cribriform plate to the fovea ethmoidalis, is critical in avoiding a cerebrospinal fluid (CSF) leak during surgery in this region. The cribriform plate is usually at a slightly lower horizontal plane than the fovea ethmoidalis forming a shallow olfactory groove. This configuration is known as Keros type I (**Fig. 10.4**). However, the cribriform plate may be moderately or significantly lower than the fovea ethmoidalis resulting in a medium (Keros type II) or deep (Keros type III) olfactory groove. The topography of the roof may also be asymmetrical (Fig. 10.4).

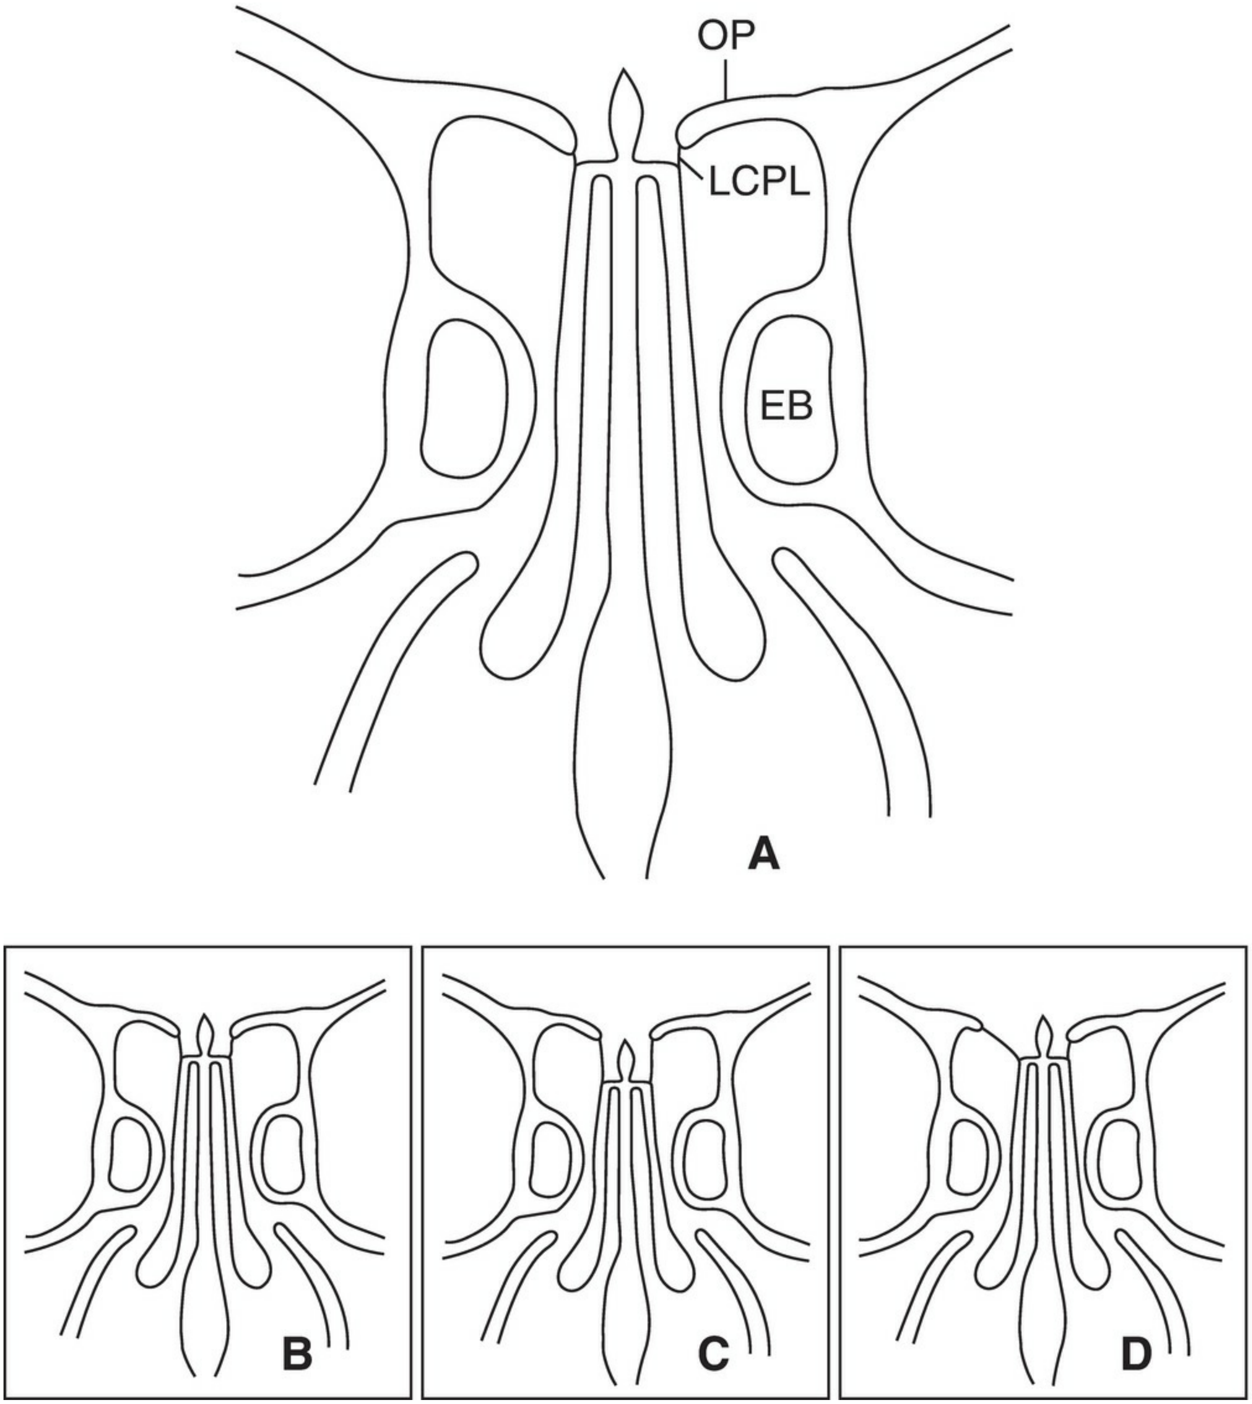

Figure 10.4. Anatomy of the ethmoid roof and lateral lamella of the cribriform plate. **A:** Keros type I. **B:** Keros type II. **C:** Keros type III. **D:** Asymmetrical ethmoid roof. Note that the right lateral lamella of the cribriform plate is very thin and long and is obliquely oriented including much of the right ethmoid roof. OP, orbital plate of frontal bone; LCPL, lateral cribriform plate lamella; EB, ethmoid bulla.

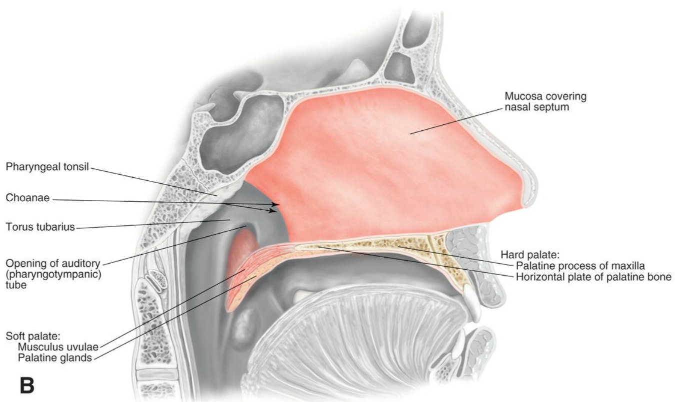
The *floor* of the nasal cavity is concave from side to side and almost horizontal anteroposteriorly. The palatine process of the maxilla forms the anterior three-fourths, and the horizontal process of the palatine bone forms the posterior fourth of the nasal floor (Fig. 10.2C).

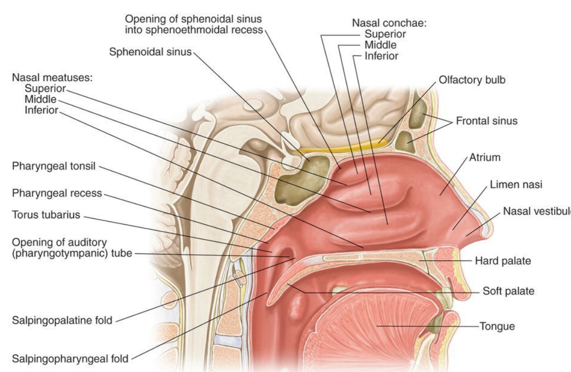
The majority of the nasal cavity is lined by pseudostratified ciliated columnar epithelium, which contains mucous and serous glands (respiratory epithelium). Specialized olfactory epithelium lines the most superior portion of the nasal cavity and has direct connections with the olfactory tracts through openings in the cribriform plate.

The *arteries* of the nasal cavities are the anterior and posterior ethmoidal branches of the ophthalmic artery, which supply the ethmoid and frontal sinuses and roof of the nose. The sphenopalatine artery supplies the mucous membrane covering the lateral nasal wall. The septal branch of the superior labial artery supplies the anterior inferior septum. The *veins* form a close cavernous plexus beneath the mucous membrane. This plexus is especially well marked over the lower part of the septum and over the middle and inferior turbinates. Venous drainage follows a pattern similar to arterial supply. The *lymphatic drainage* from the anterior part of the nasal cavity, similar to that of the external nose, is to the submandibular group of lymph nodes (level I). Lymphatics from the posterior two-thirds of the nasal cavities and from the paranasal sinuses drain to the upper jugular (level II) and retropharyngeal lymph nodes.

The sensory *nerves* of the nasal cavity transmit either somatoautonomic or olfactory sensation. *Somatoautonomic* nerves include the nasociliary branch of the ophthalmic, which supplies the anterior septum and lateral wall. The anterior alveolar nerve, branch of the maxillary (V2), supplies the inferior meatus and inferior turbinate. The nasopalatine nerve supplies the middle of the septum. The anterior palatine nerve supplies the lower nasal branches to the middle and inferior turbinates. The nerve of the pterygoid canal (vidian) and the nasal branches from the sphenopalatine ganglion supply the upper and posterior septum and superior turbinate. The *olfactory nerve* fibers arise from the bipolar olfactory cells and unite in fasciculi, which form a plexus beneath the mucous membrane and then ascend passing into the skull through the foramina in the cribriform plate. Intracranially, olfactory nerve fibers enter the under surface of the olfactory bulb, in which they ramify and form synapses with the dendrites of the mitral cells of the

olfactory tract.





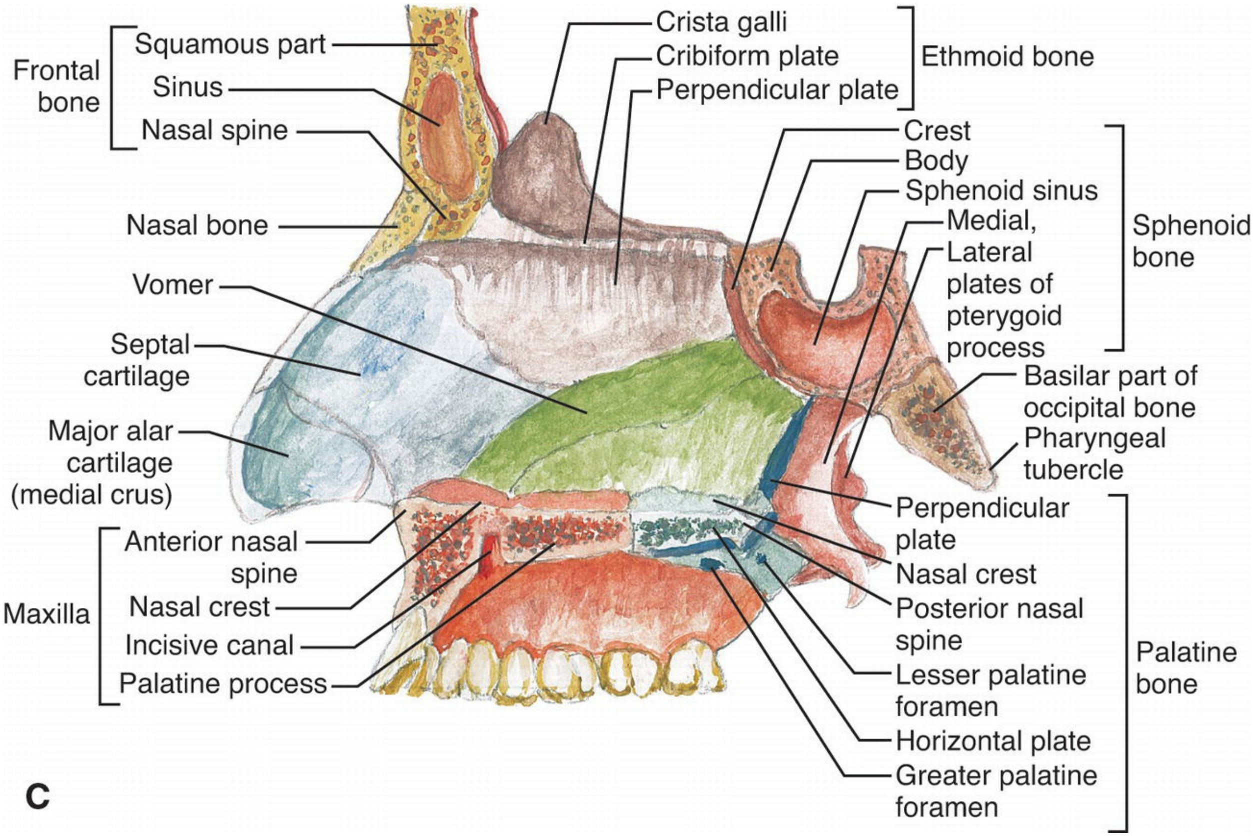


Figure 10.2. A: Anatomy of the external nose. (From Chung KW, Chung HM, Halliday NL, eds. *Gross Anatomy*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2015.) B:Anatomy of the nasal septum. (From Pansky B, Gest TR, eds. *Lippincott's Concise Illustrated Anatomy: Head and Neck* (vol. 3). Philadelphia, PA: Wolters Kluwer Health; 2014.) C:Skeletal framework of the nasal septum. (From Chung KW, Chung HM, Halliday NL, eds. *Gross Anatomy*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2015.)

Maxillary Sinus

The maxillary sinus (*antrum of Highmore*), the largest of the accessory sinuses of the nose, is a pyramidal cavity in the body of the maxilla (**Figs. 10.5 and 10.6**). Its base is formed by the lateral wall of the nasal cavity, and its apex extends into the zygomatic process. Its roof or orbital wall is frequently ridged by the infraorbital canal, whereas its floor is formed by the alveolar process of the maxilla and is usually 1 to 10 mm below the level of the floor of the nose. Projecting into the floor are several conical elevations corresponding with the roots of the first and second molar teeth, and in some cases, the floor is perforated by one or more of these roots. The natural

ostium of the maxillary sinus is partially covered by the uncinate process and communicates with the lower part of the hiatus semilunaris of the lateral nasal wall (Figs. 10.3 and 10.5). An accessory ostium is frequently seen in, or immediately behind, the hiatus. The maxillary sinus appears as a shallow groove on the medial surface of the bone about the 4th month of fetal life but does not reach its full size until after the second dentition.

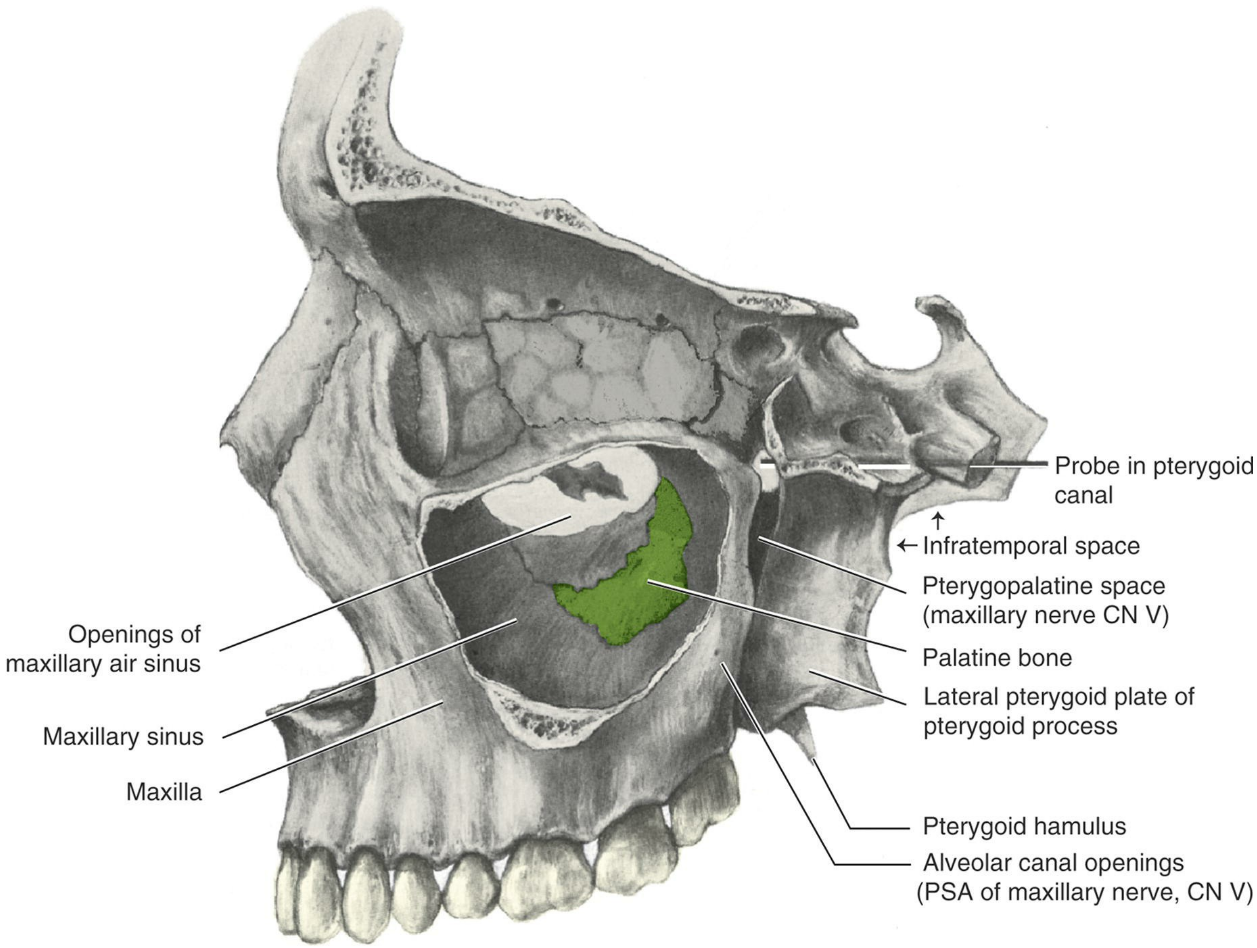

Figure 10.5. Anatomy of the maxillary sinus (lateral wall removed). (From Scheid RC, Weiss G, eds. *Woelfel's Dental Anatomy*. 8th ed. Philadelphia, PA: Wolters Kluwer Health; 2012.)

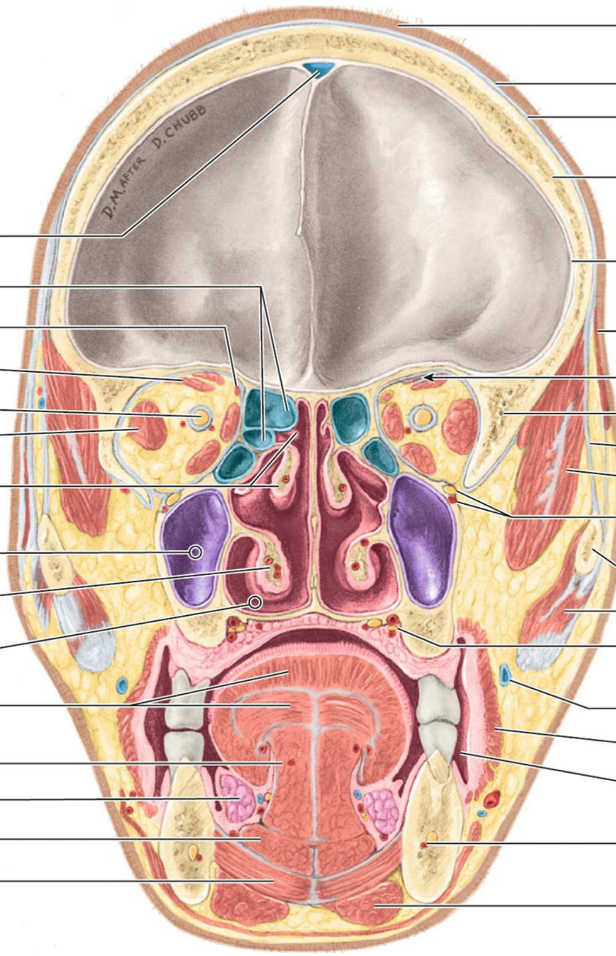

Figure 10.6. Anatomy of the ethmoid and maxillary sinuses (Coronal section). (From Moore KL, Agur AMR, Dalley AF, eds. *Clinically Oriented Anatomy*. 7th ed. Philadelphia, PA: Wolters Kluwer Health; 2013.)

Ethmoid Sinus

The ethmoidal air cells consist of numerous thin-walled cavities situated in the ethmoidal labyrinth and bounded by the frontal, maxillary, lacrimal, sphenoid, and palatine bones. They lie in the upper part of the nasal cavity between the orbits (Fig. 10.6). The ethmoid sinuses are separated from the orbital cavity by a thin bony plate, the lamina papyracea. On either side, they are arranged in three groups, *anterior*, *middle*, and *posterior*. The anterior and middle groups open into the middle meatus of the nose, the former by way of the infundibulum, and the latter on or above the bulla ethmoidalis (Fig. 10.3). The posterior cells open into the superior meatus under cover of the superior nasal concha. Sometimes one or more ethmoid air cells extend over the

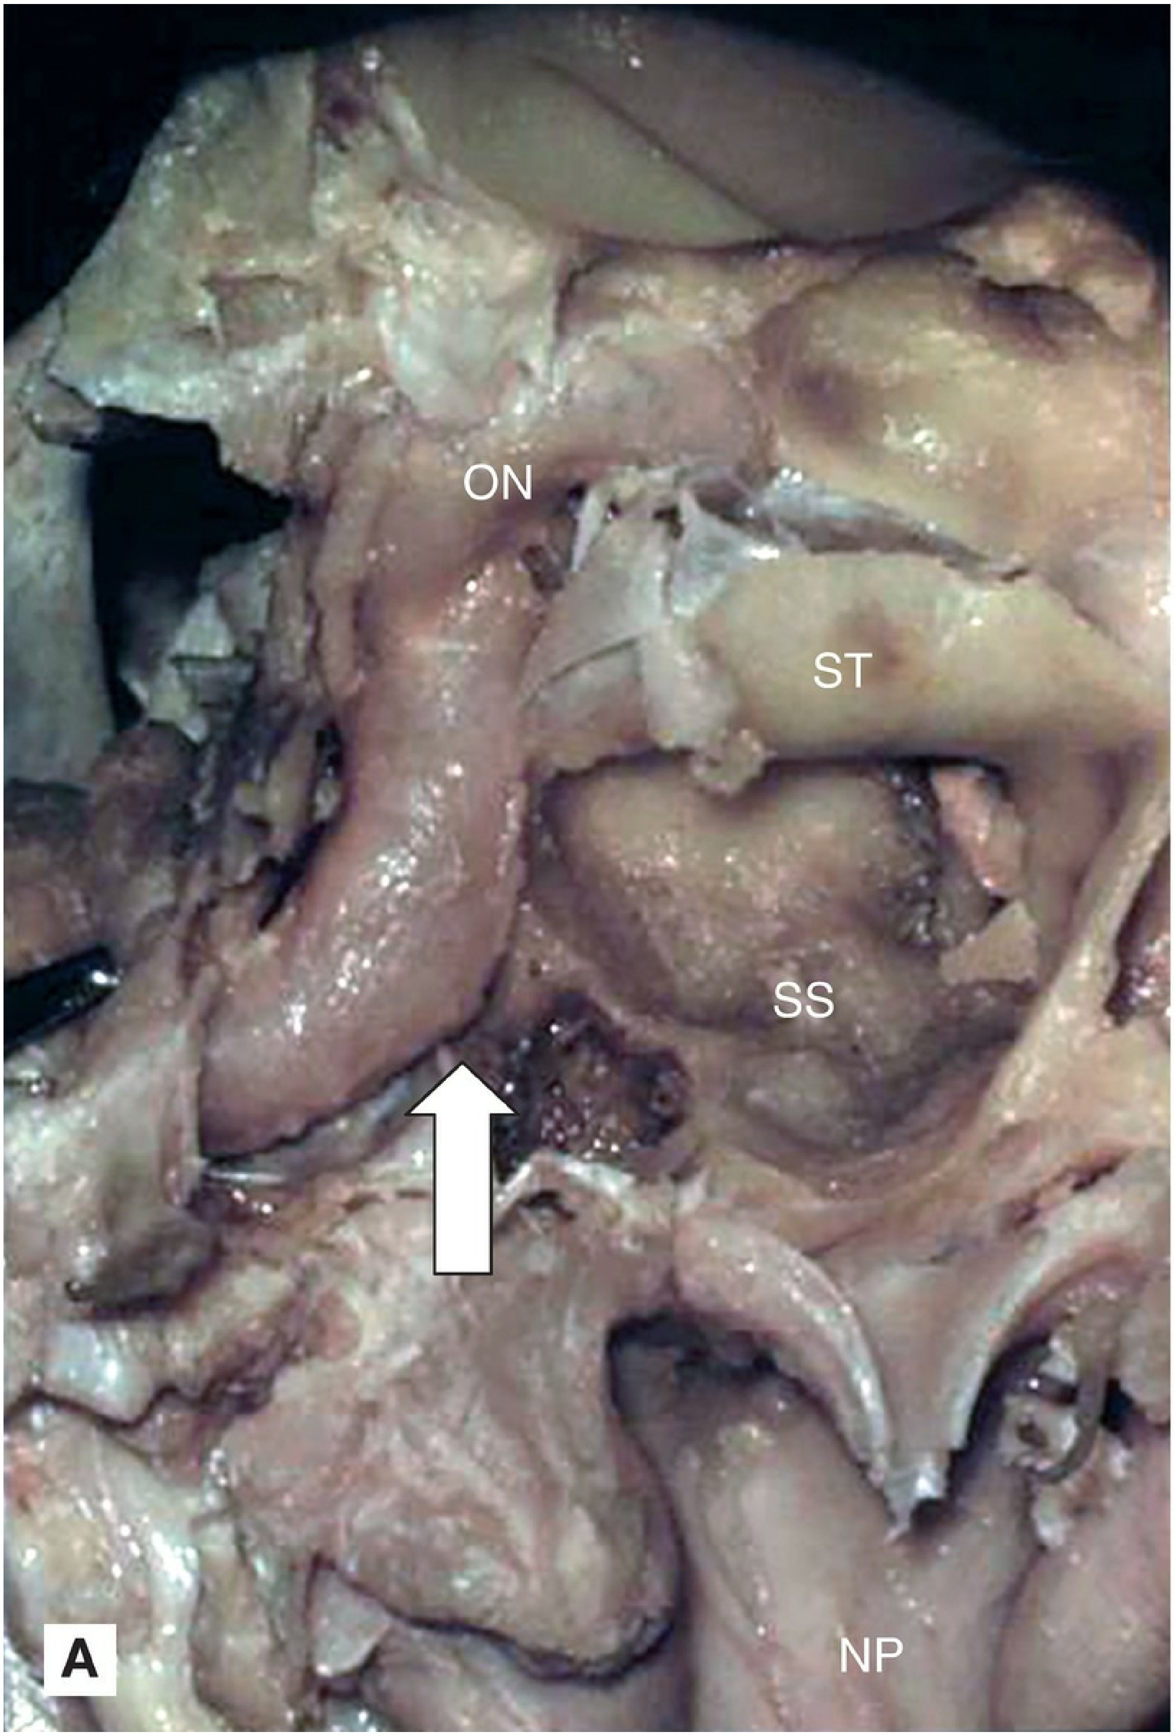
orbital cavity (supraorbital ethmoid cells) or the optic nerve (Onodi cell). The ethmoidal cells begin to develop during fetal life.

Frontal Sinus

The paired frontal sinuses appear to be outgrowths from the most anterior ethmoidal air cells. They are situated behind the superciliary arches, are rarely symmetrical, and the septum between them frequently deviates to one or the other side of the middle line. Absent at birth, the frontal sinuses are generally fairly well developed between the 7th and 8th years but only reach their full size after puberty. The frontal sinus is lined with respiratory epithelium and drains into the anterior part of the corresponding middle meatus of the nose through the frontonasal duct, which traverses the anterior part of the labyrinth of the ethmoid. The soft tissues of the forehead are located anteriorly, the orbits are located inferiorly, and the anterior cranial fossa is located posteriorly (Fig. 10.3). Blood and neural supply is from the supraorbital and supratrochlear neurovascular bundles.

Sphenoid Sinus

The sphenoid sinus begins at the most posterior and superior portion of the nasal cavity (Fig. 10.3). This midline structure, which is contained within the body of the sphenoid bone, is irregular and often has an eccentrically located intersinus septum. When exceptionally large, the sphenoid sinus may extend into the roots of the pterygoid processes or great wings and may pneumatize the basilar part of the occipital bone. The sphenoid sinus ostium is located on the anterior wall of the sinus and communicates directly with the sphenoethmoidal recess above and medial to the superior turbinate (Fig. 10.3). The sphenoid sinuses are present as minute cavities at birth, but their main development takes place after puberty. The posterior superior wall of the sphenoid sinus displays the forward convexity caused by the floor of the sella turcica, which contains the pituitary gland. The optic nerve and the internal carotid artery are closely related to the superior lateral wall of the sphenoid sinus, and their bony canals may be dehiscent within the sinus cavity (**Fig. 10.7**). Vascular and neural supplies come from the sphenopalatine and posterior ethmoidal arteries and the branches of the sphenopalatine ganglion, respectively.



ON
ST
SS
NP
A

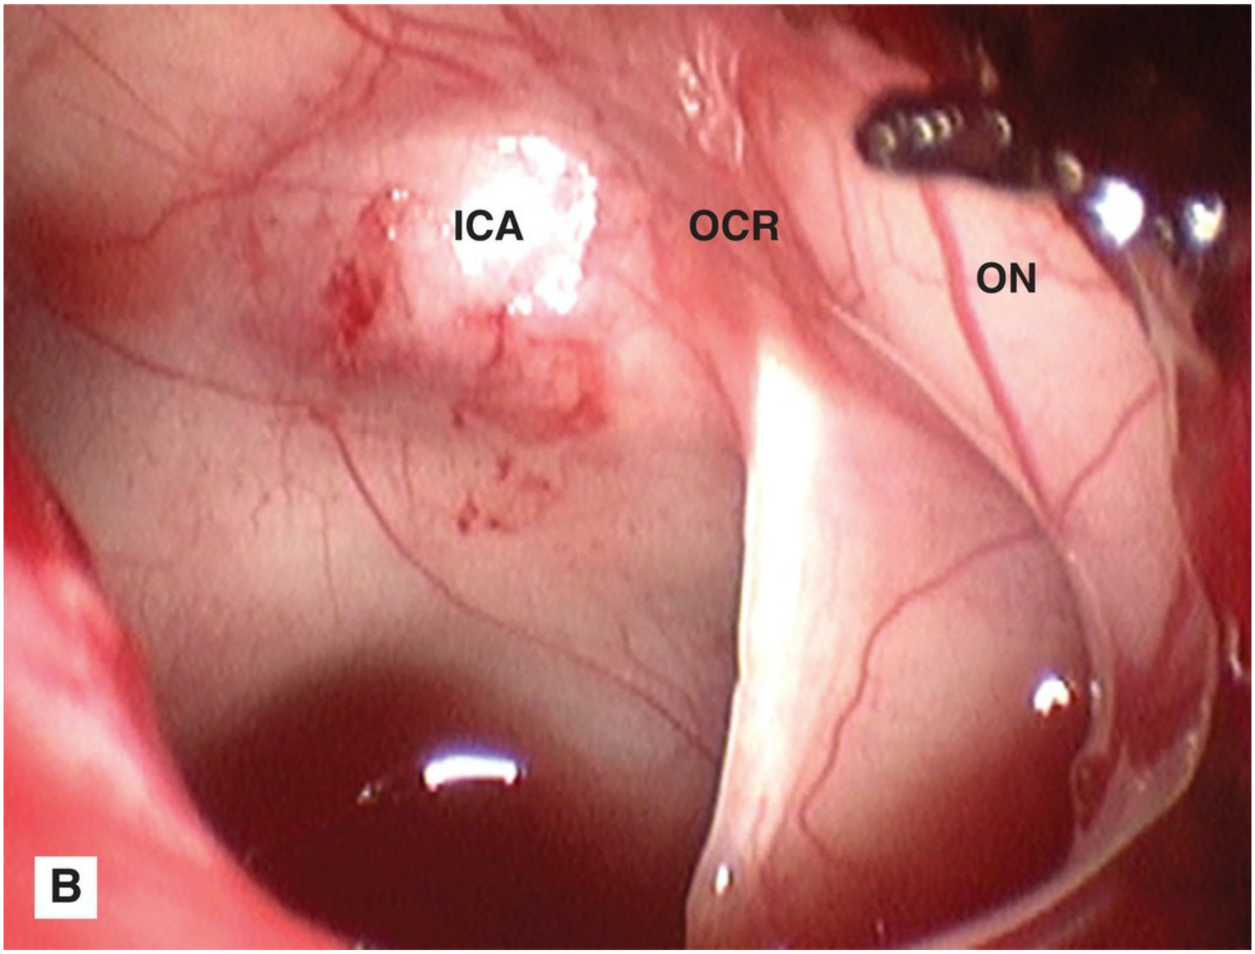


Figure 10.7. A: Cadaver dissection of the sphenoid sinus (SS). The sinus is located in the midline superior to the nasopharynx (NP). The sella turcica (ST) forms a convexity in the posterior superior wall. The internal carotid artery (*arrow*) courses through the lateral wall of the sinus and is related superiorly to the optic nerve (ON). **B:** Endoscopic view of the left sphenoid sinus. Note the internal carotid artery (ICA) and optic nerve (ON) impressions on the lateral and superior walls. A bony septum within the sinus inserts into the opticocarotid recess (OCR).

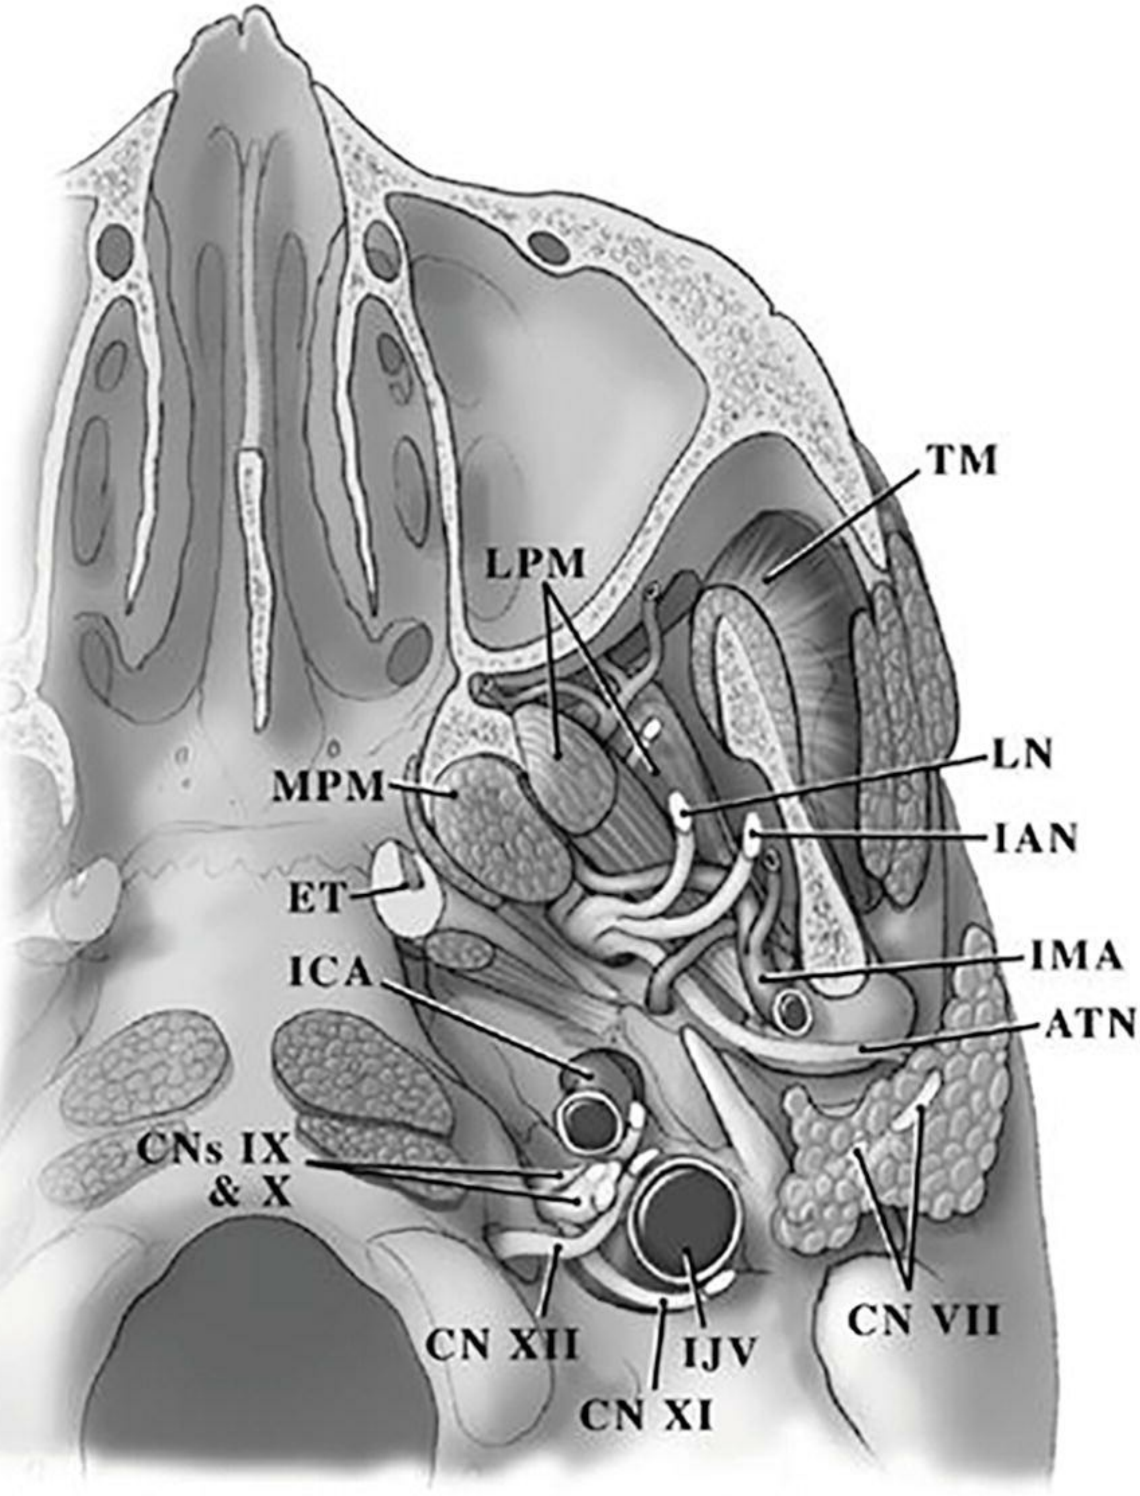
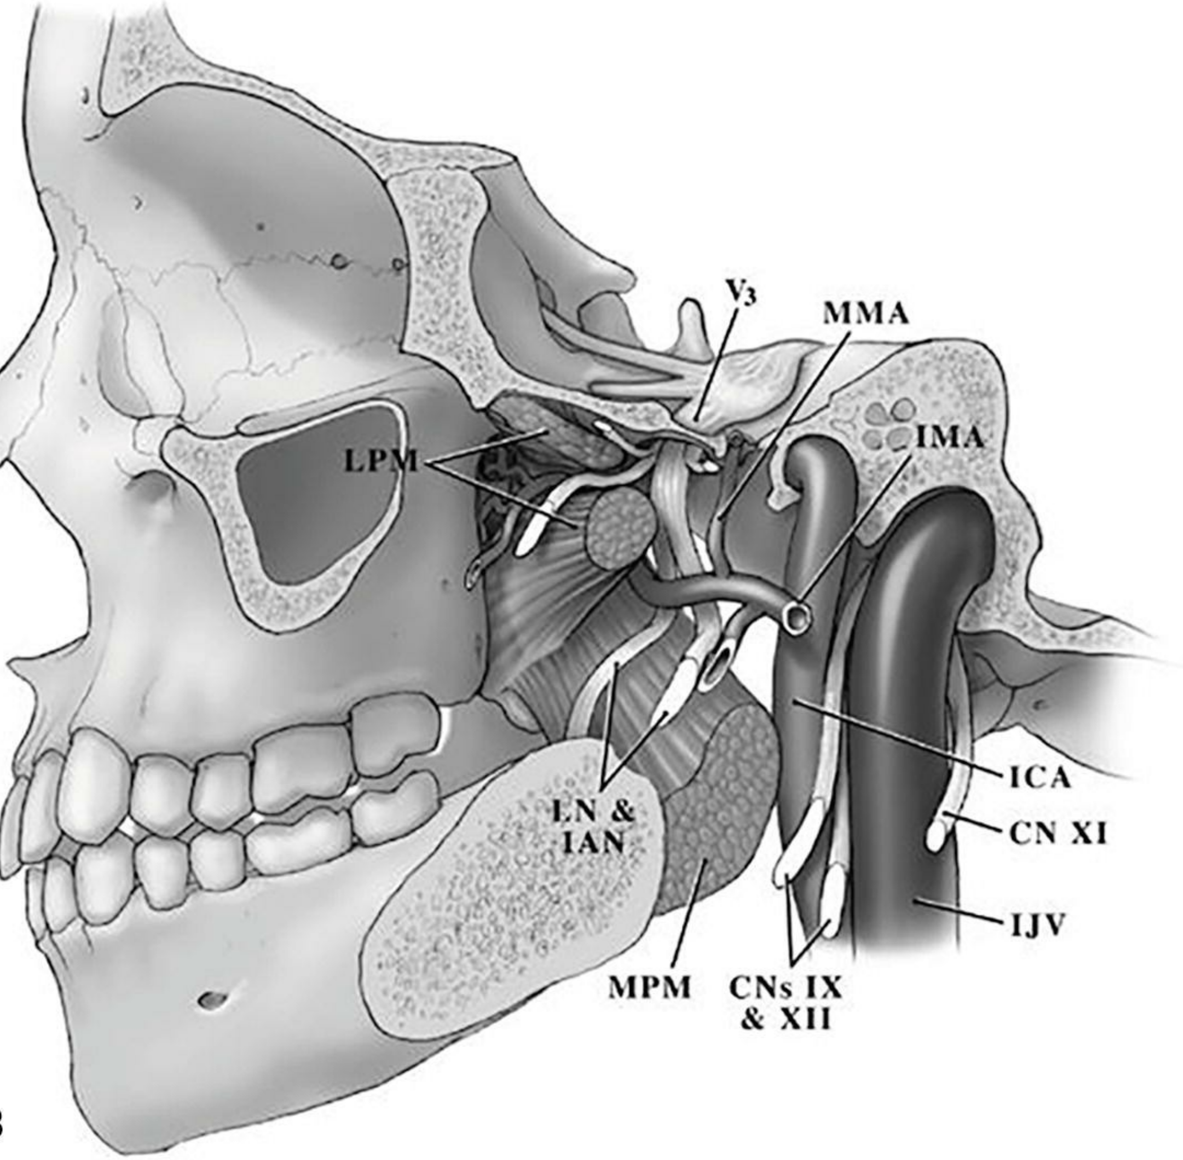
Infratemporal Fossa

The infratemporal fossa is an irregularly shaped space, situated below and medial to the zygomatic arch. It is bounded anteriorly by the posterior surface of the maxilla; superiorly by the greater wing of the sphenoid and by the under surface of the squamous portion of the temporal bone; medially by the lateral pterygoid plate; and laterally by the ramus of the mandible. It contains the inferior aspect of the temporalis muscle and the medial and lateral

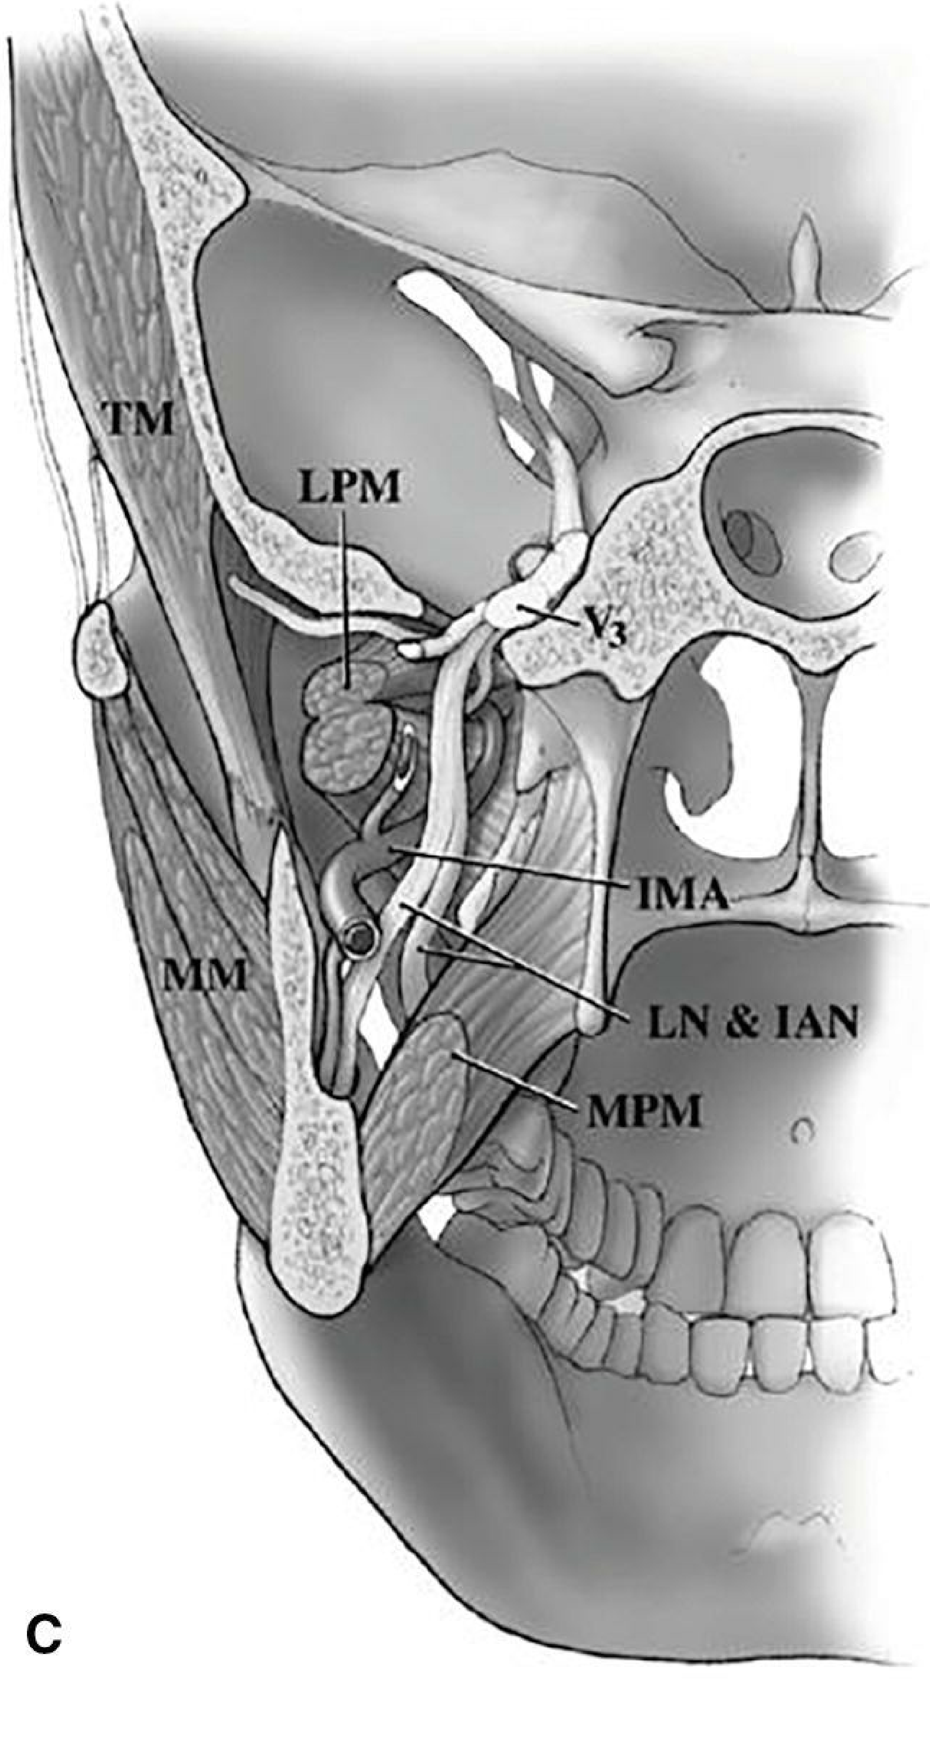
pterygoid muscles (Fig. 10.8). It also contains branches of the internal maxillary vessels including the middle meningeal artery and the mandibular (V3) nerves including the lingual, inferior alveolar, and auriculotemporal nerves. The foramen ovale and foramen spinosum open on its roof and the alveolar canals on its anterior wall. The inferior orbital and pterygomaxillary fissures communicate with and may act as routes of spread of cancer to the infratemporal fossa. The infratemporal fossa also contains the upper carotid sheath including the internal carotid artery, internal jugular vein, and the last four cranial nerves (Fig. 10.8).



A



B



C

Figure 10.8. Anatomy of the infratemporal fossa: (**A**) inferior view, (**B**) lateral view, and (**C**) anterior view. TM, temporalis muscle; MM, masseter muscle; MPM, medial pterygoid muscle; LPM, lateral pterygoid muscle; IMA, internal maxillary artery; MMA, middle meningeal artery; ICA, internal carotid artery; IJV, internal jugular vein; LN, lingual nerve; IAN, inferior alveolar nerve; ATN, auriculotemporal nerve; V3, third division of the trigeminal nerve; ET, eustachian tube; CN, cranial nerve (VII, IX, X, XI, and XII).

Pterygopalatine Fossa

The pterygopalatine fossa (PPF) is a small, triangular space situated behind the maxillary sinus, in front of the pterygoid plates, and beneath the apex of the orbit. This fossa communicates with the orbit by the inferior orbital fissure, with the nasal cavity by the sphenopalatine foramen, and with the infratemporal fossa by the pterygomaxillary fissure (Fig. 10.5). Five foramina open into it. Of these, three are on the posterior wall, which are the *foramen rotundum*, the *pterygoid canal*, and the *pharyngeal canal*, in this order downward and medial. On the medial wall is the *sphenopalatine foramen*, and below is the superior orifice of the *pterygopalatine canal* (Fig. 10.5). The fossa contains the maxillary nerve, the sphenopalatine ganglion, and the terminal part of the internal maxillary artery. The fissures and foramina of the PPF serve as “highways” for spread of cancer from the sinonasal region to the orbit, infratemporal fossa, and cranial base.

Anterior Cranial Fossa

The floor of the anterior fossa is formed by the orbital plates of the frontal bone, the cribriform plate of the ethmoid, and the lesser wings and front part of the body of the sphenoid. In the midline, it presents, from anterior to posterior, the *frontal crest* for the attachment of the falx cerebri; the *foramen cecum*, which usually transmits a small vein from the nasal cavity to the superior sagittal sinus (SSS); and the *crista galli*, the free margin of which affords attachment to the falx cerebri (**Fig. 10.9**). On either side of the crista galli is the *olfactory groove* formed by the cribriform plate, which supports the olfactory bulb and presents foramina for the transmission of the olfactory nerves. Lateral to either olfactory groove are the internal openings of the anterior and posterior ethmoidal foramina; the anterior, situated about the

middle of the lateral margin of the olfactory groove transmits the anterior ethmoidal vessels and the nasociliary nerve; the nerve runs in a groove along the lateral edge of the cribriform plate; and the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid and transmits the posterior ethmoidal vessels and nerve. More laterally, the cranial floor forms the orbital roof and supports the frontal lobes of the cerebrum. Farther back in the middle is the planum sphenoidale, forming the roof of the sphenoid sinus, and the anterior margin of the chiasmatic groove, running laterally on either side to the upper margin of the optic foramen (Fig. 10.9).

CP
PS
ON

Figure 10.9. The floor of the anterior cranial fossa. The cribriform plate (CP) is characterized by the presence of foramina for the olfactory nerves on each side of the crista galli (CG), which is seen in the midline. Lateral to the CP is the ethmoidal roof (ER) and even more lateral the roof of the orbit. Posterior to the cribriform plate is the planum sphenoidale (PS). The optic nerves (ON) form the optic chiasm behind the planum sphenoidale.

Orbit

The orbits are two quadrilateral pyramidal cavities, their bases being directed forward and lateral, and their apices backward and medial, so that their long axes diverge at a 45-degree angle and if continued backward would meet over the body of the sphenoid. The orbit is anatomically defined by seven bones (**Fig. 10.10**): frontal, zygomatic, maxillary, lacrimal, ethmoid, sphenoid, and palatine, and by the orbital septum, which originates at the arcus marginalis, fusing with the levator aponeurosis above and the capsulopalpebral fascia below. It is bounded by the ethmoid and sphenoid sinuses at its medial aspect, the frontal sinus superomedially, the cranial vault superiorly and posteriorly, the temporal fossa laterally, and the maxillary sinus inferiorly. Each orbital cavity has a *roof*, a *floor*, a *medial* and a *lateral wall*, a *base*, and an *apex.*

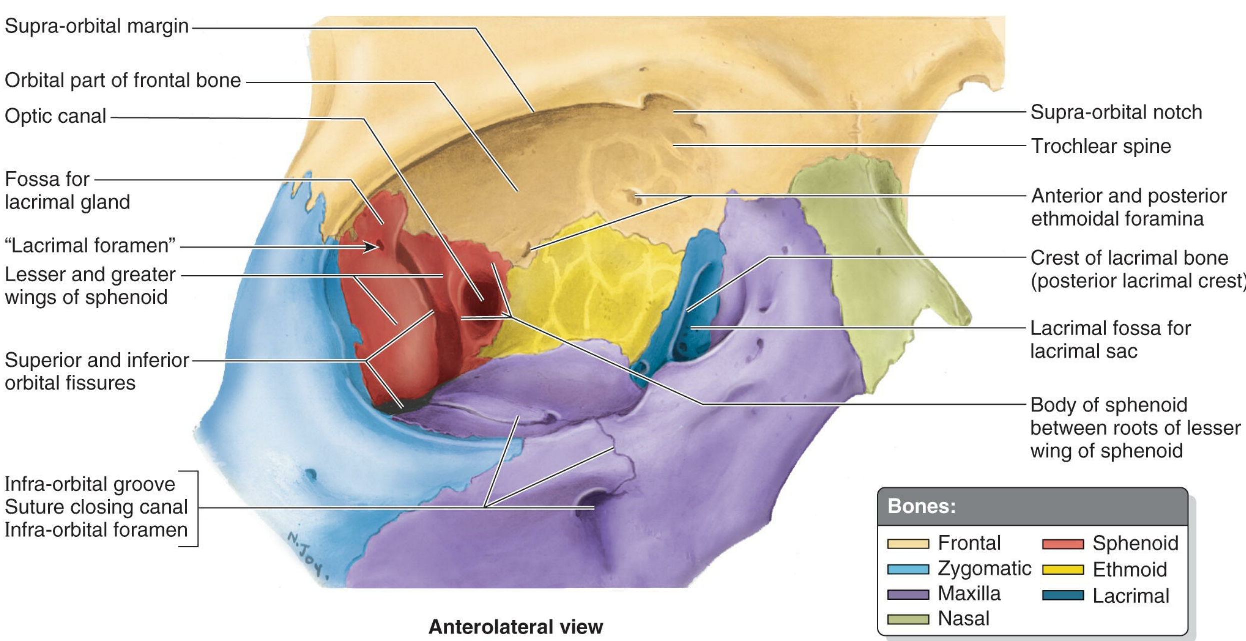

Figure 10.10. Anatomy of the right orbit. (From Moore KL, Agur AMR,

Dalley AF, eds. *Clinically Oriented Anatomy*. 7th ed. Philadelphia, PA: Wolters Kluwer Health; 2013.)

The *roof* is formed anteriorly by the orbital plate of the frontal bone and posteriorly by the lesser wing of the sphenoid. It presents *medially* the *trochlear fovea* for the attachment of the cartilaginous pulley of the superior oblique muscle and *laterally* the *lacrimal fossa* for the lacrimal gland.

The *floor* is formed mainly by the orbital surface of the maxilla, anteriorly and *laterally* by the orbital process of the zygomatic bone, and posterior and *medially*, to a small extent, by the orbital process of the palatine bone. At its medial angle is the superior opening of the nasolacrimal canal, immediately to the lateral side of which is a depression for the origin of the inferior oblique muscle. Running anteriorly near the middle of the floor is the *infraorbital canal*, ending anterior to the maxilla in the infraorbital foramen and transmitting the infraorbital nerve and vessels.

The *medial wall* is formed anteriorly to posteriorly by the frontal process of the maxilla, the lacrimal bone, the lamina papyracea of the ethmoid, and a small part of the body of the sphenoid anterior to the optic foramen. Anteroinferiorly, the lacrimal sac is situated between the anterior and posterior lacrimal crests at the junction between the medial wall and the floor. The lacrimal part of the orbicularis oculi arises from the posterior lacrimal crest. At the junction of the medial wall and the roof, the frontoethmoidal suture presents the *anterior* and *posterior ethmoidal foramina*, the former transmitting the nasociliary nerve and anterior ethmoidal vessels and the latter the posterior ethmoidal nerve and vessels. These foramina indicate the level of the cranial base within the orbit.

The *lateral wall* is formed by the orbital process of the zygomatic and the orbital surface of the greater wing of the sphenoid. On the orbital process of the zygomatic bone are the orbital tubercle (Whitnall) and the orifices of one or two canals, which transmit the branches of the zygomatic nerve. Between the roof and the lateral wall, near the apex of the orbit, is the *superior orbital fissure (SOF)*. Through this fissure, the oculomotor, the trochlear, the ophthalmic division of the trigeminal (V1), and the abducens nerves enter the orbital cavity, also some filaments from the cavernous plexus of the sympathetic and the orbital branches of the middle meningeal artery. Passing posteriorly through the fissure are the ophthalmic vein and the recurrent

branch from the lacrimal artery to the dura mater. The lateral wall and the floor are separated posteriorly by the *inferior orbital fissure*, which transmits the maxillary nerve (V2) and its zygomatic branch, the infraorbital vessels, and the ascending branches from the sphenopalatine ganglion.

The *base* of the orbit (orbital rim), quadrilateral in shape, is formed superiorly by the supraorbital arch of the frontal bone, in which is the *supraorbital notch* or *foramen* for the passage of the supraorbital vessels and nerve; inferiorly by the zygomatic bone and maxilla, united by the zygomaticomaxillary suture; *laterally* by the zygomatic bone and the zygomatic process of the frontal joined by the zygomaticofrontal suture; and *medially* by the frontal bone and the frontal process of the maxilla united by the frontomaxillary suture.

The *apex* is situated in the posterior aspect of the orbit. The optic foramen is a short, cylindrical canal, through which passes the optic nerve and ophthalmic artery.

The *extraocular muscles*—four rectus muscles and two obliques—effect movement of the eye. The third cranial nerve innervates all but the lateral rectus and the superior oblique muscles, which are innervated by the fourth and sixth cranial nerves, respectively. The rectus muscles originate at the annulus of Zinn and insert on the globe forming a muscle cone, which is the central anatomic space in the orbit.

The *lacrimal system* is composed of secretory and drainage systems. Secretory glands—the glands of Moll, Krause, and Wolfring—may be found along the margin of the eyelid. The lacrimal gland with its palpebral and orbital lobes is located in the superotemporal orbit (**Fig. 10.11**). The lacrimal drainage system, located in the inferonasal orbit, is represented by the puncta, canaliculi, lacrimal sac, and nasolacrimal duct. Tumor involvement of the lacrimal system may present with epiphora.

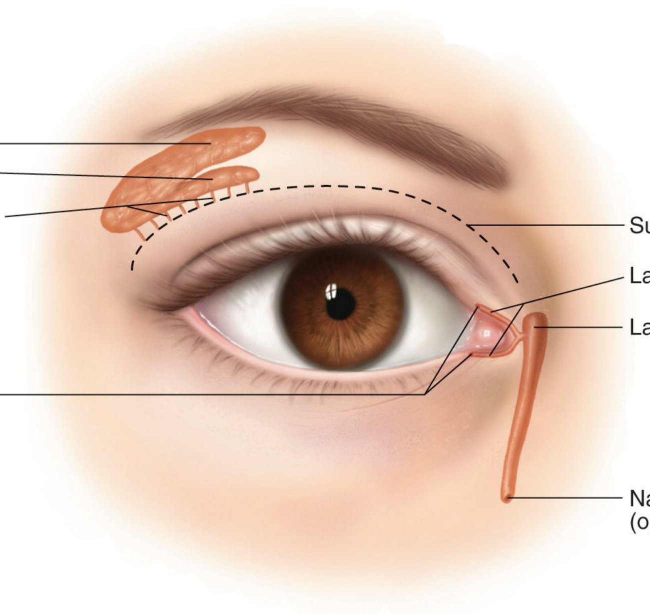

Figure 10.11. Anatomy of the lacrimal system. (From Pansky B, Gest TR, eds. *Lippincott's Concise Illustrated Anatomy: Head and Neck*. Vol. 3. Philadelphia, PA: Wolters Kluwer Health; 2014.)

The skin of the *eyelid* is continuous with the palpebral and bulbar conjunctivae, which are, in turn, contiguous with the globe. Each of these epithelial surfaces represents a potential site of origin for cancer.

ETIOLOGY

The cause of sinonasal neoplasms is unknown. There is some epidemiologic evidence, however, to support an occupational risk for developing cancer of the sinonasal tract (SNT).[1] Occupational exposure to inhalation of certain metal dusts or aerosols can cause loss of olfactory acuity, atrophy of the nasal mucosa, mucosal ulcers, perforated nasal septum, dysplasia of the nasal mucosa, or sinonasal cancer.[2] Cancer of the nose and paranasal sinuses has been reported to be more frequent in workers exposed to nickel compounds in nickel refining, cutlery factories, and alkaline battery manufacture or to chromium in chromate production and chrome plating.[3] In a report on the risk of developing sinonasal cancer in Scandinavian countries, nickel workers involved with electrolytic work for more than 15 years were found to have a 250-fold increased incidence of cancer of the sinus. In the same study, random biopsy of the middle turbinate showed evidence of dysplasia in 21%

of workers. These changes were independent of their smoking history. All workers had been employed for at least 10 years, and there was an average latent period of 18 to 36 years before the development of carcinoma, most of which were squamous cell or anaplastic.[4] Similarly, in a Swedish cohort of workers (n = 6,454) from seven aluminum foundries and three secondary aluminum (scrap) smelters, significantly elevated risk estimates for sinonasal cancer were observed.[5]

In animals, several heavy metals (e.g., Al, Cd, Co, Hg, Mn, Ni, Zn) have been shown to pass via olfactory receptor neurons from the nasal lumen through the cribriform plate to the olfactory bulb. Some metals (e.g., Mn, Ni, Zn) can even cross synapses in the olfactory bulb and migrate via secondary olfactory neurons to distant nuclei of the brain. The olfactory bulb tends to accumulate certain metals (e.g., Al, Bi, Cu, Mn, Zn) with greater avidity than other regions of the brain. The molecular mechanisms responsible for metal translocation in olfactory neurons and deposition in the olfactory bulb are unclear, but chelation by metal-binding molecules such as carnosine (beta-alanyl-L-histidine) may be involved.[3]

Other occupational exposures may also increase the risk of developing cancer of the SNT.[6] A European case–control study revealed that exposure to leather and wood dust was associated with an excess risk of sinonasal cancer.[7] Both wood and leather dusts were associated more with adenocarcinoma than SCC.[6,8] Recent large-scale studies suggest that this increased risk is specifically linked to the development of intestinal-type adenocarcinoma rather than other types of sinonasal adenocarcinomas (SNACs).[9–11] In European populations, occupation was associated with about 11% of all sinonasal cancers in women and 39% in men. A meta-analysis of 12 large case–control studies estimated that male wood workers had a summary odds ratio of sinonasal cancer of 2.6 (95% confidence interval [CI] = 2.1 to 3.3).[12] The risk was greatest among men who had been employed in jobs with the highest wood dust exposure and increased with duration of exposure.[13] Employment in the boot and shoe industry has been also associated with adenocarcinoma of the nasal cavity in England and Italy.[14] Data from a case–control study conducted at 27 hospitals in France showed exposure to textile dust were associated with an elevated risk of SCC and adenocarcinoma of the SNT and that the risk increased with the duration

and the level of exposure.[15]

Although epidemiologic studies have not addressed the relationship between outdoor air pollution and sinonasal malignant neoplasms, a report on the incidence of sinonasal cancer in urban polluted cities suggests such a correlation.[16] Both primary and environmental (secondary) tobacco smoke appear to be also related to increase in the incidence of sinonasal cancer, particularly sinonasal squamous cell carcinoma (SNSCC).[7,17,18] Recent studies have found a correlation in the development of lung cancer and SNSCC, propagating a possible causal relationship between SNSCC and smoking.[19]

High-risk human papillomavirus (HR-HPV) is an established cause of head and neck carcinomas arising in the oropharynx. The presence of HPV has also been reported in some carcinomas arising in the SNT, but little is known about their overall incidence or their clinicopathologic profile. In a recent study by Takahashi et al.[20] of 70 patients with SNSCCs treated with surgery between 1999 and 2009 at MD Anderson Cancer Center (MDACC), high-risk HPV and its surrogate p16 were found in only 10% and 18% of tumor tissues, respectively. However, Bishop et al.[21] reported higher prevalence rates of both high-risk HPV and p16 in sinonasal cancers. Of 161 sinonasal carcinomas, 34 (21%) were positive for HR-HPV DNA, including type 16 (82%), type 31/33 (12%), and type 18 (6%). Immunohistochemistry for p16 was positive in 59/161 (37%) cases, and p16 expression strongly correlated with the presence of HPV DNA: 33 of 34 (97%) HPV-positive tumors exhibited high p16 expression, whereas only 26 of 127 (20%) HPV-negative tumors were p16 positive ($p < 0.0001$). A trend toward improved survival was observed in the HPV-positive group (hazard ratio [HR] = 0.58, 95% CI [0.26, 1.28]). The presence of HR-HPV in 21% of sinonasal carcinomas suggests that HPV may be an important oncologic agent of carcinomas arising in the SNT. Although nonkeratinizing SCC is the most common histologic type, there is a wide morphologic spectrum of HPV-related disease that includes a variant that resembles adenoid cystic carcinoma (ACC). The distinctiveness of these HPV-related carcinomas of the SNT with respect to risk factors, clinical behavior, and response to therapy remains to be clarified.[21]

PATHOLOGY

The mucosal lining of the nose—*the schneiderian membrane*—is derived from ectoderm. This is uniquely different from the mucosa of the rest of the upper respiratory tract, which is derived from endoderm. Olfactory neuroepithelium lines the superior portion of the nasal cavity and the roof of the nose and gives rise to neuroectodermal tumors such as olfactory neuroblastoma and neuroendocrine carcinoma (NEC).[22–24] The sinonasal epithelium also has minor salivary glands (SGs) and gives rise to SG tumors such as ACC and mucoepidermoid carcinoma (MEC).[25–28] However, the most common epithelial neoplasms of the SNT are those arising from "metaplastic" squamous epithelium namely SCC and those originating from the seromucinous glands of the mucosal lining, collectively known as adenocarcinomas.[29] The unique histology of this region is reflected in the histogenesis of a complex variety of epithelial and nonepithelial tumors (**Table 10.1**). These tumors have a wide range of biologic behavior, and a few arise only in the SNT (e.g., inverted papilloma, olfactory neuroblastoma). Nonepithelial tumors are similar to those in other regions in the head and neck.

INCIDENCE

Overall, sinonasal cancer accounts for about 1% of all malignancies and ~3% of cancer of the head and neck. There is a male predominance (**Fig. 10.12A**), with a strong predilection for Caucasians (**Fig. 10.12B**). The majority of patients are over 50 years of age at the time of diagnosis (**Fig. 10.12C**). The most common malignant tumor of the nasal cavity and paranasal sinuses is SCC (**Fig. 10.12D**). Although the maxillary antrum is the most commonly involved sinus (**Fig. 10.12E**), anterior skull base invasion is most frequently encountered with malignant neoplasms of the nasal cavity and ethmoid sinus. Upward extension of these neoplasms toward the cribriform plate or fovea ethmoidalis is not uncommon and heralds intracranial extension.[30] Primary carcinoma of the frontal sinus is uncommon, and those arising in the sphenoid sinus are rare.[31] Unfortunately, despite significant improvement in diagnostic techniques such as nasal endoscopy and high-resolution imaging, most patients present with advanced stage disease (**Fig. 10.12F**).

SPREAD

Local Spread

The most common route of local spread of cancer of the SNT is through direct extension. As most sinonasal cancers are relatively asymptomatic when small, it is often the manifestation of local spread that prompts patients to seek medical attention. In the maxillary sinus, direct extension may occur anteriorly into the soft tissues of the cheek, superiorly into the orbit with resultant proptosis and diplopia, inferiorly into the oral cavity, or posteriorly into the pterygomaxillary space where it may spread along the branches of the maxillary division of the trigeminal nerve (V2). Cancer of the frontal sinus is quite rare, but the most significant direct extension is posteriorly to the frontal lobes. Cancer of the ethmoid sinus often presents with medial extension to the orbit, superior extension to the cribriform plate, and posterior extension into the sphenoid sinus and nasopharynx. Cancers involving the sphenoid sinus may quickly become problematic because of proximity to the optic nerves, the cavernous sinus (CS), and the pituitary fossa (Fig. 10.7).

In addition to direct local extension, cancer of the paranasal sinuses can spread to nearby structures via the many fissures and foramina located in this region. Cancer of the maxillary sinus frequently erodes posteriorly into the

PPF (Fig. 10.8). Once in the PPF, the tumor may extend laterally through the pterygomaxillary fissure into the infratemporal fossa, superiorly into the orbit via the inferior orbital fissure or into the middle cranial fossa through the foramen rotundum, posteriorly into the vidian canal with extension to the petrous portion of the temporal bone, or inferiorly into the oral cavity by way of the palatine canal or the sphenopalatine foramen.

From the frontal sinus, cancer may extend into the nasal cavity through the nasofrontal duct. Cancer of the ethmoidal sinuses may also extend into the nasal cavity through the middle meatus and the sphenoethmoidal recess, posteriorly into the nasopharynx and along the eustachian tube, or inferiorly along the nasolacrimal duct (Fig. 10.3).

Perineural Spread

The dissemination of cancer cells along nerves is a frequent pathologic finding among a variety of cancers, including head and neck, upper gastrointestinal, pancreatic, and prostate carcinomas. Tumors that have a considerable propensity to disseminate along nerves are known as *neurotropic cancers*. In the head and neck, the most common tumors with a predilection to invade nerves are ACCs, followed by SCCs.[32,33] Tumors of the paranasal sinus that exhibit perineural invasion (PNI) may use this route to spread in a retrograde fashion to the skull base and even progress intracranially. Alternatively, they may spread in an antegrade fashion and along the involved nerve and its terminal branches. In either case, this neural spread makes surgical resection more complicated and achieving negative surgical margins less certain. Imaging particularly MRI is critical in determining the extent of neural spread of sinonasal cancers as will be discussed later in this chapter under the section on Imaging.[34]

Gil et al.[35] reported the incidence and pattern of neural invasion (NI) in 208 patients with cancers of the paranasal sinuses and anterior skull base. Forty-one specimens (20%) had evidence of NI. Sinonasal undifferentiated, adenoid cystic, and SCC had a high propensity for NI, whereas melanoma and sarcoma rarely invaded nerves. Intraneural invasion was found in 32% of these cases, and 34% invaded more than 1 cm distal to the tumor. NI was associated with a high rate of positive margins, maxillary origin, and previous surgical treatment ($p < 0.04$) but not with stage, orbital invasion, or dural invasion. Patients with NI were more likely to undergo adjuvant radiotherapy

($p = 0.003$), which significantly improved survival in patients with minor SG carcinomas ($p = 0.04$).

Regional Metastases

The lymphatic drainage of the posterior nasal cavities and paranasal sinuses is primarily to the retropharyngeal and lateral pharyngeal nodes at the base of the skull and then to the upper jugular lymph nodes. Cancer of the anterior nasal cavity and those that erode through the maxilla into the soft tissues of the face spread to the submandibular and upper jugular lymph nodes.

Regional metastases from paranasal sinus cancer are relatively uncommon and have been characterized to a greater extent for maxillary sinus cancer than for other paranasal sites.[36] Regional disease is evident on initial presentation in ~10% of patients, and an additional 15% of patients will develop lymph node metastasis at some point after treatment. In patients with SCC of the maxillary sinus, the risk of having lymph node metastasis on presentation correlates with extension of the primary tumor to the nasopharynx or oral cavity. The risk of developing regional metastasis after treatment correlates with local tumor recurrence. The role of elective neck dissection or radiation has yet to be defined in patients with cancer of the maxillary sinus.[37] Development of regional metastasis, however, is associated with worse prognosis.

Distant Metastases

Although distant metastasis from cancer of the paranasal sinus does occur, failure to control the disease secondary to local recurrence is far more common. For SCC of the maxillary sinus, the rate of distant metastasis is ~10% and rarely occurs in the absence of local recurrence. Cancer of the ethmoid has a similar rate of distant metastasis, with adenocarcinoma having a slightly higher rate than squamous cell cancer (15% to 20% vs. 10%). In general, the most common sites for metastasis are the lung and bone.[36–38]

STAGING

The most widely used staging system for sinonasal cancers is the American Joint Committee on Cancer (AJCC) tumor–node–metastasis (TNM) system.

There is a different staging system for tumors of the maxillary sinus from that used for ethmoid sinus and nasal cavity tumors. The nodal staging system for maxillary, ethmoid, and nasal cavity tumors is the same as for other sites in the head and neck and depends on the number, size, and laterality of involved lymph nodes. There is a separate staging system for esthesioneuroblastoma (ENB). The classification from the most recent version, 7th edition,[39] is shown in **Table 10.2**.

Table 10.2 Classification of Sinonasal Cancer According to the AJCC 7th Edition

Primary Tumor (T stage)		
Maxillary sinus	T1	Limited to the maxillary sinus mucosa with no erosion or bone destruction
	T2	Bone erosion/destruction including hard palate, middle nasal meatus, except for posterior wall of maxillary sinus and pterygoid plates
	T3	Invasion of bone of posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall or orbit, pterygoid fossa, ethmoid sinuses
	T4a	Invasion of anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
	T4b	Invasion of orbital apex, dura, brain, middle cranial fossa, nasopharynx, clivus, or cranial nerves except for V2
Nasal cavity and ethmoid sinus	T1	Limited to any one subsite, with or without bony invasion
	T2	Invasion into two subsites in a single region or extending to adjacent region in the nasoethmoidal complex, with or without bony invasion
	T3	Invasion of medial wall or floor of orbit, maxillary sinus, palate or cribriform plate
	T4a	Invasion into anterior orbital contents, skin of nose or cheek, minimal extension into anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
	T4b	Invasion into orbital apex, dura, brain, middle cranial fossa, nasopharynx, clivus, or cranial nerves other than V2
Olfactory esthesioneuroblastoma	T1	Tumor isolated to nasal cavity and ethmoid sinuses
	T2	Tumor extends to sphenoid sinus or cribriform plate
	T3	Tumor extends to anterior cranial fossa or orbit, no dural invasion
	T4	Tumor invades dura or brain parenchyma
Regional Lymph Nodes (N stage)[a]		
	N0	No regional lymph node metastasis
	N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
	N2a	Metastasis in a single ipsilateral lymph node, >3 cm and ≤6 cm
	N2b	Metastasis in multiple ipsilateral lymph nodes, none >6 cm
	N2c	Metastasis in bilateral or contralateral lymph nodes, none >6 cm
	N3	Metastasis in a lymph node >6 cm
Distant Metastatic Disease (M stage)[b]		
	M0	No distant metastasis
	M1	Distant metastasis present

[a]Definitions apply to all subsites except for olfactory ENB, which uses a N0 vs. N1 system for positive and negative nodal metastases, respectively.

[b]Definitions apply to all subsites.

PATIENT EVALUATION

Clinical evaluation of patients with cancer of the nasal cavity, paranasal sinuses, and orbit should help to achieve three objectives: (1) establishment of the diagnosis, (2) determination of the extent of disease, and (3) development of a plan for treatment. These objectives are usually achieved through a detailed history, comprehensive clinical examination of the head and neck, imaging, and biopsy.

History and Clinical Examination

The signs and symptoms of *early* sinonasal tumors are very subtle and nonspecific. Early lesions are often completely asymptomatic or mimic more common benign conditions such as chronic sinusitis, allergy, or nasal polyposis. Since early detection of sinonasal tumors is probably the most important factor in improving prognosis, a high degree of suspicion is necessary to diagnose smaller lesions. Common symptoms include nasal obstruction, “sinus pressure” or pain, nasal discharge that may be bloody, anosmia, or epistaxis. Failure of these symptoms to respond to adequate medical therapy or the presence of unilateral signs and symptoms should alert the physician to the possibility of malignancy and warrants further investigation by high-resolution imaging. Comprehensive examination of the nasal cavity should be done after topical decongestion and anesthesia using rigid or flexible endoscopy (**Fig. 10.13**). The presence of intranasal masses, ulcers, or areas of contact bleeding may indicate a malignant tumor. Although unilateral “polyps” may be inflammatory, they are more commonly neoplastic. Tumors may also present as submucosal masses without changes in the mucosa, other than displacement. Any suspicious lesions should be biopsied, preferably after high-resolution imaging has been obtained to avoid severe bleeding and/or CSF leak as discussed below.

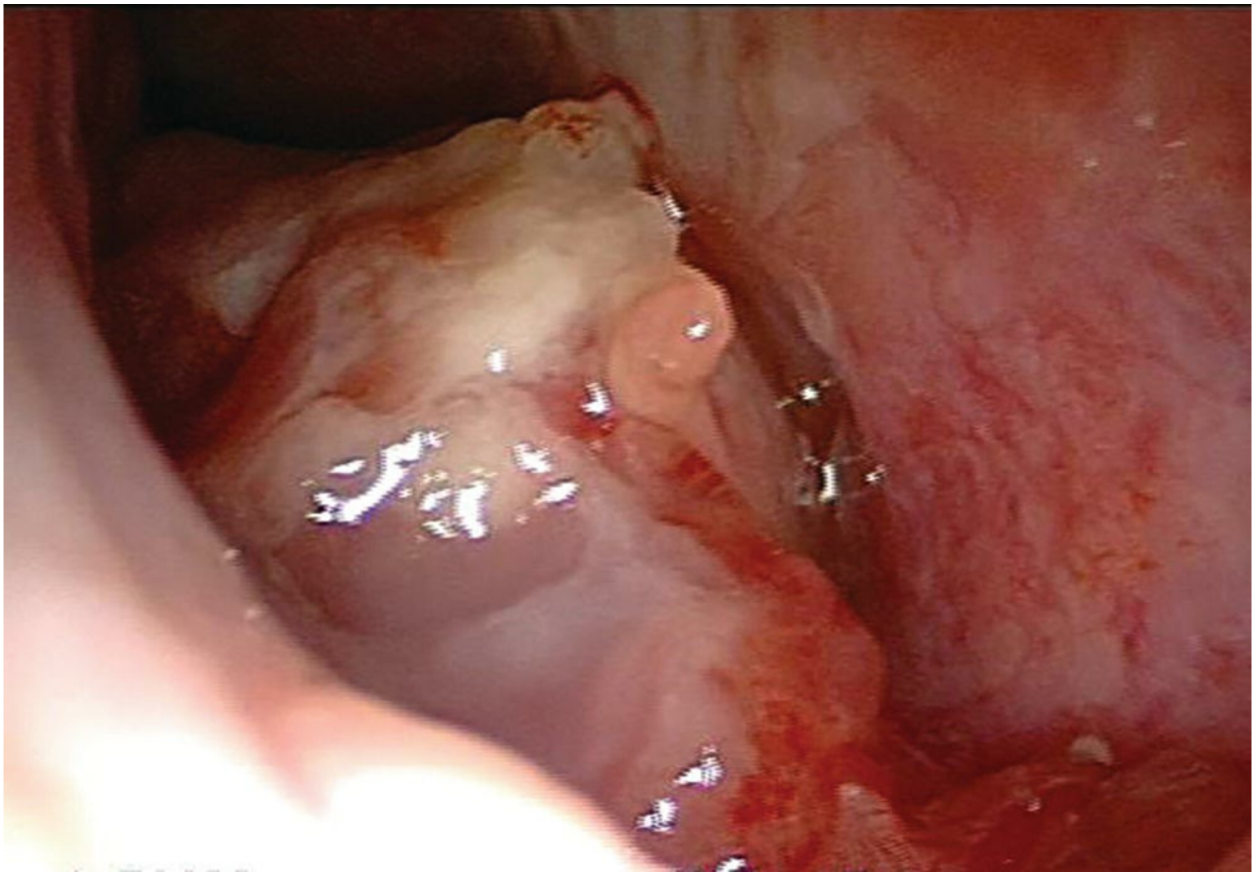

Figure 10.13. Carcinoma of the nasal cavity. Endoscopic view showing a tumor arising from the floor of the right nasal cavity. Biopsy revealed SCC.

Extension of sinonasal tumors to adjacent structures renders the diagnosis obvious, but is a late manifestation of the disease. Soft tissue swelling of the face may indicate tumor extension through the anterior bony confines of the nose and sinuses (**Fig. 10.14**). Inferior extension toward the oral cavity may present with an ulcer or a submucosal mass in the palate or the alveolar ridge (**Fig. 10.15**). Middle ear effusion may indicate tumor involvement of the nasopharynx, eustachian tube, pterygoid plates, or tensor veli palatini muscle. Extension to the skull base may lead to involvement of the cranial nerves leading to anosmia, blurred vision, diplopia, or in hypoesthesia along the branches of the trigeminal nerves. The presence of associated neck masses usually represents metastatic disease in the cervical lymph nodes.

A

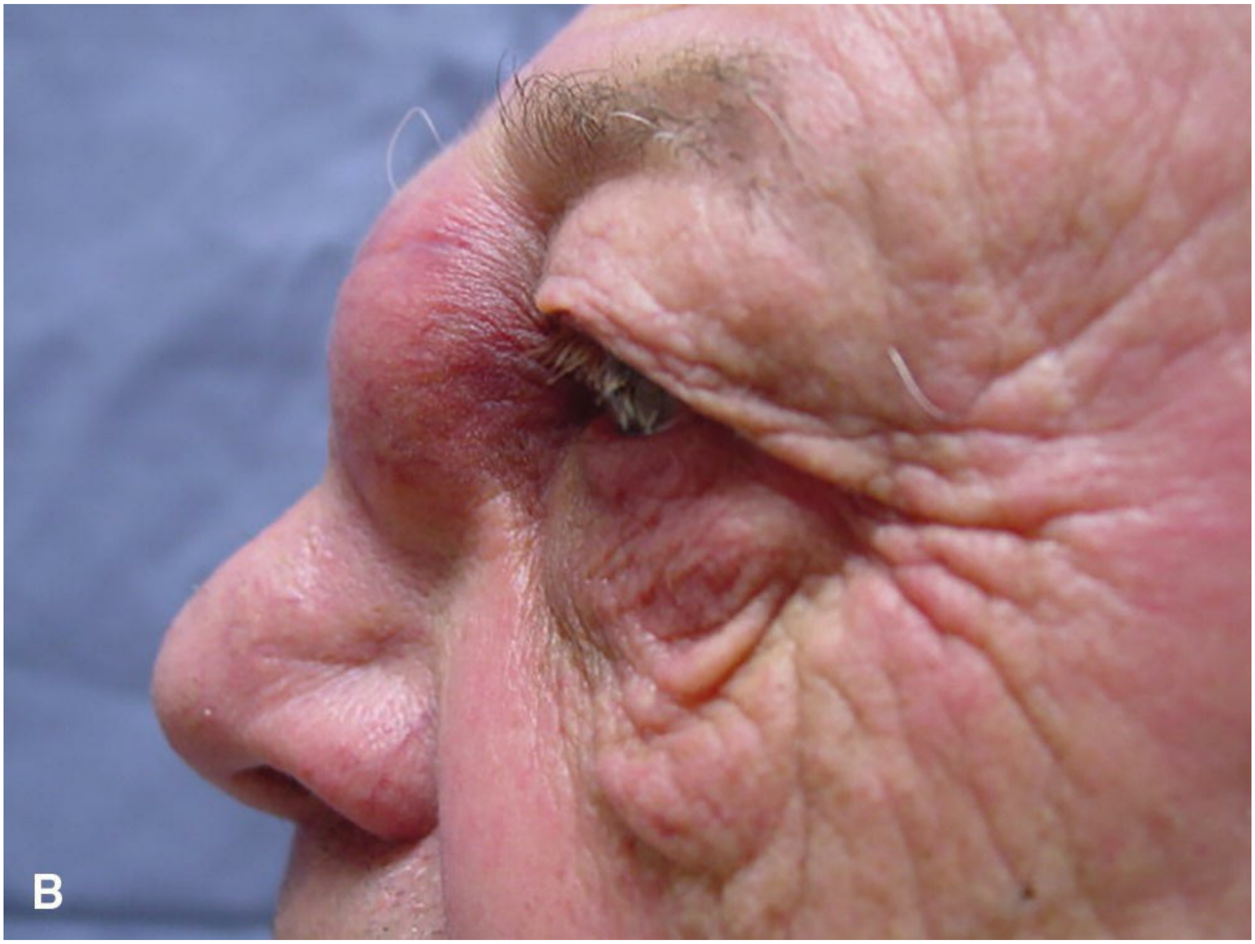

Figure 10.14. Advanced ethmoid carcinoma. **A and B:** Clinical photographs showing the mass centered on the nasion, and causing widening of the interpalpebral distance (telecanthus). The mass shows involvement of the overlying skin and destruction of the underlying nasal bone.

A

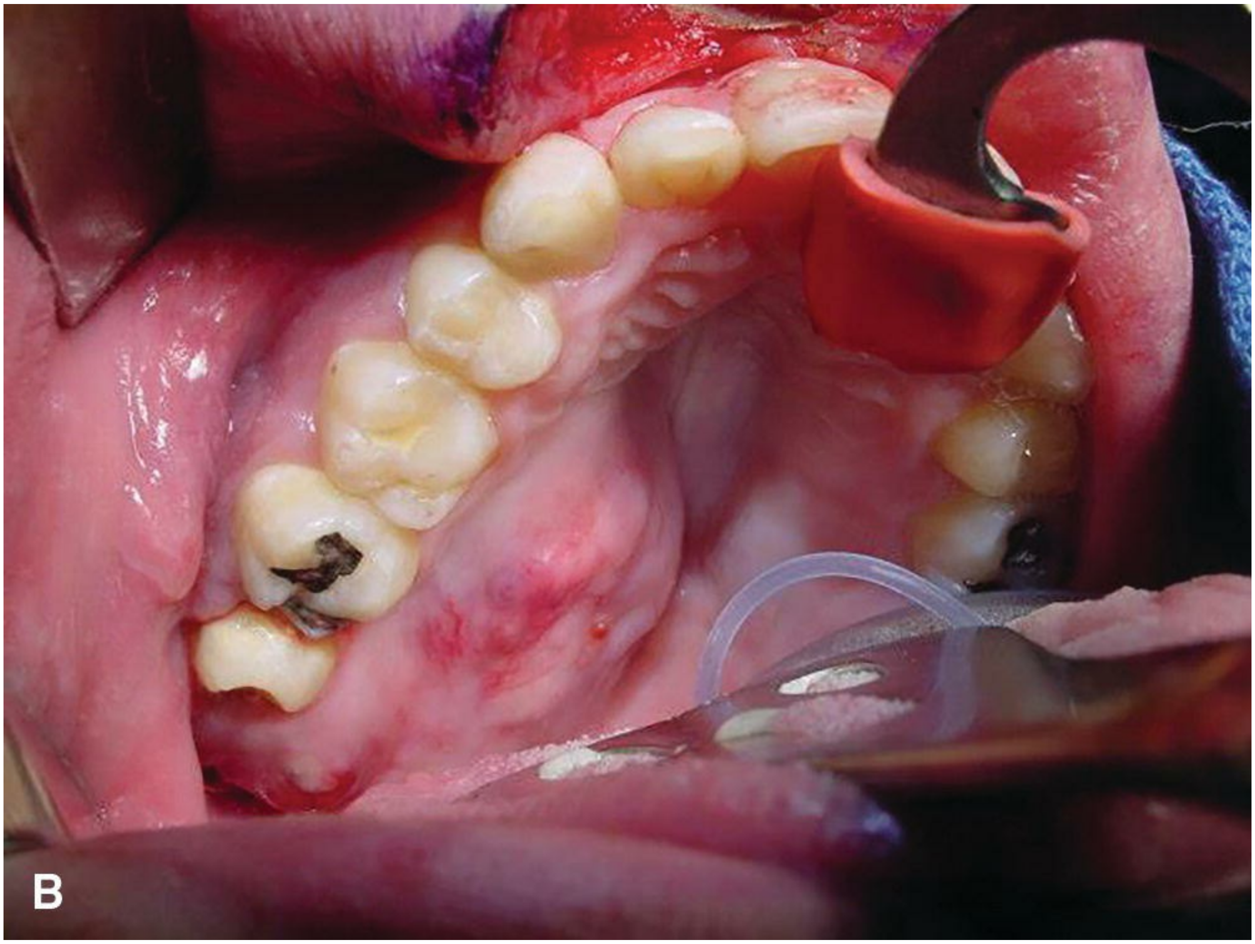

Figure 10.15. Carcinoma of the maxillary sinus may extend inferiorly and destroys the palate presenting as an ulcer **(A)** or submucosal mass **(B)**.

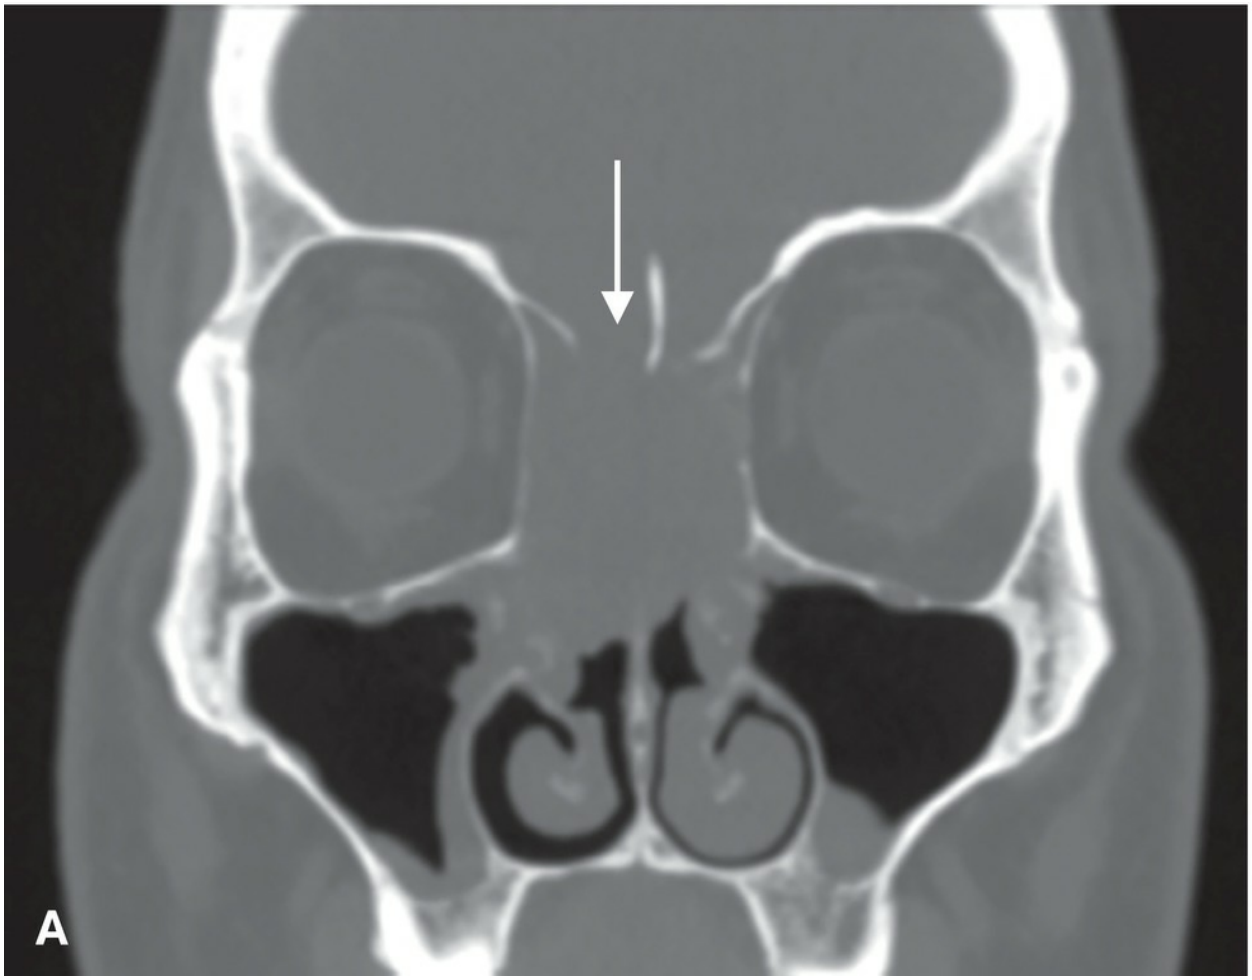
Orbital involvement is common in patients with cancer arising from the ethmoid, maxillary sinuses, frontal, and sphenoid sinuses in descending order of frequency. Less commonly, the orbit is involved by a primary tumor of the eye or its adnexa. Signs and symptoms of tumors in the orbit are usually due to mass effect or neuromuscular dysfunction. The patient may complain of proptosis, irregular shape of the eyelid, or blepharoptosis. Epiphora usually indicates involvement of the nasolacrimal duct (Fig. 10.11). Double vision may result from compression or infiltration of ocular nerves or muscles. Visual loss secondary to optic nerve involvement is usually a late sign, although more subtle signs of optic nerve dysfunction, including afferent pupillary defect, loss of color vision, and visual field defect are more frequently encountered. Finally, orbital involvement may be asymptomatic and is only discovered on computed tomography (CT) or magnetic resonance imaging (MRI) evaluation of patients with sinonasal complaints.

Evaluation of patients with suspected primary or secondary malignancy in the orbit should include a detailed neuro-ophthalmologic examination. This usually includes detailed assessment of visual acuity, visual fields, and ocular motility. Other ophthalmologic evaluation includes careful pupillary examination for afferent pupillary defect or anisocoria, external examination to include Hertel exophthalmometry, and marginal reflex distance as an indicator of eyelid position. Slit lamp examination of the conjunctivae, cornea, anterior chamber, and lens is appropriate. Finally, detailed examination of the fundus may reveal compressive effect, intraocular malignancy, or an unrelated reason for visual loss. Formal testing of color vision and automated visual fields are commonly appropriate.

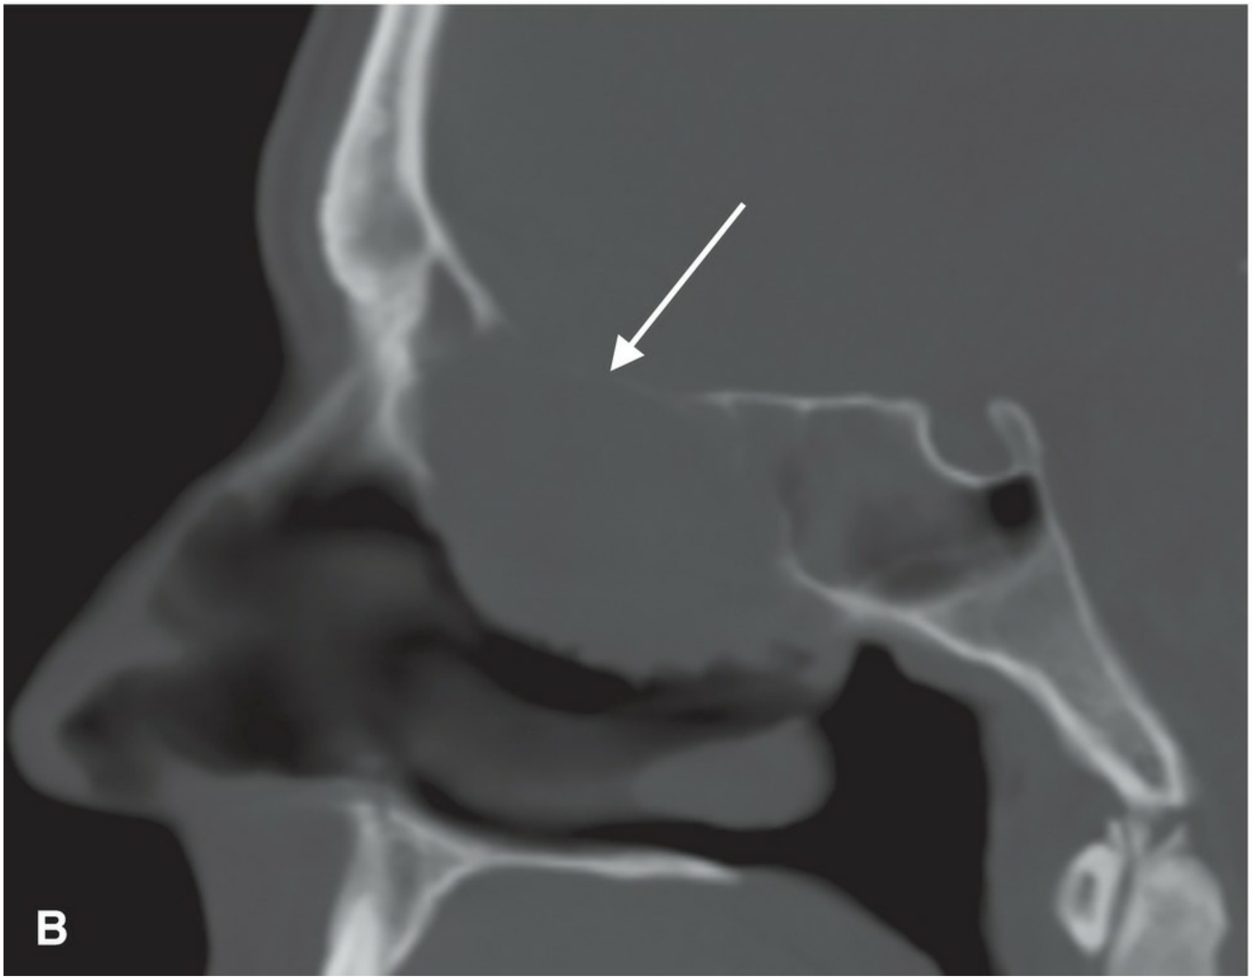
Imaging

Imaging of the nasal cavity, paranasal sinuses, and orbit is indicated whenever there is clinical suspicion of a neoplastic process. Imaging is also indicated for obtaining pretreatment information regarding the location, size, extent, and invasiveness of the primary tumor, as well as the presence of regional and distant metastasis. Such information is crucial in deciding on therapeutic options and for proper preoperative planning of the optimal surgical approach. Imaging also plays an important role in the posttreatment follow-up, indicating areas of residual or recurrent disease, and defining suspicious areas for biopsy.

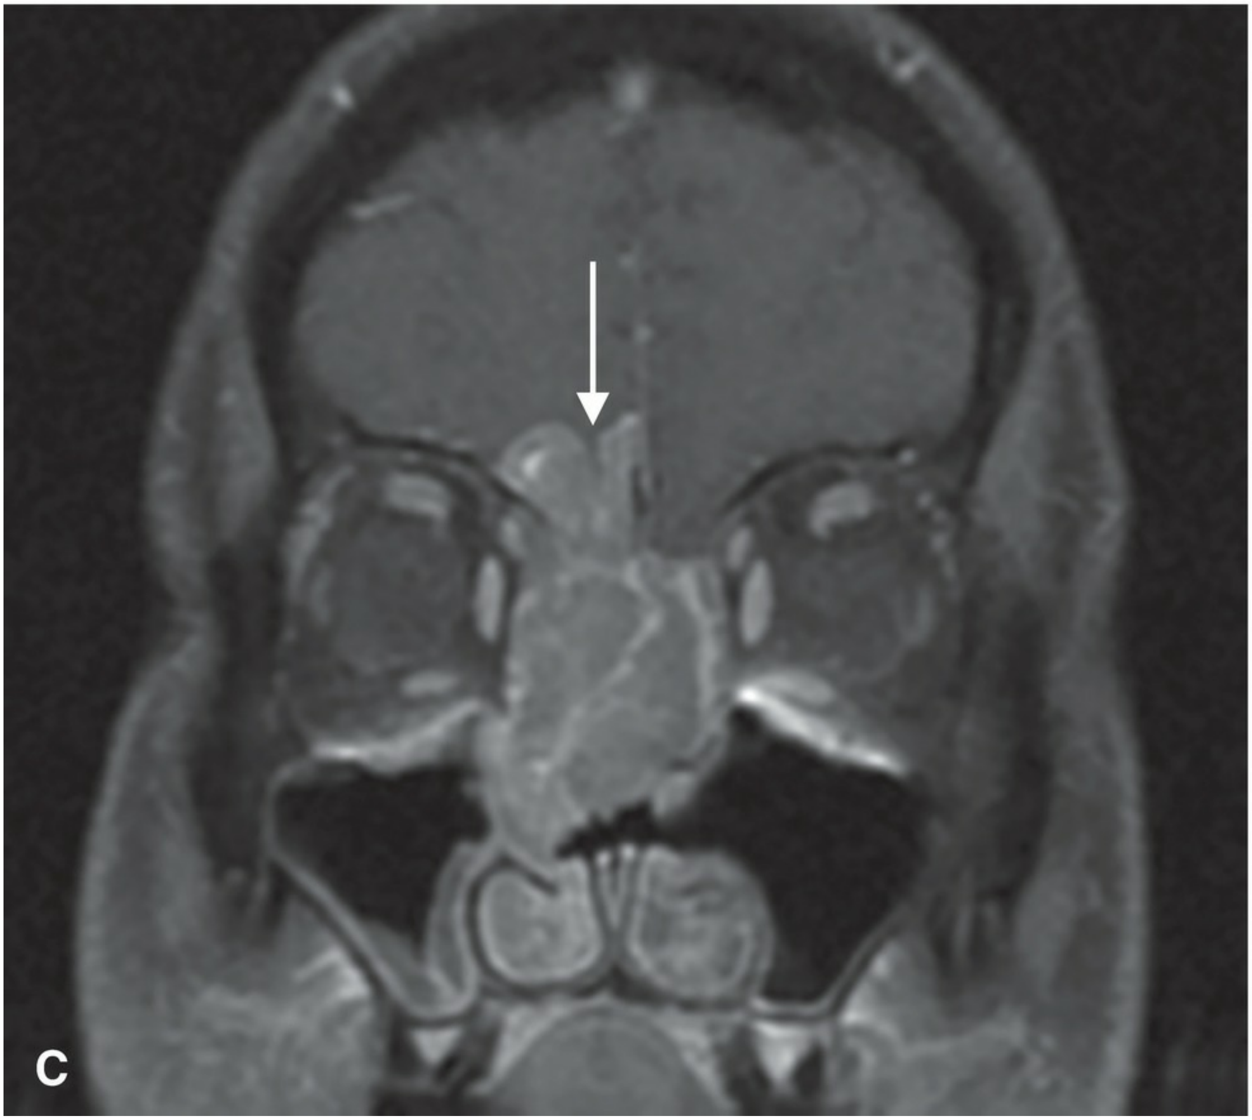
Both CT and MRI might be needed for optimum radiologic assessment of sinonasal malignancy, particularly in assessing the cranial base, orbit, and pterygopalatine and infratemporal fossae. Coronal images best delineate involvement of the orbital walls and invasion of the skull base, particularly the cribriform plate. Axial images are particularly helpful in demonstrating tumor extension through the posterior wall of the maxillary sinus into the PPF and infratemporal fossae. Sagittal images are particularly helpful in evaluating extension along the cribriform plate, planum sphenoidale, and clivus (**Fig. 10.16**).



A



B



C

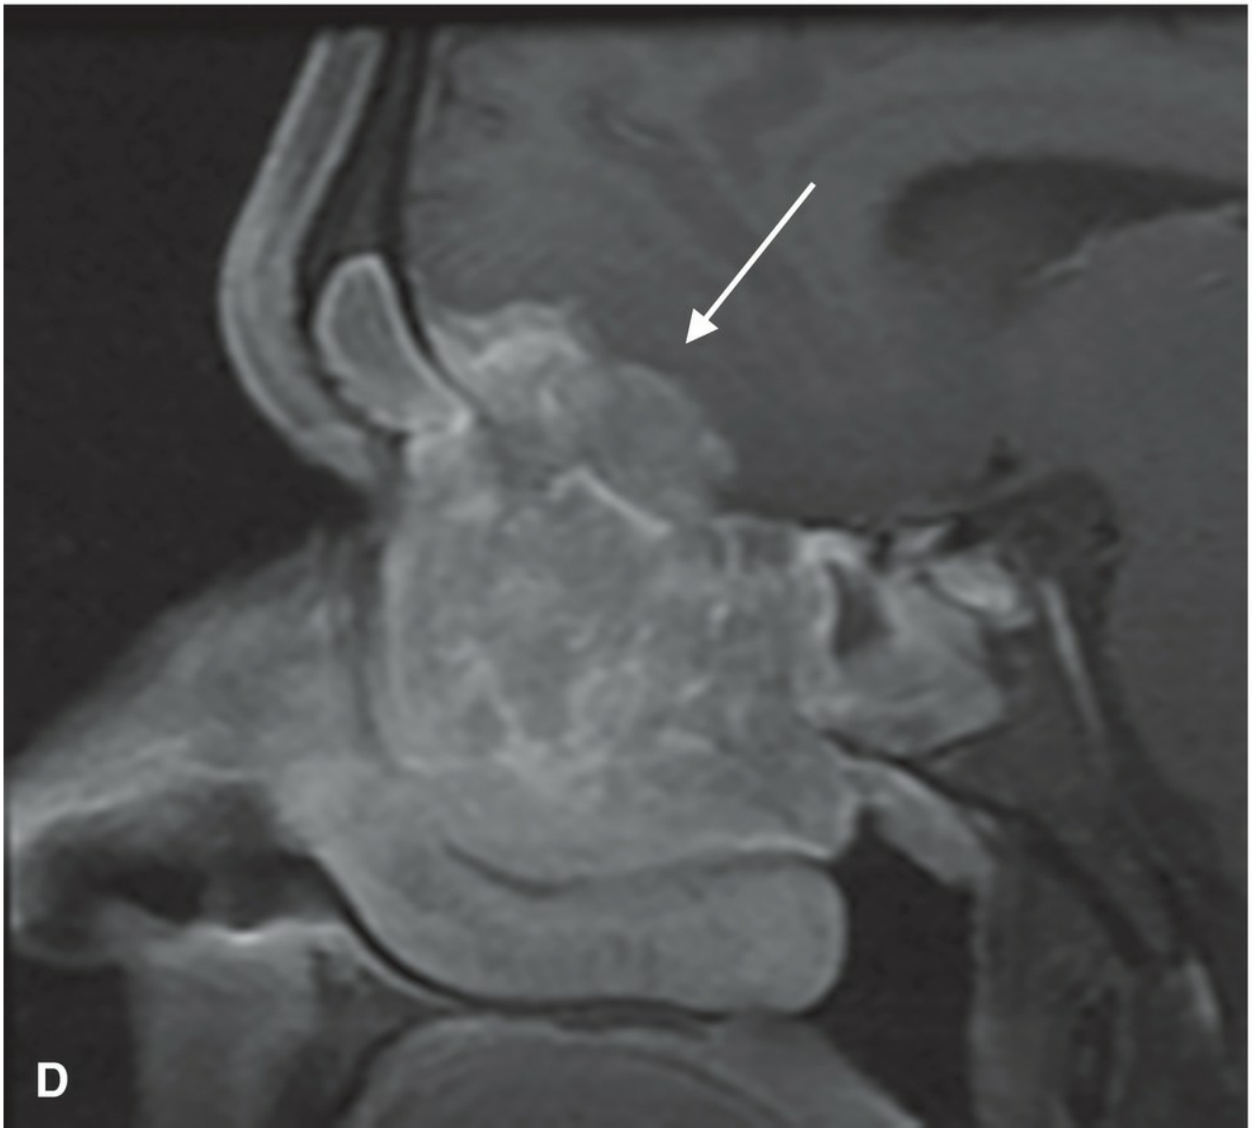


Figure 10.16. Ethmoid carcinoma. Coronal and sagittal images showing bony destruction on CT scan **(A, B)** and intracranial invasion (*arrows*) on T1-MRI with contrast **(C, D)**.

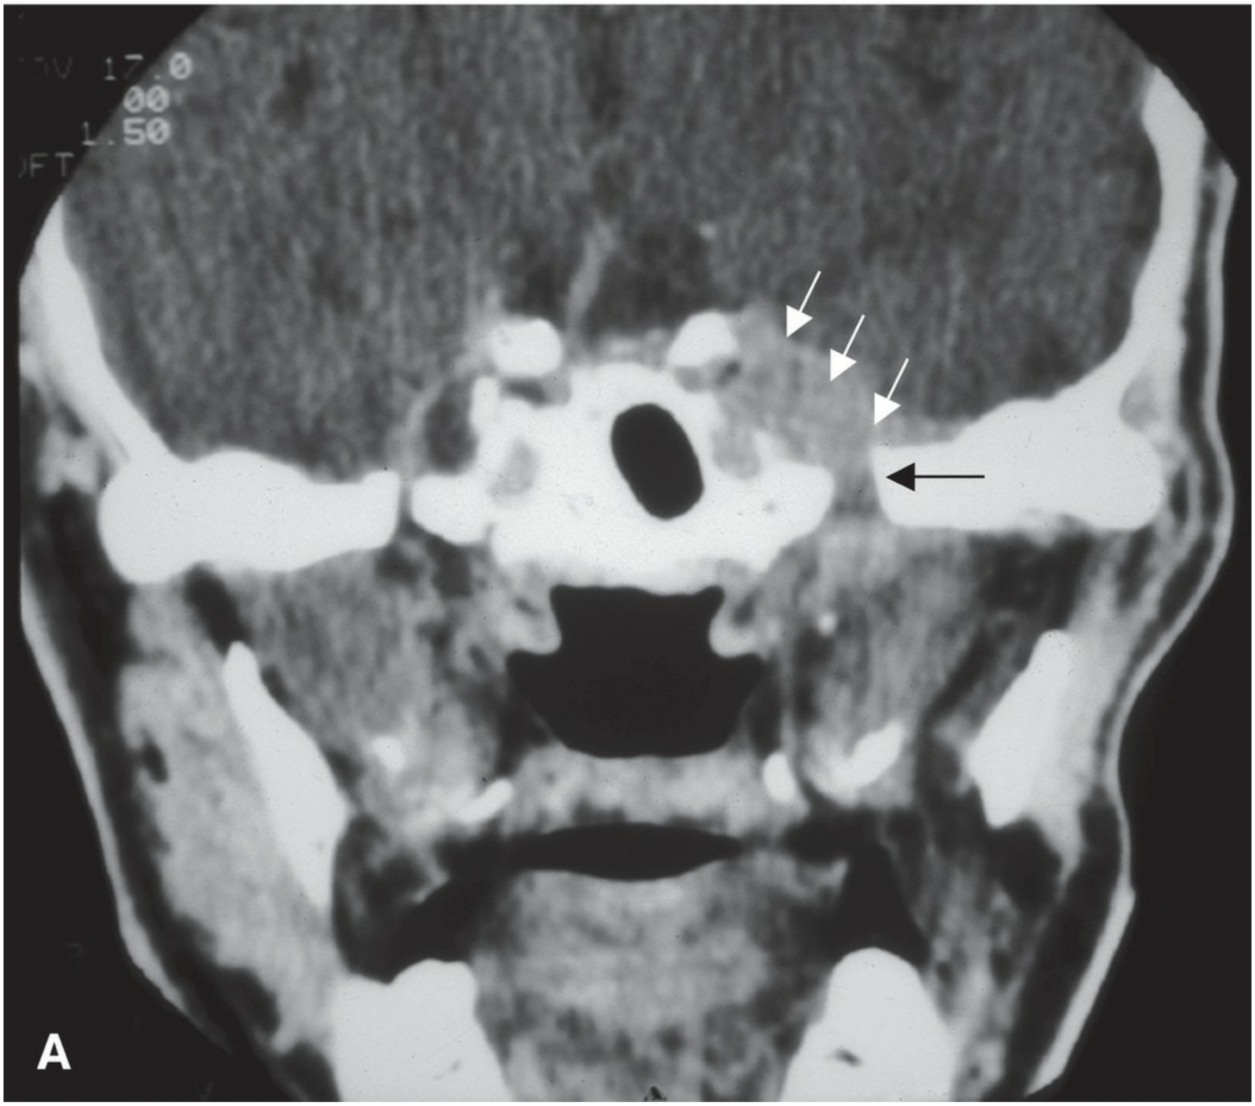
The main advantage of CT scans is in delineating the architecture of the bones, especially in "bone windows" (**Fig. 10.16A and B**). The addition of contrast enhancement increases tumor definition from adjacent soft tissue, especially intracranially. Bone destruction and soft tissue invasion suggest an aggressive lesion, usually a malignant neoplasm. Widening or sclerosis of the foramina of the infraorbital, vidian, mandibular, or maxillary nerves may indicate perineural spread (**Fig. 10.17**).



A

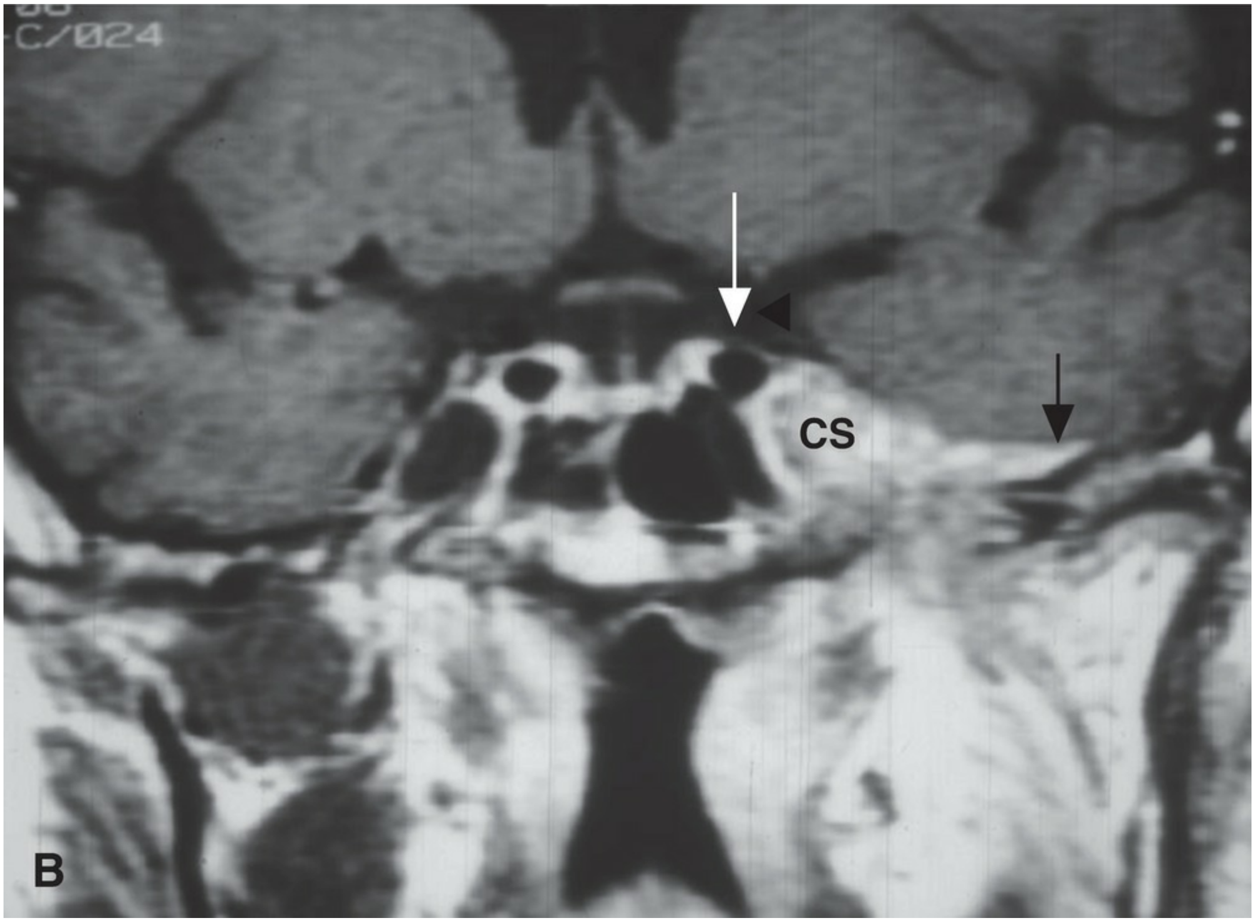


Figure 10.17. Perineural spread of ACC along the third division of the trigeminal nerve (V3). **A:** A coronal CT with IV contrast showing widening of the left foramen ovale (*black arrow*), compared to the one on the right. There is also enhancement and thickening along the left Meckel cave (*white arrows*). **B:** A coronal T1-weighted MRI with gadolinium showing marked thickening and enhancement of V3, trigeminal ganglion, and the lateral cavernous sinus (CS). The tumor abuts the cavernous carotid artery (*white arrow*). There is enhancement of the dura along the floor of the middle cranial fossa (*black arrow*). This "dural tail" is usually a sign of involvement of the dura with tumor.

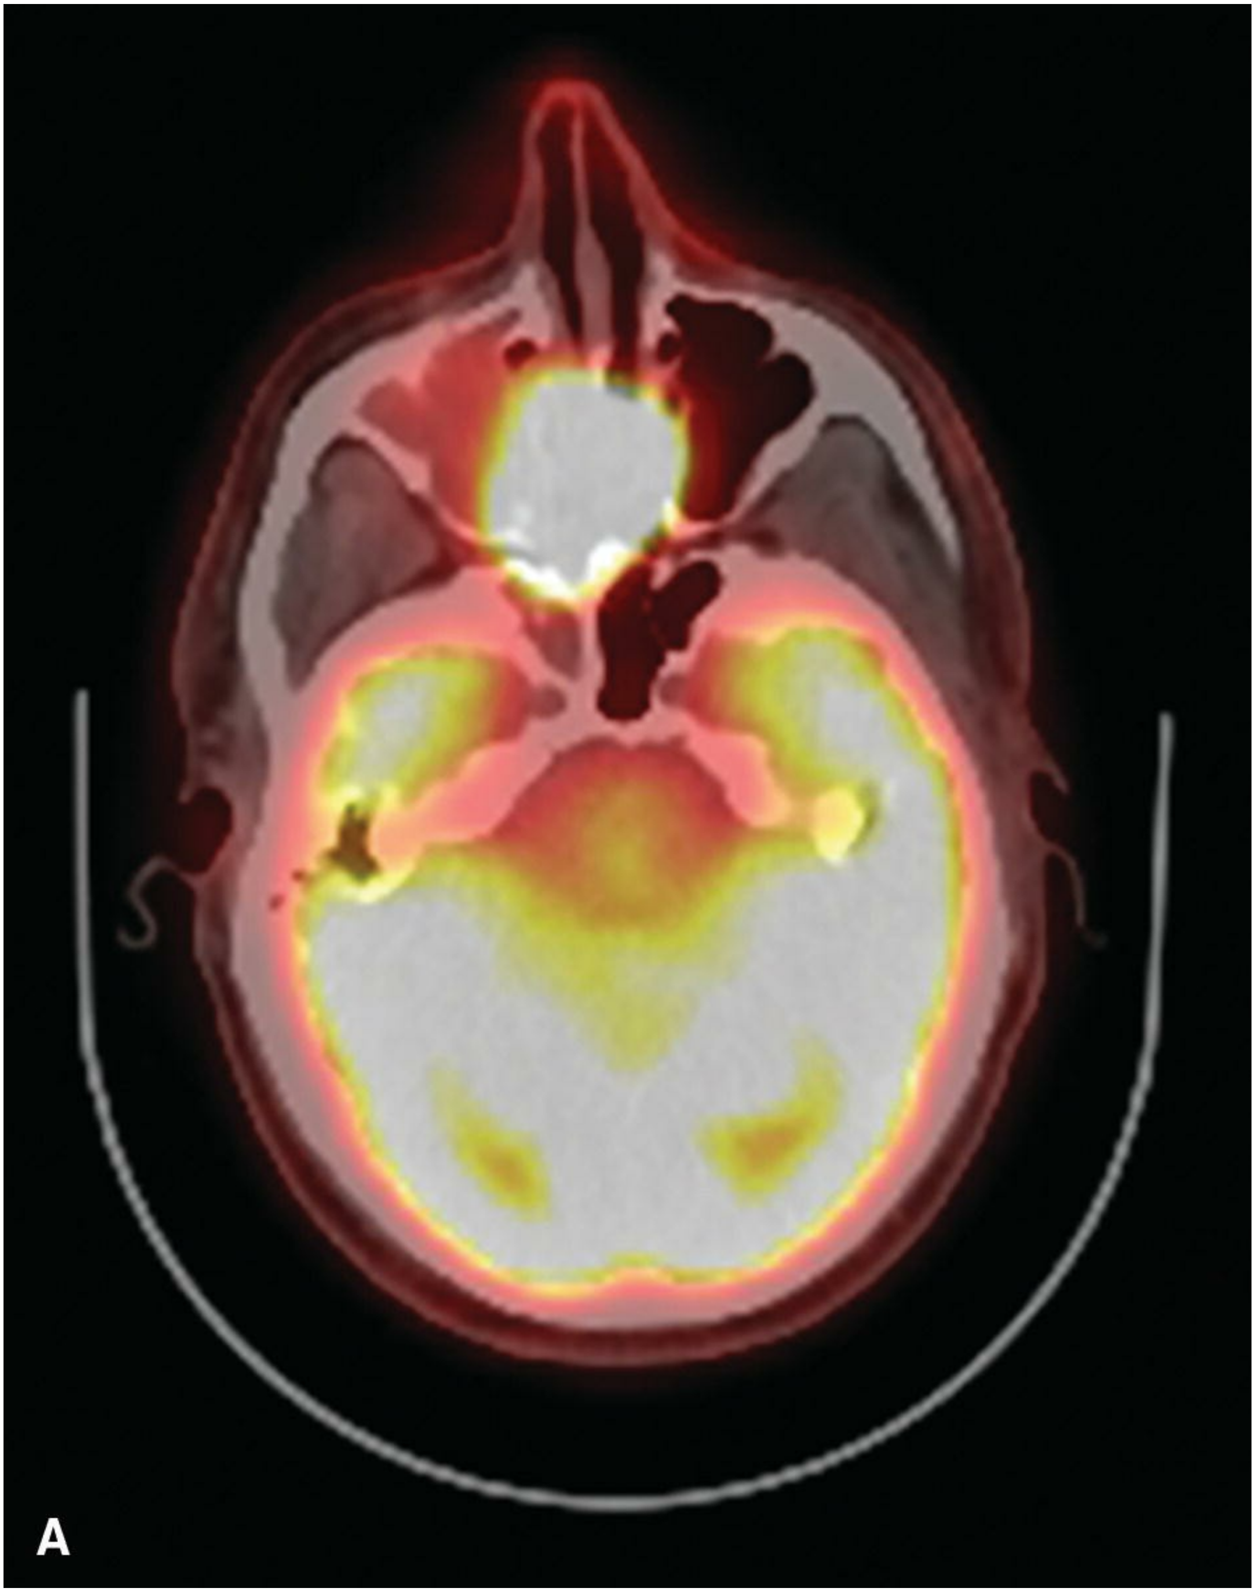
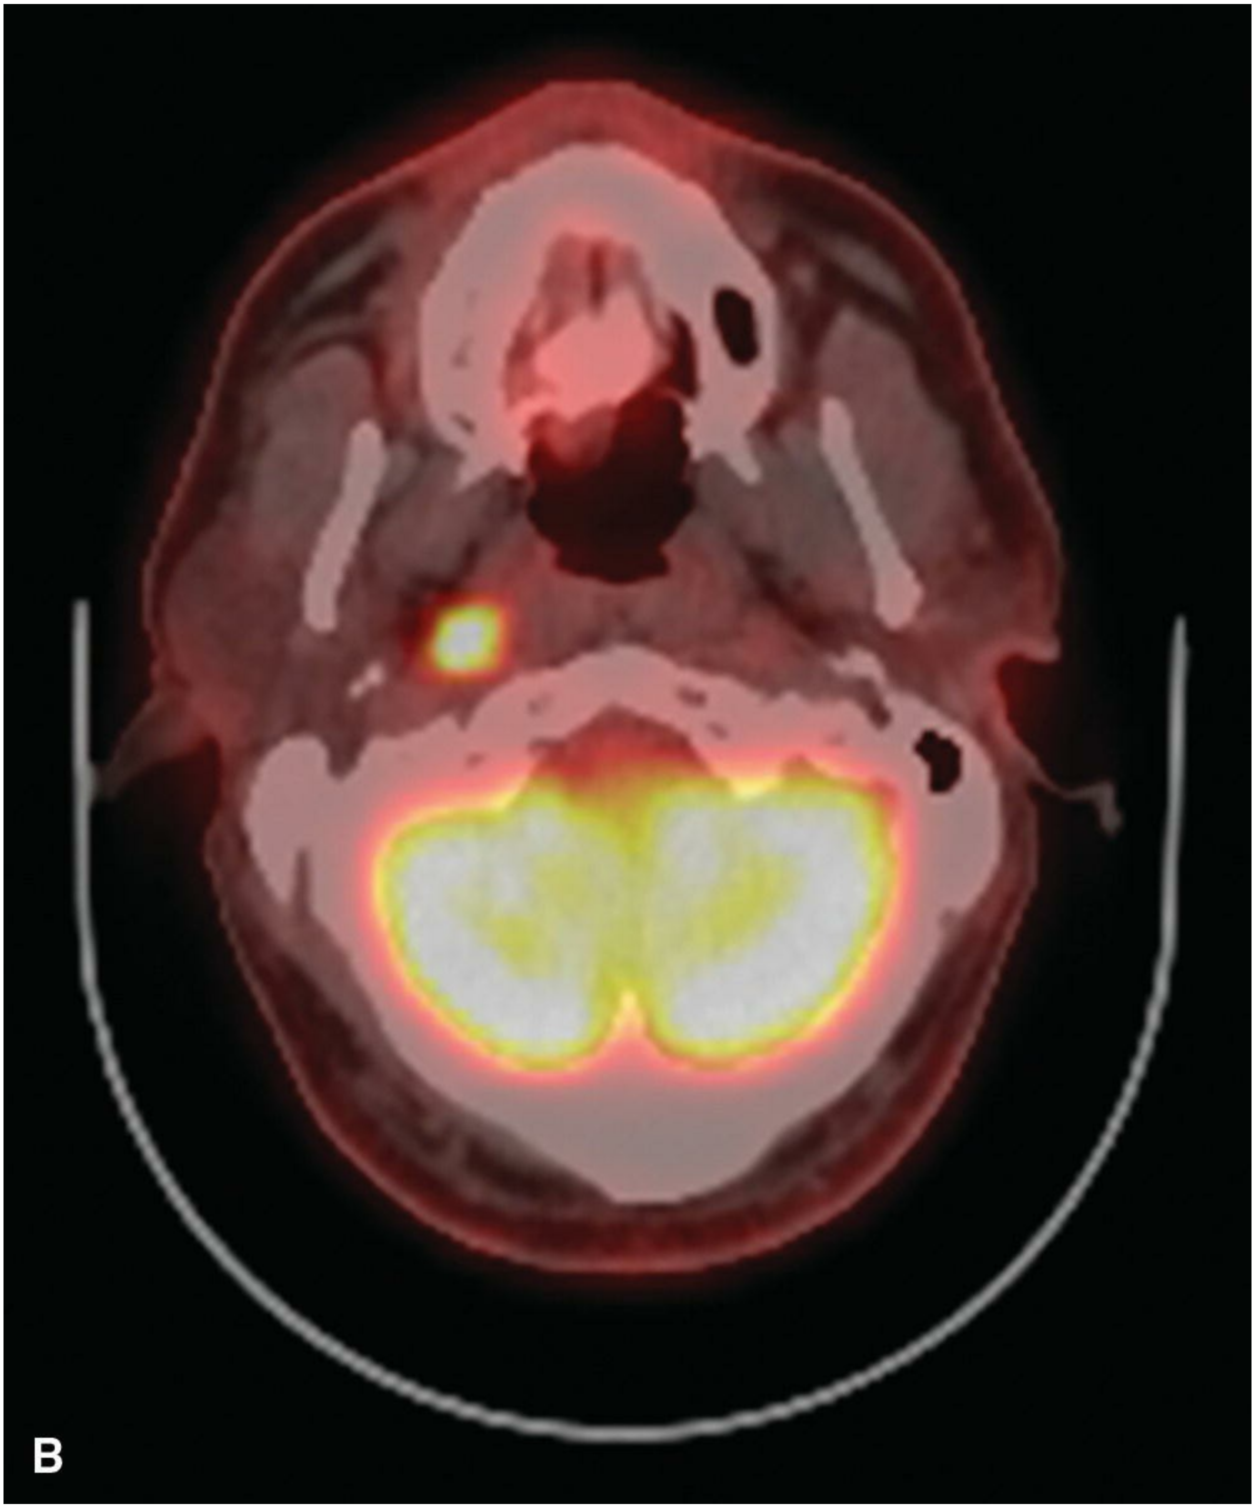
MRI with its superior soft tissue contrast and multiplanar capability is superior to CT in pretreatment evaluation of primary malignant tumors of sinonasal cavity.[40] MRI is unsurpassed in delineating soft tissue detail, both intra- and extracranially (Fig. 10.16). Obliteration of fat planes in the PPF, infratemporal fossa, and nasopharynx usually indicates tumor transgression along these boundaries. Dural thickening or enhancement is usually an

indication of tumor involvement, and evaluation of critical structures such as the brain and carotid artery is best delineated by MRI. Similarly, enhancement or thickening of cranial nerves indicates perineural spread, which is better detected on MRI than CT[34] (Fig. 10.17). Perhaps one of the most significant advantages of MRI is the ability to distinguish tumor from retained secretions secondary to obstruction of sinus drainage (**Fig. 10.18**). MRI is also particularly helpful in monitoring patients in the postoperative follow-up period, although this role may be supplanted by positron emission tomography (PET) scans because of its ability to distinguish between tumor recurrence and posttreatment fibrosis. *PET–CT* is also helpful in delineating regional and distant metastasis (**Fig. 10.19**).

Figure 10.18. Sinonasal melanoma. **A:** Coronal CT scan demonstrating opacification of the right nasal cavity as well as the maxillary and ethmoid sinuses. There appears to be destruction of the lateral nasal wall and the nasal septum. The lesion is abutting the orbital floor and the cribriform plate, but it is unclear whether or not these structures are involved. **B:** Coronal T1-weighted MRI with gadolinium of the same patient revealing that the lesion is limited to the nasal cavity and ethmoid sinuses and that the changes in the maxillary sinuses are due to retained secretions secondary to obstruction of the ostium, rather than soft tissue involvement. It also demonstrates that the lesion does not invade the orbit or the cranial base. The presence of low signal areas within the lesion gives it a heterogeneous appearance, which is characteristic of sinonasal melanoma.



A



B

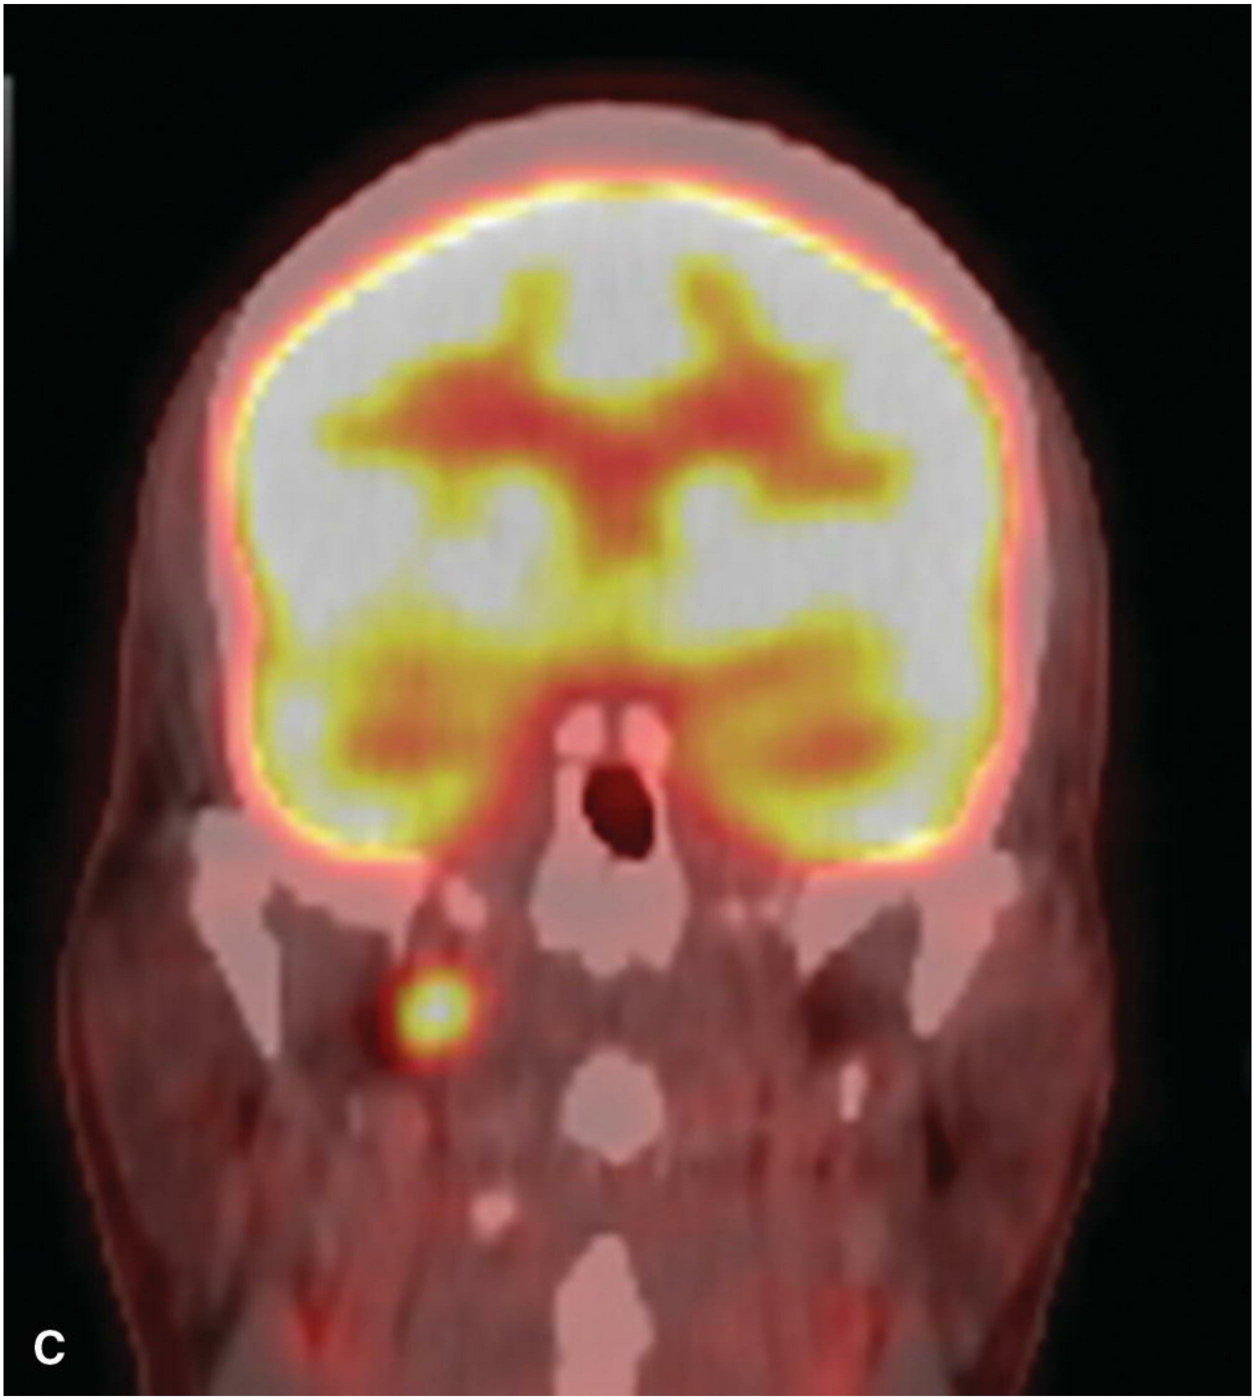


Figure 10.19. PET–CT of the head and neck. These images are from the same patient whose CT and MRI are depicted in Figure 10.16. The fused PET–CT images show ethmoid carcinoma **(A)** with metastasis to the retropharyngeal lymph nodes **(B, C)**, which were not detected on CT or MRI.

Angiography is not indicated in the routine assessment of patients with neoplasms of the nose, paranasal sinuses, and orbit. In certain selected cases,

however, angiography may be necessary. These cases include vascular neoplasms of the sinonasal region, where angiography will not only delineate the tumor extent and the blood supply but also permit the use of selective embolization of the vascular supply to the tumor (**Fig. 10.20**). This reduces intraoperative blood loss, facilitating surgical resection.

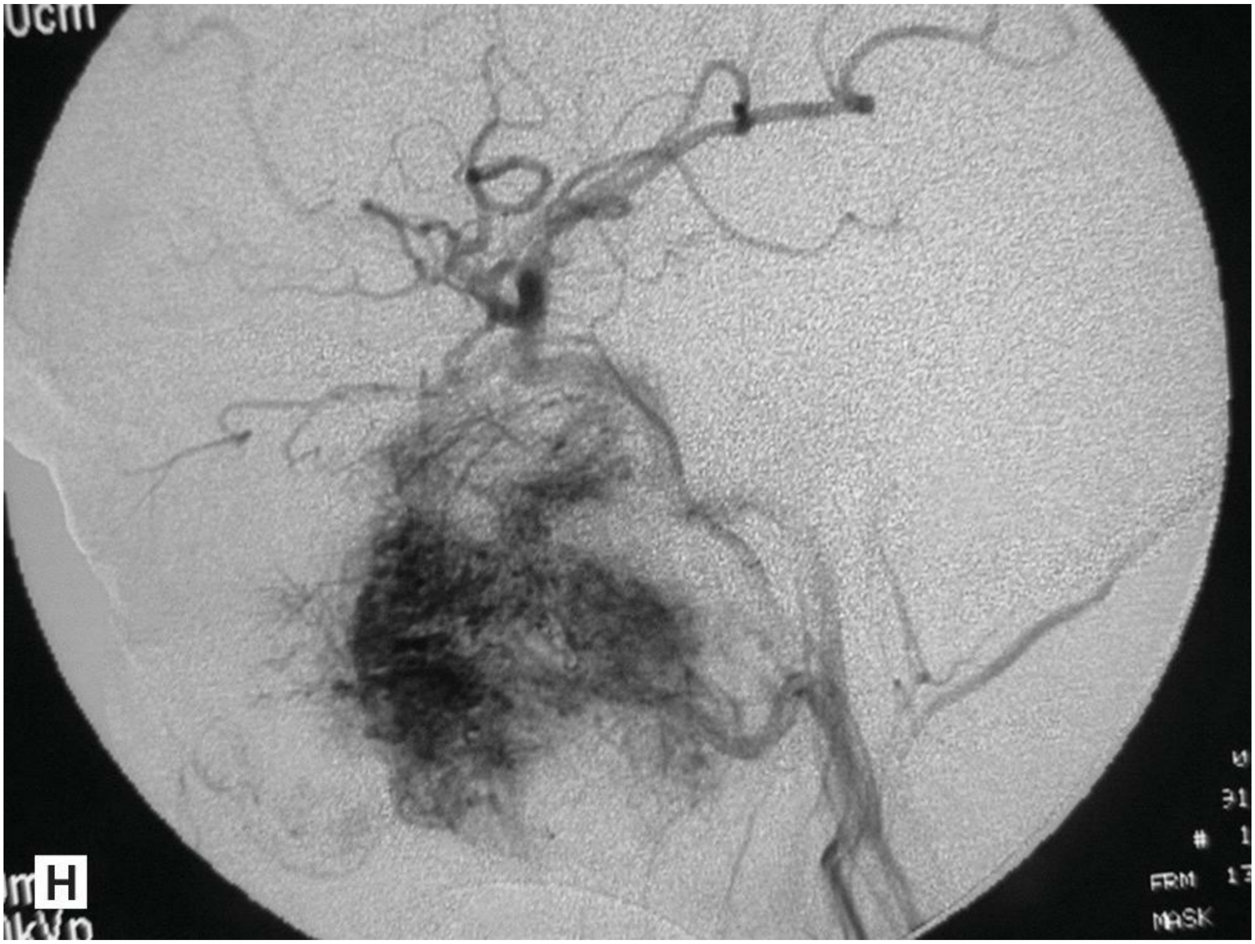

Figure 10.20. Juvenile nasopharyngeal angiofibroma. Coronal **(A, B)** and axial **(C)** CT with contrast and axial T1 axial MRI with contrast (**D**) showing the mass in the nasal cavity, maxillary sinus, nasopharynx, sphenoid sinus, pterygoid plates, and pterygopalatine and infratemporal fossa. The mass involves the floor of the middle cranial fossa and extends intracranially to the cavernous sinus. T1 sagittal MRI **(E, F)** show flow voids of increased extensive vascular supply coming from the internal maxillary artery **(E)** and internal carotid artery **(F)**. Early-phase angiogram showing the blood supply from the internal maxillary artery **(G)** and late phase showing significant tumor vascular blush and contribution from the internal carotid artery **(H)**.

Biopsy

The definitive diagnosis of a neoplasm of the nasal cavity and paranasal sinuses relies on expert histopathologic review of any biopsy specimens by a head and neck pathologist to confirm the exact diagnosis prior to treatment. This is critical because the treatment and prognosis of sinonasal cancer is

greatly influenced by histology.[41,42] This is particularly true for neuroendocrine tumors in which the misdiagnosis rate is particularly high. In a study from MDACC, patients referred with a presumed diagnosis of ENB were frequently reclassified to other types of tumors including NEC, sinonasal undifferentiated carcinoma (SNUC), melanoma, and even pituitary adenoma.[43] The implications of this misdiagnosis are far reaching and required significant alteration in the initially proposed treatment plan in a significant number of patients.

Biopsy of Tumors of the Nasal Cavity

The vast majority of sinonasal neoplasms are accessible for biopsy through a strictly endonasal approach. A wide variety of rigid nasal endoscopes offer superb visualization of intranasal lesions with a high degree of optical resolution and bright illumination (Fig. 10.13). The application of topical anesthetics and decongestants improves visualization and allows thorough examination of the nasal cavity. The site of origin of the lesion and its relation to the nasal walls (septum, floor, roof, and lateral nasal wall) should be noted. An adequate specimen should be obtained, avoiding crushing of tissue, and submitted for histopathologic examination. If the diagnosis of lymphoma is suspected, fresh tissue should be sent in saline, rather than fixed in formalin. Most endonasal biopsies can be performed in the outpatient setting with minimal discomfort to the patient. In certain cases, the diagnosis of a highly vascular neoplasm, such as angiofibroma, may be suspected on clinical grounds. Under these circumstances, it is prudent not to perform the biopsy until imaging and angiography (possibly with embolization) are performed (Fig. 10.20). Preoperative biopsy can then be performed in the operating room under controlled conditions to confirm the diagnosis before surgical resection. If a nasal mass is suspected to have an intracranial communication such as an encephalocele, meningocele, or nasal glioma, this should be confirmed with imaging to avoid inadvertent CSF leak and subsequent meningitis (**Fig. 10.21**).

of such lesions may lead to CSF leaks and should be avoided.

Biopsy of Tumors of the Paranasal Sinuses

In the unusual case where a paranasal sinus neoplasm is confined to the sinus cavity and does not present itself intranasally, a biopsy should be obtained by direct access to the involved sinus. Tumors of the maxillary sinus can still be accessed through an endoscopic approach by creating a wide antrostomy in the region of the natural ostium. Otherwise, the maxillary sinus is accessible through a sublabial incision in the canine fossa via an anterior antrostomy. The ethmoidal sinus can be approached endonasally through endoscopic ethmoidectomy. Alternatively, an external ethmoidectomy approach provides a direct access via a Lynch incision.

The sphenoid sinus is easily approached endoscopically in the vast majority of cases. The use of C-arm fluoroscopy or more recently computer-assisted three-dimensional (3-D) intraoperative imaging is sometimes used in cases with difficult access or unusual anatomy. Isolated tumors of the frontal sinus are rare. A trephination through the floor of the sinus is utilized for biopsy of lesions within its cavity.

TREATMENT

Surgical Treatment

Indications

Surgical resection, alone or more commonly combined with adjunctive therapy, remains the mainstay of treatment of cancers of the SNT. This approach seems to provide the best chances for cure or control of disease. For early-stage disease (T1 to T2), surgery alone may be adequate treatment, but for more advanced stage resectable disease, postoperative adjuvant radiation or chemoradiation is commonly used to improve tumor control. Surgery is indicated whenever there is adequate evidence that the tumor can be completely resected with acceptable morbidity. The development of new combined craniofacial approaches has extended the indications of surgery to include some patients with skull base and even intracranial extension.[44,45]

The advent of new reconstructive techniques, including microvascular free flaps, pericranial flaps, and prosthetic rehabilitation, has reduced morbidity and improved rehabilitation following extensive resections of advanced sinonasal cancer.[46–48] In the presence of tumor extension to the CS, internal carotid artery, optic chiasm, extensive brain parenchymal involvement, or distant metastasis, surgery is usually contraindicated. However, in selected cases, surgery with proper adjuvant therapy may still offer the most effective local disease palliation even in the presence of extensive disease.

Preoperative Preparation

A thorough preoperative assessment should determine the candidacy of a patient for surgical management of his or her neoplasm. This involves a careful “mapping” of the tumor extent, as well as the general medical condition and functional status of the patient. This is usually accomplished by a detailed history and physical examination and comprehensive examination of the head and neck region including endoscopy of the sinonasal region. Cranial nerve examination as well as ophthalmologic evaluation should be done to evaluate cranial base and orbital extension, respectively. High-resolution imaging should be obtained using CT or MRI, or both, to accurately assess the tumor extent. In certain cases, angiography will be needed to determine the extent of carotid arterial involvement. The balloon occlusion test should be performed if carotid artery resection or reconstruction is contemplated. Preoperative embolization may be indicated in certain vascular tumors.

Neurosurgical consultation is needed if a combined craniofacial approach is anticipated. If free vascularized flaps will be utilized for reconstruction, expertise with microvascular surgery is needed, and appropriate consultation should be obtained. Evaluation by a maxillofacial prosthodontist is required in most patients to obtain preoperative dental impressions and design surgical obturators or splints for maintenance of proper dental occlusion and oral rehabilitation. Similar expertise is essential in cases where prosthetic orbital, nasal, or facial rehabilitation is required. Consultations with medical and radiation oncology colleagues should be done to consider incorporation of chemotherapy or radiation in the treatment plan. Radiation and/or chemotherapy may be used preoperatively as induction (neoadjuvant) or postoperatively as adjuvant therapy. This is particularly important in patients

with advanced stage disease (e.g., dural or orbital involvement) or high-grade lesions (e.g., SNUC). In selected cases, chemotherapy and/or radiation may be reasonable alternatives to surgery. Such decisions are best discussed in the format of a multidisciplinary tumor board. If surgery is chosen as a treatment modality, the plan for the surgical approach, the extent of resection, and reconstructive options should then be formulated. This plan should be communicated clearly among the various members of the surgical team particularly the otolaryngologists, head and neck surgeons, neurosurgeons, and plastic and reconstructive surgeons.

Careful assessment of the patient’s general medical condition should be carried out prior to surgery. Preoperative chest radiograph, blood counts, liver and renal function tests, blood sugar, electrolytes, coagulation studies, and an electrocardiogram (ECG) should be performed routinely. Appropriate consultations from medical colleagues should be obtained in order to optimize the patient’s medical status before surgery and help in management postoperatively. The patient’s nutritional status should be evaluated, and if indicated, enteral or parenteral feeding may be considered. High-resolution imaging for metastatic workup is not routinely performed, unless indicated by history, clinical examination, chest radiograph results, or blood test abnormalities.

Finally, the surgical team should discuss with the patient and family the nature of the disease, the evaluation, and the indications, risks, possible complications, sequelae, and alternatives of therapy. The expected postoperative course including length of stay in the hospital, feeding, rehabilitation, and need for adjunctive therapy should be described. This ongoing communication should be maintained in a clear, honest, and sympathetic fashion throughout the course of patient care.

Surgical Principles

When dealing with the subject of surgical treatment of sinonasal cancer, a distinction has to be made between the terminology used to describe the surgical approach on the one hand and the extent of resection on the other hand. A surgical approach describes the various incisions, soft tissue dissection, and skeletal osteotomies required to expose the tumor and adjacent structures to perform a complete and safe resection. On the other hand, the extent of tumor resection describes the various structures that need

to be surgically extirpated to achieve total tumor removal with tumor-free margins. Obviously, both the surgical approach and the extent of resection are closely related and depend on the extent of tumor, its aggressiveness, and related critical structures. The various surgical approaches and extent of resection are listed in **Table 10.3**.[44] The choice of surgical approach and extent of resection will generally depend on the location and the extent of the tumor. In some cases, different approaches may be equally effective for resection of a particular tumor. For example, a tumor of the nasal cavity, lateral nasal wall, ethmoid, sphenoid, and medial maxillary sinus requiring a medial maxillectomy and a total sphenoethmoidectomy may be adequately resected using a transfacial, endoscopic, or sublabial approach (Figs. 10.18 and **10.22**). However, the following principles should always guide the surgeon in choosing the optimal approach and extent of resection for all patients undergoing surgical treatment of sinonasal cancer:

Table 10.3 Surgical Approaches and Extent of Resection of Cancers of the Sinonasal Tract

Surgical Approach

Surgical Approaches

Endonasal.

Endoscopic endonasal approaches (EEAs) are being increasingly used for surgical excision of selected tumors of the SNT, either alone or in combination with open approaches. Endoscopic surgery avoids craniofacial soft tissue dissection, skeletal disassembly, and brain retraction. Other advantages of EEA include direct bilateral access to the tumor, superior illumination, magnification and visualization of the surgical field (Fig. 10.7), wider angles of vision using angled endoscopes, and relatively less morbidity compared to the open surgical approaches.

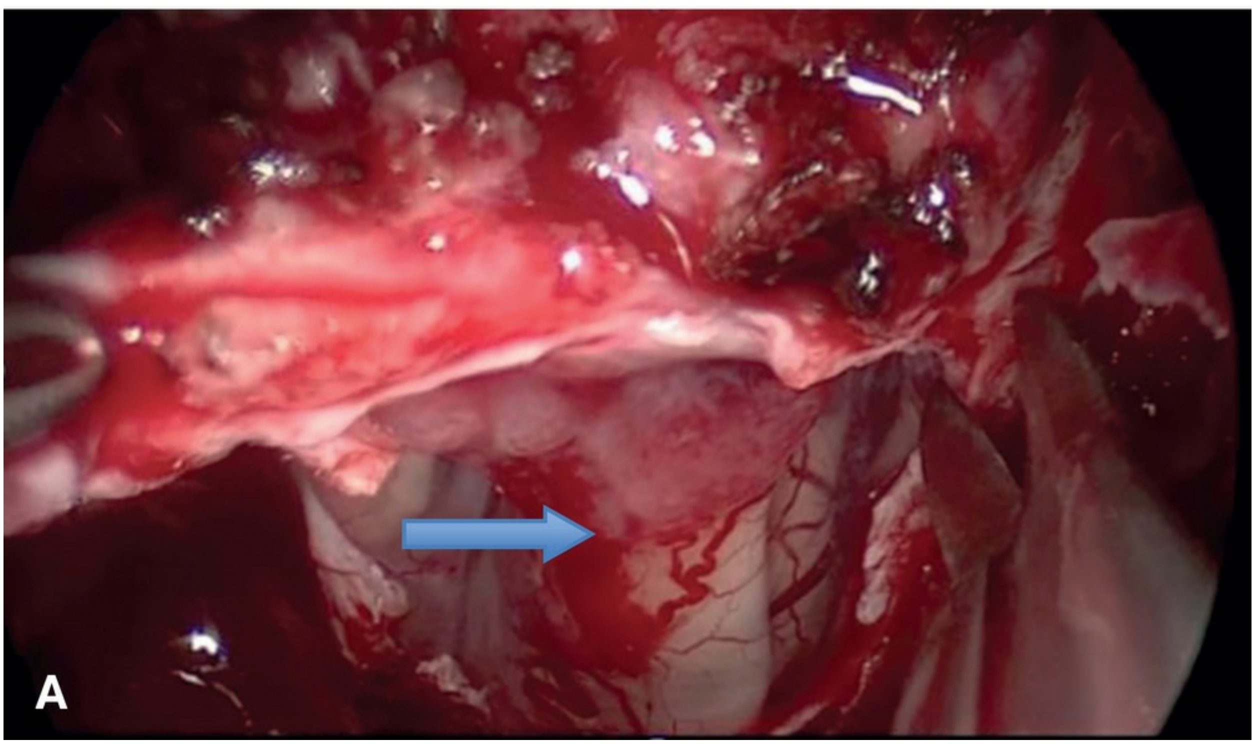
When endoscopic endonasal surgery was first advocated for the treatment of sinonasal malignancies, concerns were raised regarding the oncologic soundness of the procedure.[49] Criticisms have centered on the inability of the endoscopic approach to perform an en bloc resection. Proponents of the endoscopic technique argue that unless the tumor is small, en bloc resection is rarely achievable with open surgery.[50,51] Several studies have shown that the method of resection (en bloc vs. piecemeal) does not significantly impact on oncologic outcomes and that what is paramount, however, is achieving negative resection margins, regardless of the surgical approach.[52,53]

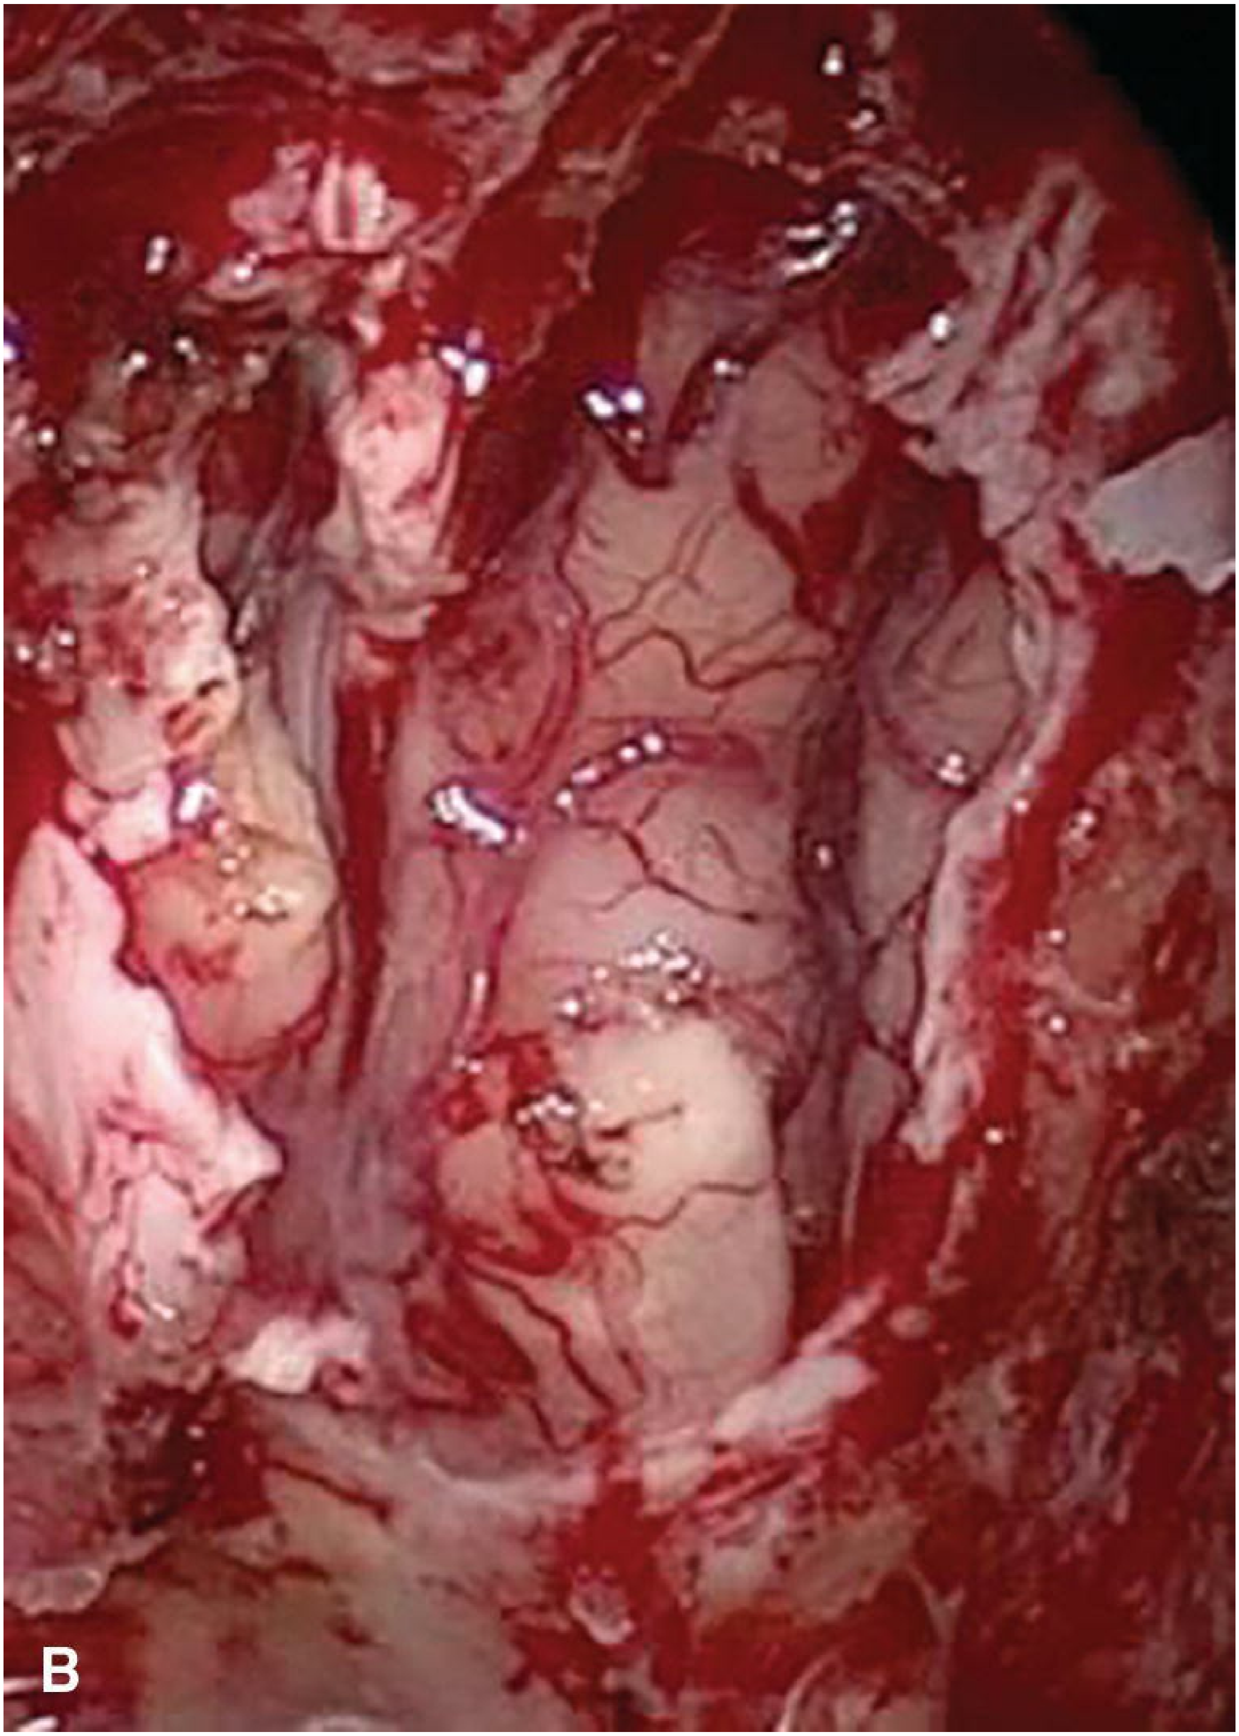
Over the past decade, there has been increasing evidence regarding the safety and oncologic effectiveness of these techniques. Several institutions have reported their experience with endoscopic surgery and have shown reduced morbidity, shorter hospital stay, better quality of life, and equivalent survival outcomes to those of open surgery in carefully selected patients.[54]

The keys to adequate oncologic results using EEA are good selection of patients and the surgeon’s experience with this approach. EEA are most suited for central tumors involving the nasal septum, nasal cavity and lateral nasal wall, ethmoid and sphenoid sinuses, and clivus (Fig. 10.22). Tumors with extension into the facial soft tissue, involvement of the anterior wall of the frontal sinus, deep orbital invasion, lateral supraorbital extension, or significant brain parenchymal invasion are not readily accessible with EEA and require the addition of an open approach.

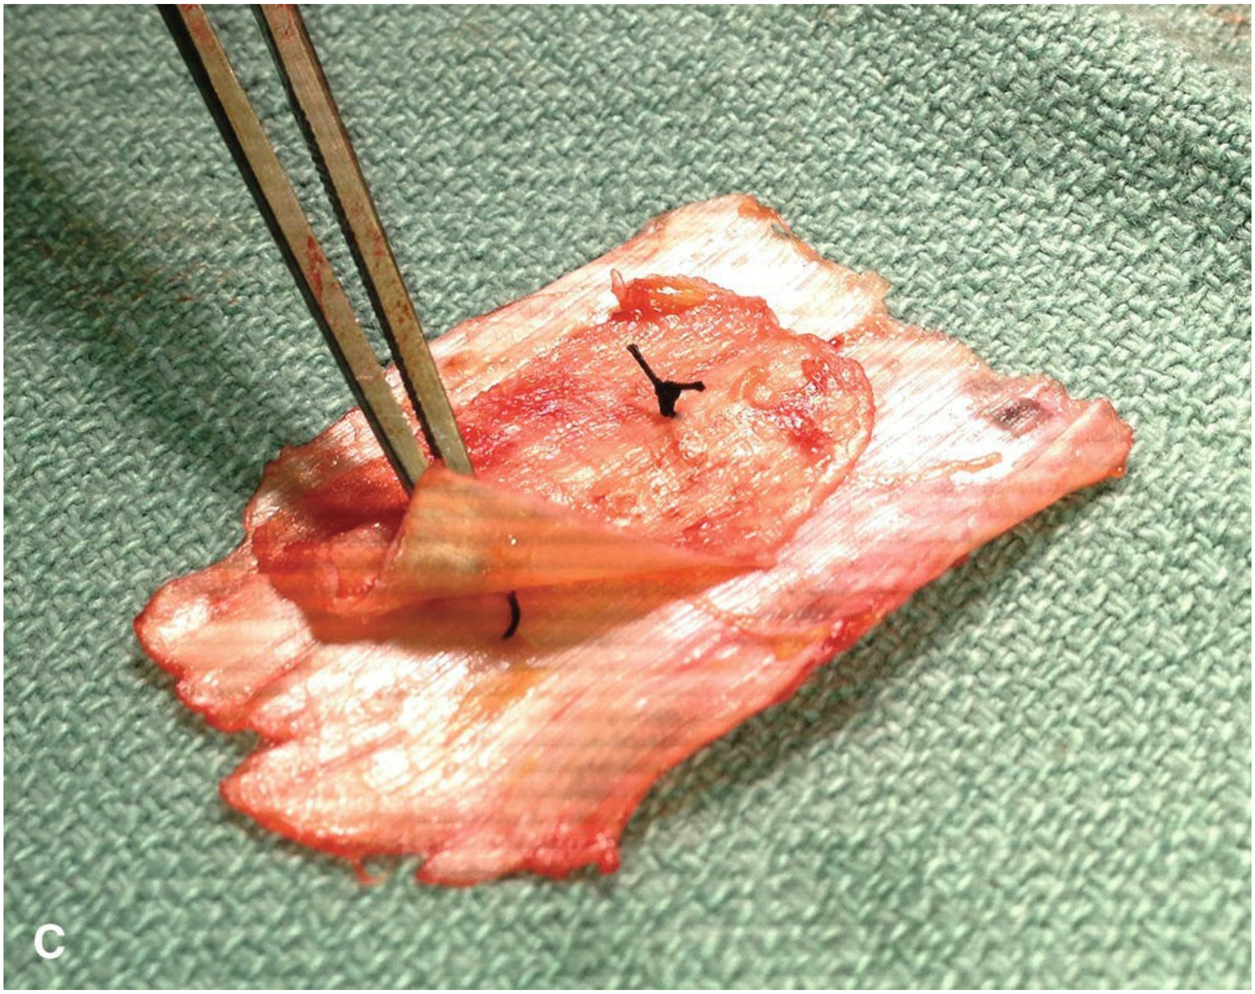
The surgical technique of EEA to the sinonasal region and the anterior skull base has been previously described in detail.[51] The standard endoscopic

endonasal “craniofacial” resection starts with debulking of the intranasal tumor, identifying the attachment of tumor origin and resection of the sinonasal component. A posterior septectomy provides a binasal approach for the surgeon and the assistant allowing a four-hand technique for dissection. If not involved by tumor, a vascularized nasal septal flap is developed contralaterally based on the posterior septal branch of the sphenopalatine artery. In some cases, when the tumor does not involve the septum, this flap can be developed ipsilaterally or bilaterally. A complete anterior and posterior ethmoidectomy are then performed, and the sphenoid sinuses are opened bilaterally. The bony skull base is skeletonized from the frontal sinus anteriorly to the planum sphenoidale posteriorly, bilaterally. The medial orbital walls are also skeletonized bilaterally, delineating the lateral extent of the surgical corridor. After control of vascular supply from the anterior and posterior ethmoid arteries, the lamina papyracea, fovea ethmoidalis, cribriform plate, crista galli, and planum sphenoidale can be removed with high-speed diamond drill with copious irrigation to avoid heat injury to critical neural structures. After removing the bone of the anterior central skull base, the dura, olfactory bulbs and tracts, and periorbita can be resected depending on the extent of tumor involvement (**Fig. 10.23**).





B



C

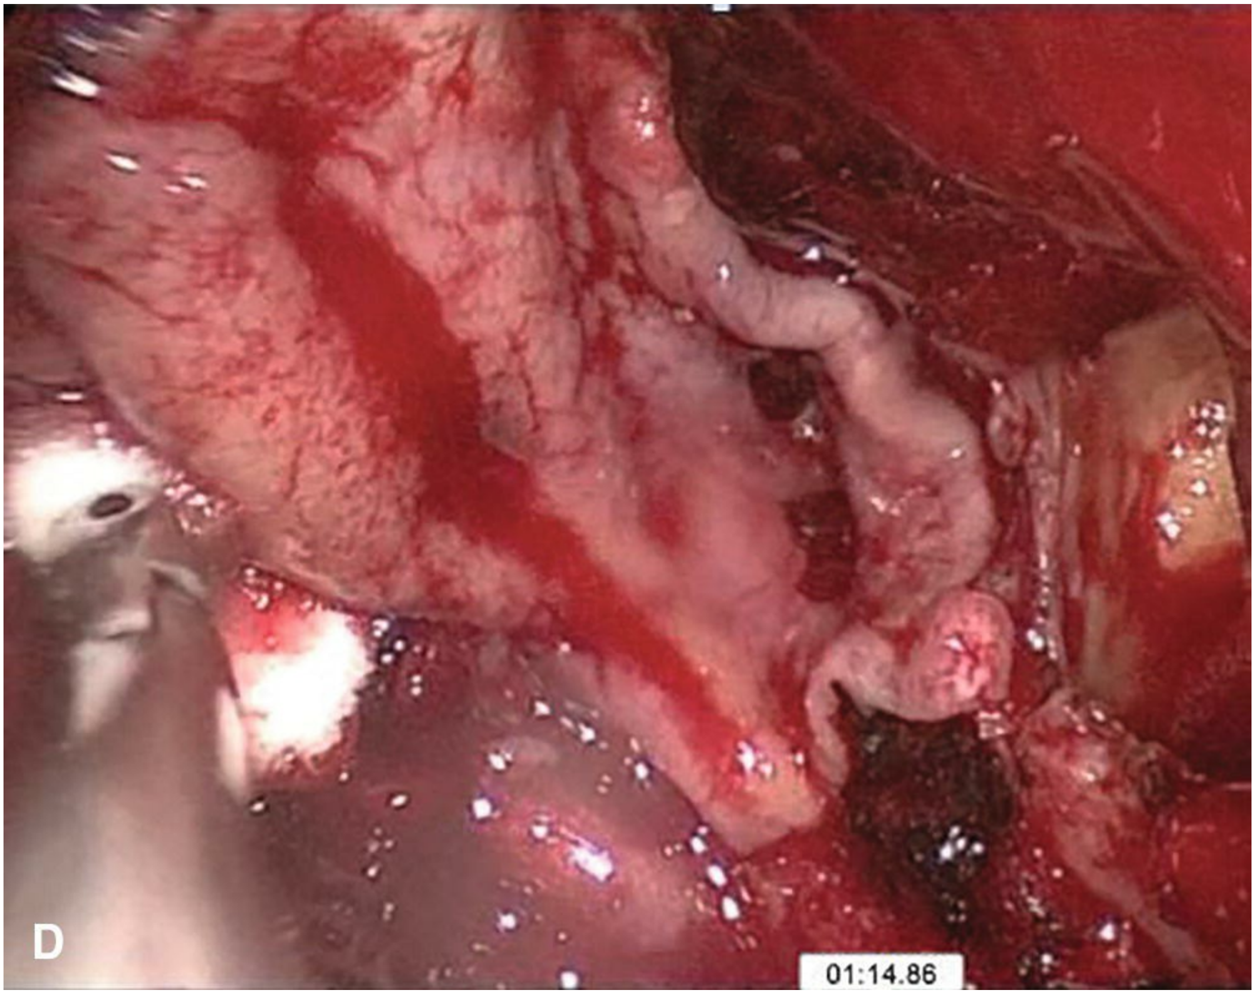


Figure 10.23. A: Intraoperative endoscopic view of a patient with ENB. The dura is opened, and the tumor is seen to arise from the olfactory bulb. **B:** Tumor resection is complete, and the dural defect is shown. **C:** Fascia lata graft is harvested. A double layer is created with the smaller one to be placed intradurally and the larger is placed extradurally but underneath the bony defect of the skull base (intracranially). Both layers are sutured together to stabilize them during placement and obliterate any dead space between them. **D:** A vascularized nasoseptal flap based on the posterior septal branch of the sphenopalatine artery is rotated to cover the double layer graft.

Reconstruction of the skull base in the early stages of development of EEA was a major challenge, but has significantly evolved over the last decade. Early reconstructive experience was associated with CSF leak rates of 20% to 30% for EEA of the anterior skull base.[55,56] The application of a nasoseptal flap placed extradurally has lowered leak rates to 5% (Fig.

10.23).[57] When there is tumor involvement of the superior nasal septum, the "extended nasoseptal flap" can be harvested from the lower septum and extended onto the floor and lateral wall of the nasal cavity.[58] Other vascularized reconstructive alternatives for the anterior skull base include minimally invasive pericranial flap,[59] the middle turbinate flap for small defects and the transpterygoid temporoparietal fascia flap.[60,61] The inferior turbinate flap, while robust, has limited reach and is best suited to clival defects.[62] Other flaps described in the literature such as the palatal flap,[63] the buccinator myomucosal flap,[64] and the occipital galeopericranial flap [65] may be considered.

Some investigators have utilized nonvascularized reconstructive options with favorable results. Gil et al.[66] described a double-layered tensor fascia lata repair with a CSF leak rate of 0.8%. Histologic examination of resected fascia lata in patients who received a second operation shows evidence of neovascularization of the fibrous tissue, even without the presence of a vascularized flap. Villaret et al.[67] proposed a three-layer reconstruction with the iliotibial tract. They report postoperative CSF leak rates of around 4%. In cases where the skull base and dural defect are too large for purely endoscopic reconstruction, an open approach may provide the safest way to achieve reliable cranionasal separation and avoid CSF leak and the risk of meningitis.[68,69]

The long-term oncologic results of EEA in treating malignant sinonasal tumors are still being defined. The two largest series from North America[69] and Europe[68] have demonstrated endoscopic resection to have comparable oncologic results to open surgery. Hanna et al.[69] reported on 120 patients treated at MDACC from 1992 to 2007. An endoscopic endonasal approach was used in 77% of patients, and the cranioendoscopic approach (CEA—defined as transnasal endoscopic approach with the addition of a frontal or subfrontal craniotomy) was used in 23% of patients. Approximately two-thirds of patients in the EEA group had T1 to T2 tumor stage, whereas 95% of patients in the CEA group had T3 to T4 disease stage ($p < 0.01$). Positive margins were reported in 15%. Postoperative radiation therapy or chemoradiotherapy was used in 50% of patients. With a mean follow-up of 37 months, the local, regional, and distant recurrence was 15%, 6%, and 5%, respectively. The 5- and 10-year disease-specific survival (DSS) were 87%

and 80%, respectively (**Fig.** 10.24**A**). Disease recurrence and survival did not significantly differ between the EEA and CEA group (**Fig. 10.24B**). The authors emphasized the role of appropriate adjuvant therapy and treatment by expert multidisciplinary teams in the management of sinonasal malignancies. Nicolai et al.[68] reported on 184 patients from the University of Brescia and the University of Pavia/Insubria-Varese, treated from 1996 to 2006. The overall 5-year DSS was 82%. At the mean follow-up of 34 months, the local, regional, and distant recurrence was 15%, 1%, and 7% of patients, respectively. Both study cohorts had similar distributions of T staging, adjuvant treatment, and the proportion of EEA to CEA (**Table 10.4**). However, compared to the MDACC group, patients in the European group were older, were predominantly male, were less likely to have had prior treatment (28% vs. 58%), and were more likely to present with adenocarcinoma (37% vs. 14%). Irrespective of these differences, the 5-year DSS for the two series is comparable to those reported in the open anterior cranio-facial resection (ACFR) cohorts. Both groups concluded that in well-selected patients, endoscopic resection of sinonasal cancers results in acceptable oncologic outcomes.

From Hanna E, et al. Endoscopic resection of sinonasal cancers with and without craniotomy: oncologic results. *Arch Otolaryngol Head Neck Surg.* 2009;135(12):1219–1224; Nicolai P, et al. Endoscopic surgery for malignant tumors of the sinonasal tract and adjacent skull base: a 10-year experience. *Am J Rhinol.* 2008;22(3):308–316.

The limitations of EEA include lack of binocular vision and depth perception, which is important when dealing with critical neurovascular structures. Ergonomic limitations include the inability of the primary surgeon to control the endoscope and two instruments simultaneously and hence the reliance on

a surgical assistant for camera control during two-handed surgery. The major limitation of EEA is the inability to repair or patch dural defects with suture techniques, which limits the reconstructive options after endoscopic resection of intradural tumors. We continue to explore novel applications in robotic endoscopic skull base surgery to overcome some of these limitations[70]–[73] (**Fig. 10.25**).

The dura is incised or resected to expose the inferior surface of the frontal lobes (FL) intracranially. **G:** Dural repair. Suturing the dural edges, making a loop, and tightening the knot.

Transfacial Approaches: Lateral Rhinotomy and Weber-Fergusson.

Transfacial approaches are the most commonly used surgical approaches for

resection of locally advanced sinonasal tumors. They allow adequate exposure of the nasal cavity, maxillary sinus, pterygopalatine fossa, pterygoid plates, ethmoid sinuses, medial and inferior orbital walls, sphenoid sinus, nasopharynx, clivus, and the medial aspect of the infratemporal fossa.

The *lateral rhinotomy* is the standard incision for exposure of sinonasal tumors through a transfacial approach[44] (**Fig. 10.26**). It can be used alone, or various extensions of the basic incision may be added for further exposure depending on the extent of tumor. The *Weber-Fergusson* incision adds a lip-splitting and subciliary incision for added exposure of the maxillary bone. We prefer to extend the lateral rhinotomy toward the medial brow, a Lynch-type extension, and avoid the subciliary incision of the classic Weber-Fergusson to minimize eye lid complications as will be discussed further under the section on "total maxillectomy."

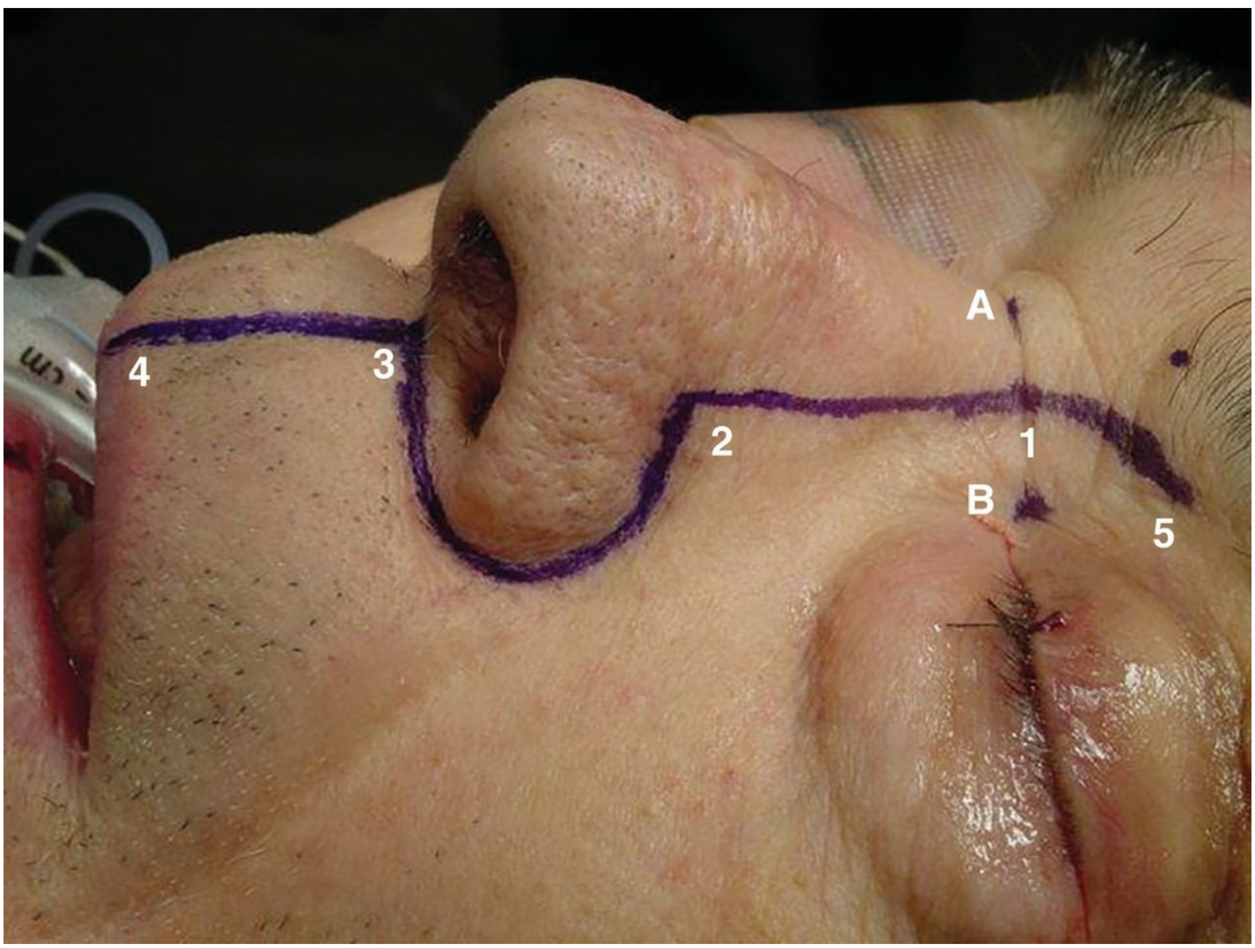

Figure 10.26. Lateral rhinotomy incision (*1*, *2*, *3*) and its extensions (*4*, *5*). The basic lateral rhinotomy incision is outlined by connecting three surface

points. The first point (*1*) is marked half way between the nasion (*A*) and the medial canthus (*B*). The second point (*2*) is where the alar crease begins, and the third point (*3*) is at the base of the columella. The basic incision provides adequate exposure for a medial maxillectomy. The basic incision may be extended to include a lip-splitting extension (*4*) or a “Lynch”-type extension (*5*) if further exposure is necessary. The extended incision provides adequate exposure for a total maxillectomy. A temporary tarsorrhaphy protects the ipsilateral globe.

The basic lateral rhinotomy incision provides adequate exposure when performing a medial maxillectomy. Elevation of the soft tissues of the cheek is done in a subperiosteal plane over the maxilla and around the inferior orbital nerve (**Fig.** 10.27**A**). The attachment of the medial canthal tendon to the nasal bone is released. The periorbita is elevated over the medial orbital wall exposing the lacrimal crest, the lamina papyracea, and the frontoethmoidal suture. This suture serves as a landmark for the position of the floor of the anterior cranial fossa, and when followed posteriorly, leads to the anterior and posterior ethmoidal foramina. The anterior and posterior ethmoidal arteries are cauterized with the bipolar electrocautery, clipped or ligated, and transected (**Fig. 10.27B**). The optic nerve is located 4 to 5 mm posterior to the posterior ethmoidal artery. The orbital floor should be dissected as far lateral as the inferior orbital fissure. The lacrimal sac is identified in its fossa between the anterior and posterior lacrimal crests. If a medial maxillectomy is performed, the lacrimal sac is elevated from the fossa, the lacrimal duct transected, and the sac marsupialized into the nasal cavity to provide adequate drainage of the lacrimal system and to prevent stenosis (**Fig. 10.27C**).

Figure 10.27. A: Elevation of the soft tissues of the cheek is done in a subperiosteal plane over the maxilla and around the inferior orbital nerve (ION). The periorbita is elevated over the anterior lacrimal crest (ACL) to expose the lacrimal sac (LS). **B:** Dissection of the medial periorbita over the lamina papyracea reveals the anterior ethmoid artery at the level of the frontoethmoid suture line, which marks the level of the anterior cranial floor. The artery is coagulated by bipolar electrocautery, clipped or ligated, and then transected. **C:** After the lacrimal sac is transected, it is marsupialized into the surgical cavity as a dacryocystorhinostomy. Silicone stents are placed through the upper and lower canaliculi and brought into the nasal cavity to prevent postoperative epiphora. These stents are removed in about 3 to 6 months. **D:** Medial Maxillectomy. Osteotomies: (*X*) vertically medial to the infraorbital foramen (*arrowhead*), (*Y*) horizontally above the level of dental roots and into the pyriform aperture, and (*Z*) obliquely along the nasomaxillary suture line. If the lateral nasal wall is to be resected, the lacrimal sac (*arrow*) is transected and marsupialized into the nasal cavity. **E:**Postoperative appearance of a lateral rhinotomy incision.

Transoral or Transpalatal Approach.

The transoral approach is ideally suited for exposure of the palate, alveolar ridge, and inferior maxilla. The approach utilizes a combination of the sublabial gingivobuccal sulcus incision, and a palatal incision. It is most commonly applied for inferior (infrastructure) maxillectomy. It can also be used for tumors limited to the upper alveolar ridge and hard palate.

The transpalatal approach is usually performed by elevating a posteriorly based palatal flap and removal of the posterior aspect of the hard palate to expose the posterior choanae and nasopharynx. It allows adequate exposure for excision of limited tumors of the posterior nasal cavity and nasopharynx such as juvenile nasopharyngeal angiofibroma.

Midfacial Degloving and Sublabial Approaches.

The midfacial degloving approach is most commonly used in the management of large benign lesions of the sinonasal region and skull base such as juvenile nasopharyngeal angiofibroma, for selected malignancy in this area and to afford access to the nasopharynx and infratemporal fossa. The main advantage of the “degloving” approach is that an external facial incision is avoided. Another advantage is providing simultaneous exposure to the inferior and medial maxilla, bilaterally (**Fig. 10.28**). This is particularly helpful when approaching tumors with bilateral involvement of the nasal cavity and maxillary sinus. A major disadvantage, however, is the limited superior and posterior exposure and the need for constant retraction of the soft tissue envelope for continued adequate exposure.

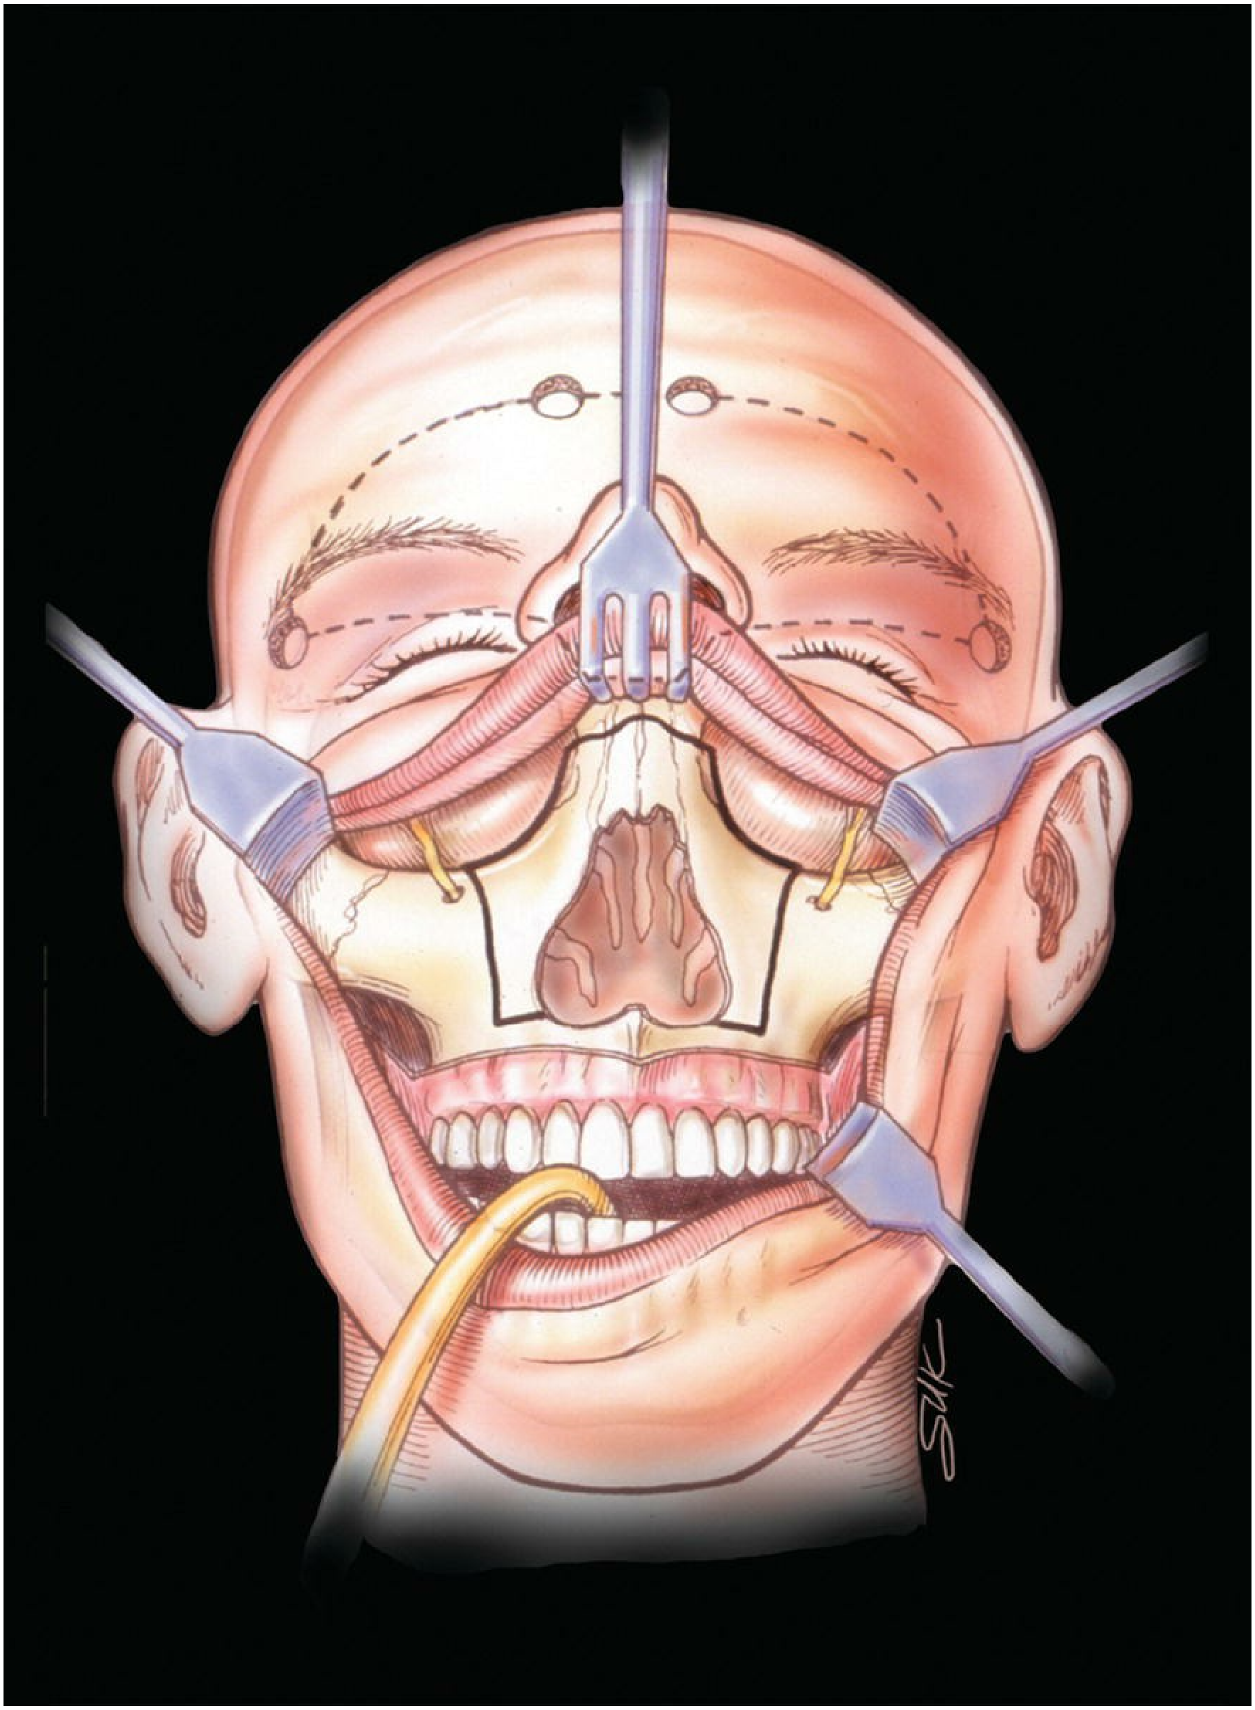

Figure 10.28. Sublabial "facial degloving" approach. In addition to avoiding facial incisions, it has the advantage of providing bilateral access to the medial and inferior maxillary segments.

The midfacial degloving approach requires a basic level of proficiency and understanding of closed rhinoplasty incisions. It involves a complete transfixion incision of the membranous septum. This is joined endonasally with a bilateral intercartilaginous incision, with soft tissue elevation over the nasal dorsum as far superior as the nasal root. The nasal skeleton is therefore "degloved" from overlying soft tissues as far lateral as the pyriform aperture. A gingivobuccal incision extends bilaterally across the midline to both maxillary tuberosities laterally. Subperiosteal dissection is continued cephalad over the face of both maxillae. The dissection joins the nasal degloving using sharp dissection over the pyriform aperture attachments (Fig. 10.28).

The sublabial approach may also be used to access tumors of the sphenoclival region such as chordoma, particularly if the lesion extends lower than the horizontal plane of the palate, for example, the lower third of the clivus and craniovertebral junction (**Fig. 10.29**). A Le-Forte I osteotomy is done, and the maxilla is displaced inferiorly after posterior osteotomies separate the maxilla from the pterygoid plates. We prefer a combination of unilateral or half a Le-Forte I osteotomy with a median or paramedian palatal osteotomy for better displacement of the maxilla inferiorly and laterally. This offers wider exposure because it avoids the cantilever effect of the posterior maxilla upward restricting exposure when the anterior maxillary segment is displaced inferiorly when the bilateral (complete) Le-Forte osteotomy is used.

Extent of Resection

Medial Maxillectomy.

The most common indication for medial maxillectomy is in the treatment tumors of the nasal cavity, lateral nasal wall, and medial maxillary sinus (Fig. 10.18). Medial maxillectomy includes removal of the lateral nasal wall and the medial maxillary segment bounded laterally by the infraorbital nerve. In addition, a complete sphenoethmoidectomy is usually performed.

The incision most commonly used for exposure is the lateral rhinotomy (Fig. 10.26). Alternatively, a midfacial degloving may be used and is preferable if bilateral medial maxillectomy is needed (Fig. 10.28). Endonasal endoscopic medial maxillectomy and sphenoethmoidectomy may be also performed for appropriately selected tumors (Fig. 10.22).

If the lateral rhinotomy is performed and soft tissue exposure is completed as discussed in the previous section, *osteotomies* are done as shown in Figure 10.27D, and the anterior wall of the maxillary sinus above the level of dental roots and medial to the infraorbital nerve is removed. Lateral to the infraorbital foramen, the anterior wall antrostomy may be enlarged to expose the zygomatic recess of the antrum.

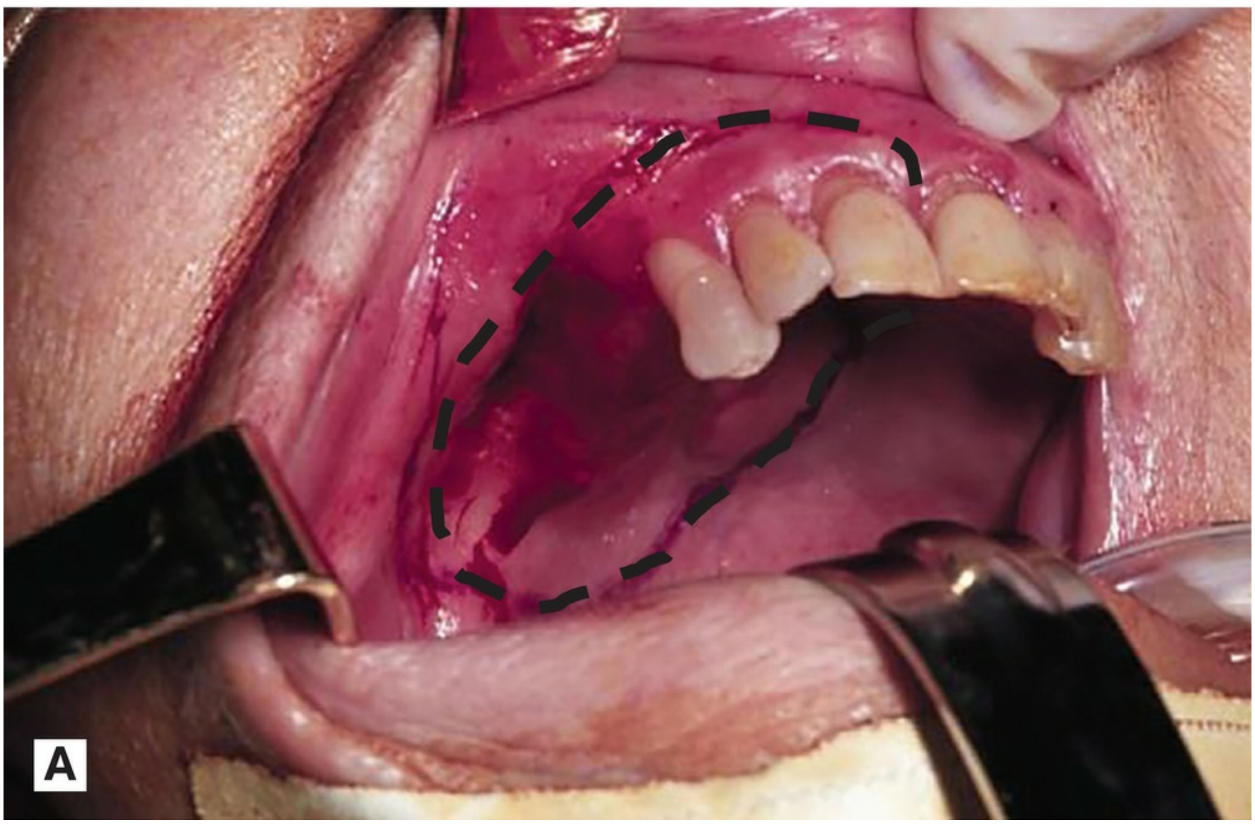
Resection of the lateral nasal wall begins with an inferior osteotomy along the nasal floor below the attachment of the inferior turbinate, starting at the pyriform aperture, and carried posteriorly to the posterior maxillary wall. With the orbit retracted laterally and protected with a malleable brain retractor, the lamina papyracea is identified and, if necessary, resected. A complete sphenoethmoidectomy is done, staying below the level of the frontoethmoidal suture to avoid injury to the floor of the anterior cranial fossa. The superior attachment of the middle turbinate is then transected along the roof of the nose. Posteriorly, the lateral nasal wall cuts are connected with right-angled scissors behind the turbinates. The specimen is thus delivered and examined for margins with frozen section control. If the tumor involves the nasal septum, it should be included in the resection specimen by adding appropriate septal cuts to allow for tumor-free margins.

Closure is begun by reattachment of the medial canthal tendon to the nasal bone in its anatomic position. Meticulous multilayered closure of the lateral rhinotomy is performed and usually results in excellent healing and acceptable postoperative appearance (Fig. 10.27E). If a sublabial approach is done, the mucosal incisions are closed with absorbable suture. Adequate

nonadherent nasal packing may be left for 1 to 2 days.

Inferior Maxillectomy.

This procedure involves resection of the inferior maxillary sinus below the plane of the infraorbital nerve. It is most commonly used for neoplasms of the alveolar process of the maxilla with minimal extension to the maxillary antrum. Similarly, lesions of the hard palate sparing the antrum can be treated by an inferior maxillectomy. A combination of sublabial and palatal incisions is usually used for exposure, and osteotomies are done around the lesion, ensuring an adequate margin of resection (**Fig. 10.30**). Alternatively, a midfacial degloving can be used for lesions crossing the midline and involving the inferior maxilla bilaterally.



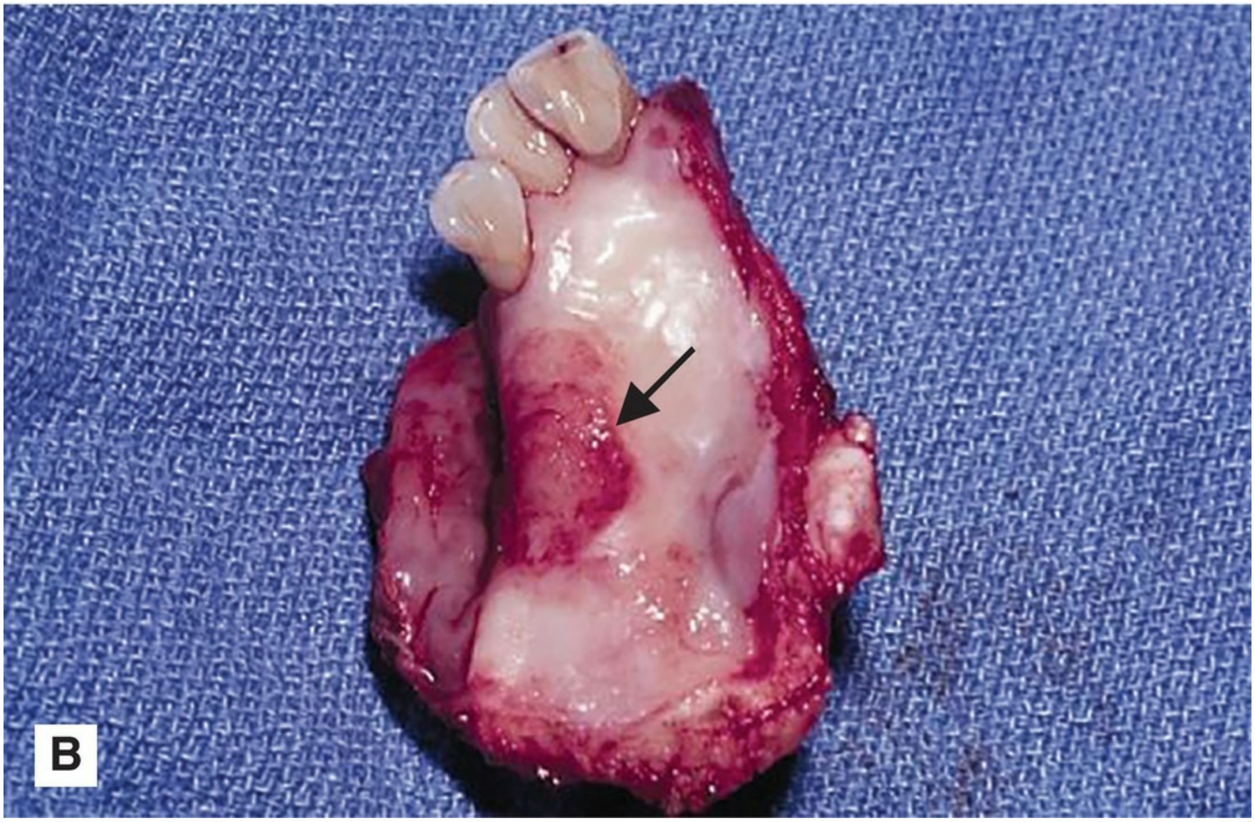


Figure 10.30. Inferior maxillectomy. Gingivobuccal and palatal incisions and osteotomies are done around the lesion as shown in **(A)**. If there is adequate space between the central incisors, the osteotomy may be performed using a micro-reciprocating saw in the interincisor space. Otherwise, the ipsilateral central incisor should be extracted and the osteotomy placed in the tooth socket in order to avoid loss of bony support to the remaining contralateral incisor. Inferior maxillectomy specimen **(B)** showing adequate surgical margins around an upper alveolar ridge carcinoma (*arrow*).

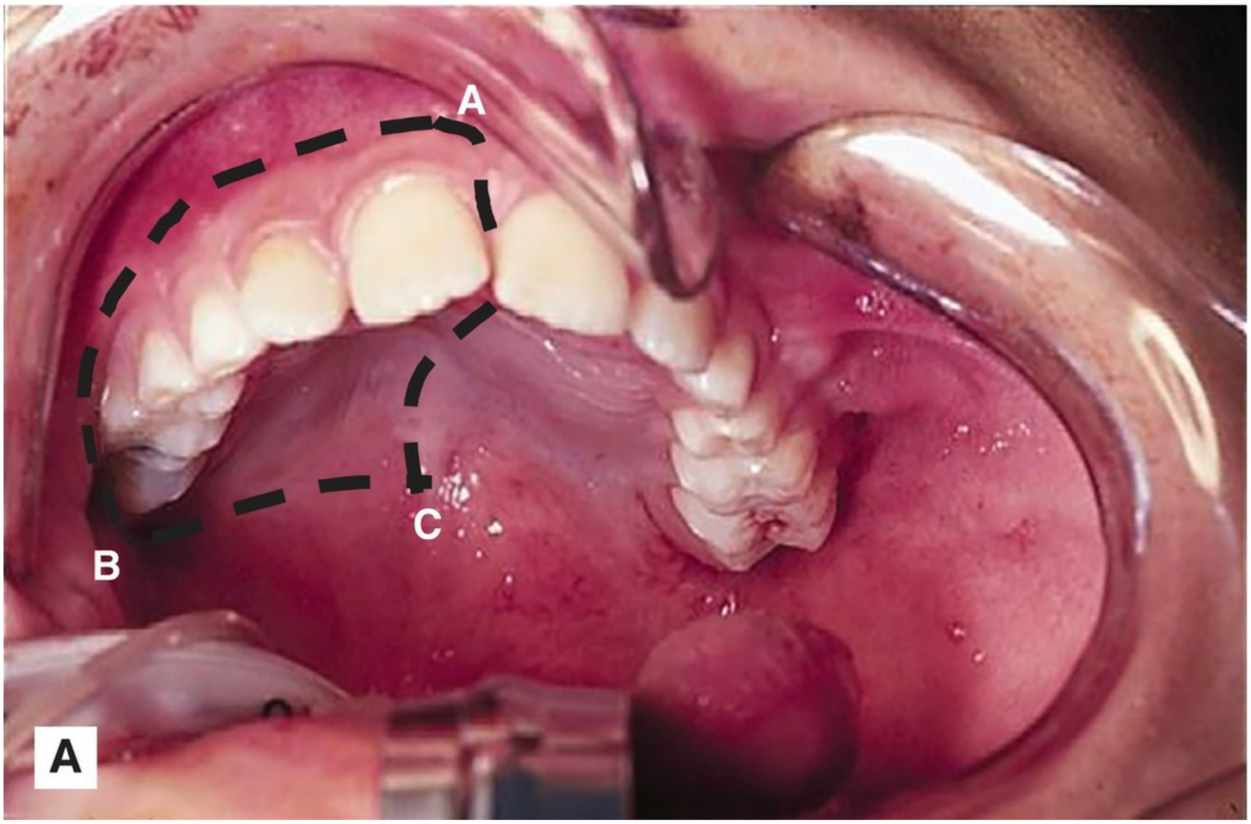
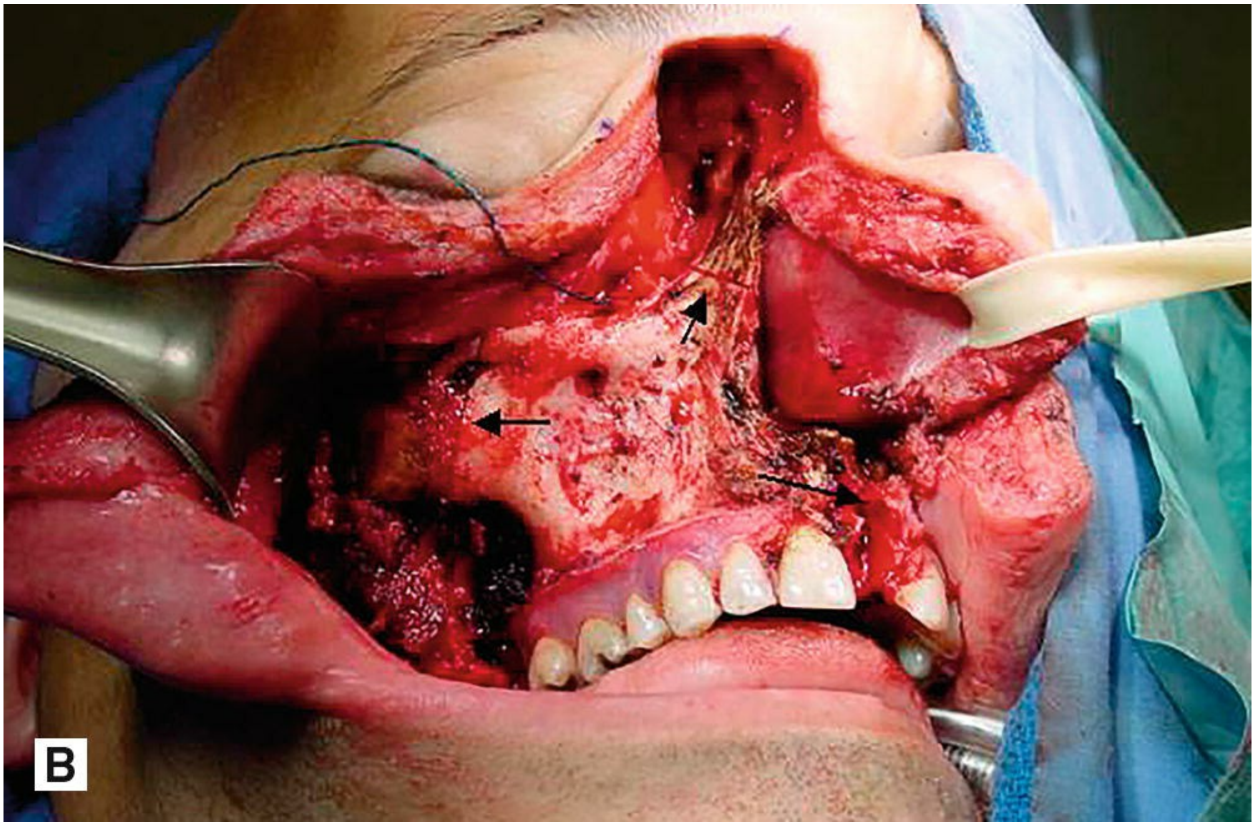
Total Maxillectomy.

If the extent of resection requires a total maxillectomy, the lateral rhinotomy incision may be extended by adding lip-splitting, gingivobuccal, and palatal incisions inferiorly. The lip-splitting incision, which may be done along the philtrum or in the midline, connects the lateral rhinotomy with the sublabial incision, thus allowing more lateral elevation of the facial flap. The gingivobuccal incision starts from the lip-splitting incision and extends as far laterally as the region of the first molar and over the lateral surface of the maxillary tuberosity. In patients undergoing total maxillectomy, a median or

paramedian palatal incision is performed over the hard palate extending from an interincisor space anteriorly, to the junction of the soft and hard palate posteriorly. The incision then continues laterally between the hard and the soft palate to curve posterolaterally around the maxillary tuberosity meeting the gingivobuccal incision (**Fig.** 10.31**A**).





B

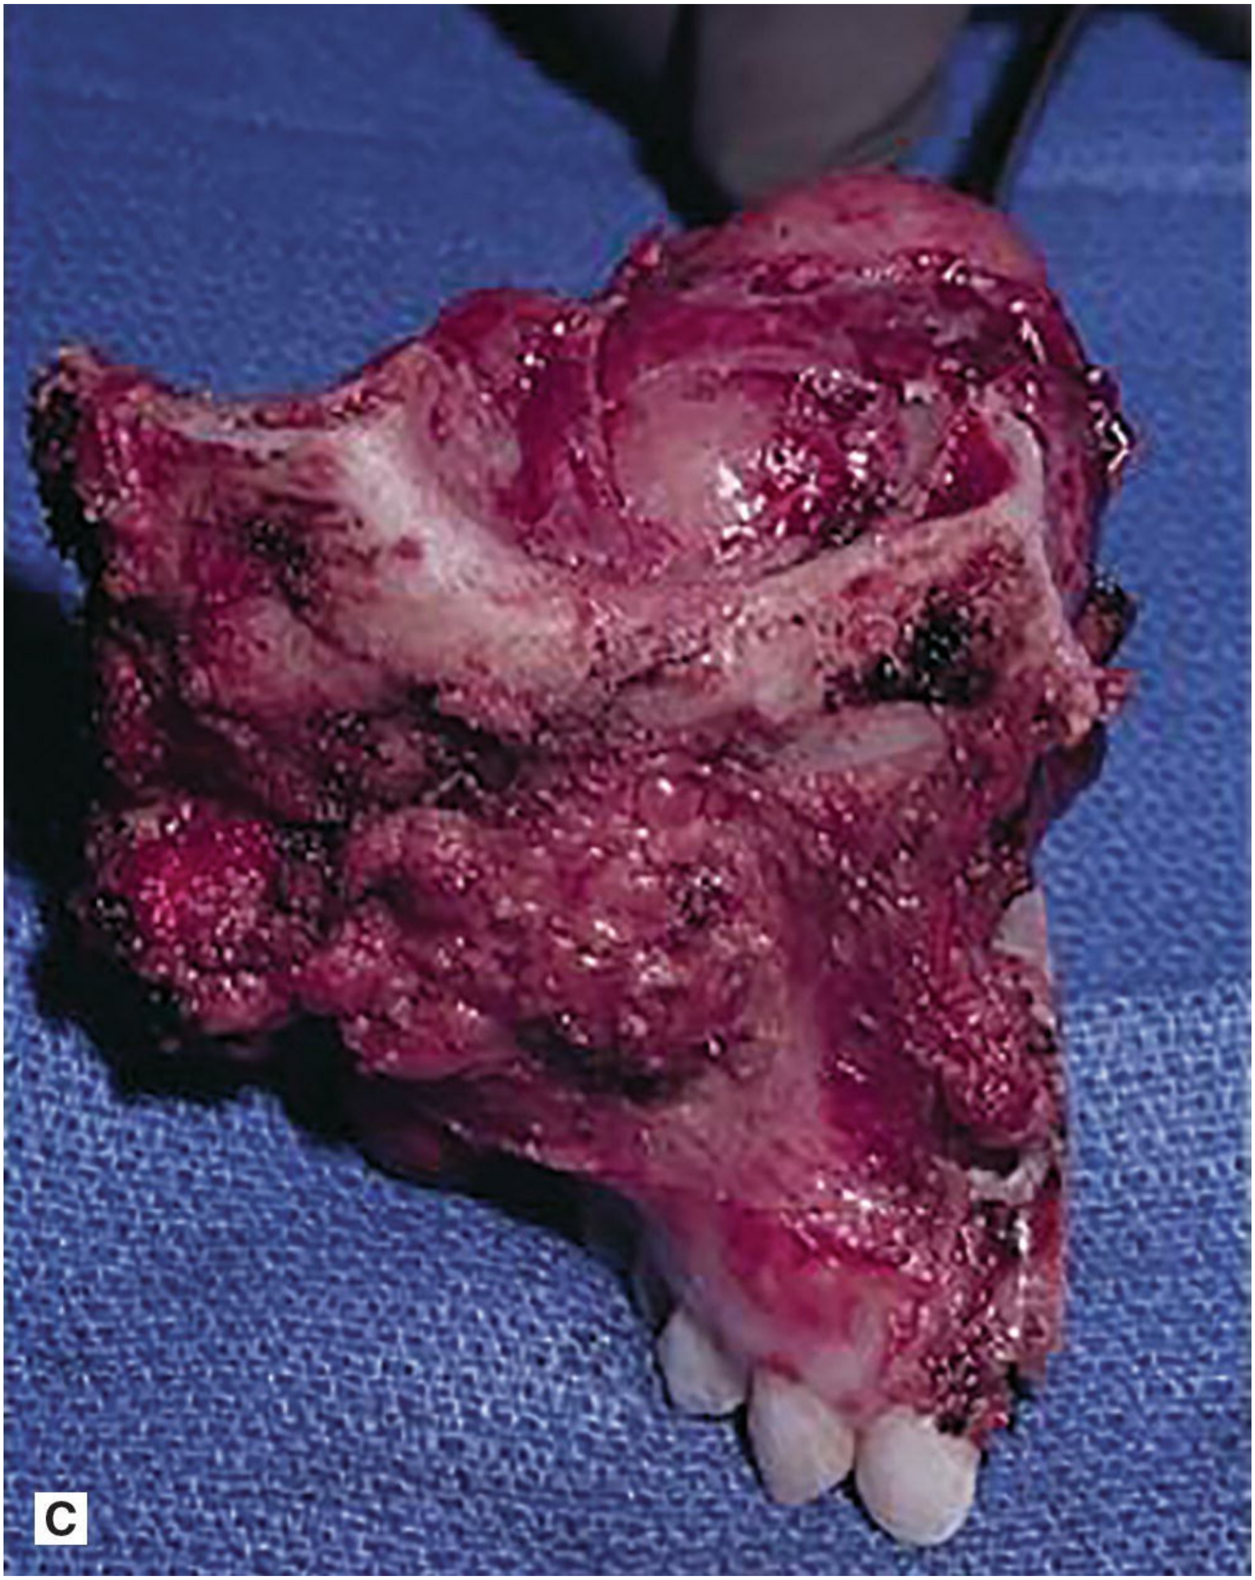


Figure 10.31. Total maxillectomy. **A:** Intraoral incisions. **B:** The exposure offered through an extended lateral rhinotomy shown in this figure is not less than that offered by the Weber-Fergusson incision. The advantage of the

former is avoiding a subciliary incision and its potential for lower eyelid ectropion and edema. Osteotomies have been performed as indicated by the *arrows*. **C:** En bloc resection specimen. Note tumor involvement of the orbital floor, which had to be resected. The tumor did not transgress the periorbita therefore the eye was preserved.

In patients undergoing total maxillectomy with orbital preservation, we prefer to extend the lateral rhinotomy superiorly beneath the medial brow rather than laterally through a subciliary incision used in the classic Weber-Fergusson approach (**Fig. 10.31B**). We described several advantages to this modification.[74] First, avoiding a subciliary incision eliminates any disruption to the lower lid skin–muscle–tarsus complex that minimizes lower eyelid complications, particularly ectropion and prolonged eyelid edema. Another advantage is avoiding trifurcation of the incision reducing the risk of skin breakdown at the medial canthal area. This is especially important for previously irradiated patients, who are more prone to develop medial canthal skin dehiscence. Similarly, because the vascularity of the thin lower eyelid skin is not affected with the extended lateral rhinotomy incision, patients who undergo orbital floor reconstruction with implants such as titanium mesh have less chance to develop wound breakdown and implant exposure. Although the extended lateral rhinotomy incision has several functional and cosmetic advantages, it does not compromise exposure and provides an adequate approach for a safe oncologic resection. The extension of the lateral rhinotomy incision beneath the medial eyebrow shifts the fulcrum of rotation of the soft tissue flap superiorly and laterally enhancing lateral exposure, which is not less from that obtained with a classic Weber-Fergusson incision (Fig. 10.31B). Transection of the infraorbital nerve allows even more lateral and posterior elevation of the soft tissues, to expose the entire maxillary bone as far lateral as its zygomatic extension and posteriorly to the pterygomaxillary fissure and over the pterygoid plates. Additionally, its postoperative cosmetic appearance is superior to the Weber-Fergusson incision (Fig. 10.27E).

Whichever incision is used, elevation of the facial flap is usually done in the subperiosteal plane. However, if the tumor has invaded the anterior wall of the maxillary antrum, a supraperiosteal plane is utilized. Occasionally, the cheek skin overlying the maxilla is included with the specimen, if it is involved with tumor. With the globe protected with a temporary tarsorrhaphy

stitch, the periorbita is dissected along the medial, inferior, and lateral orbital walls.

Lateral osteotomies are performed along the frontal and temporal processes of the zygoma (Fig. 10.31B). Medial osteotomies are done along the frontal process of the maxilla, and along the medial orbital wall just below the frontoethmoidal suture, extending posteriorly to the level of the posterior ethmoidal foramen. The medial and lateral osteotomies are then connected superiorly across the orbital floor along the inferior orbital fissure. Inferiorly, a midline sagittal osteotomy is made across the hard palate. The ipsilateral central incisor should be preserved, if possible, to enhance prosthesis retention. Finally, after the internal maxillary artery is identified at its entrance through the pterygomaxillary fissure, ligated, and transected, a posterior osteotomy is done to disarticulate the maxilla from the pterygoid plates. The maxilla is delivered by anteroinferior traction, whereas remaining soft tissue attachments are cut using a curved heavy scissors. Bleeding is usually encountered at this point and is controlled by temporary packing of the cavity, followed by electrocoagulation of bleeding mucosal surfaces or ligature of bleeding points. The pterygoid plexus of veins may be a source of persistent bleeding and can be managed by haemostatic figure-of-8 sutures and Surgicel packing. Bleeding is usually minimized if the internal maxillary artery is ligated before the posterior osteotomy is done along the pterygomaxillary fissure.

Total maxillectomy usually involves removal of the entire maxillary bone including the palate and the orbital floor (**Fig. 10.31C**). Preservation of the orbital floor (subtotal maxillectomy) or the palate (suprastructure maxillectomy) may be done if these structures are not involved by tumor. Depending on the extent of the lesion, resection may extend beyond the posterior wall to the pterygopalatine fossa and pterygoid plates. Perineural spread of tumor along V2 may be resected by following the nerve through foramen rotundum and into Meckel cave[75] (**Fig. 10.32**).

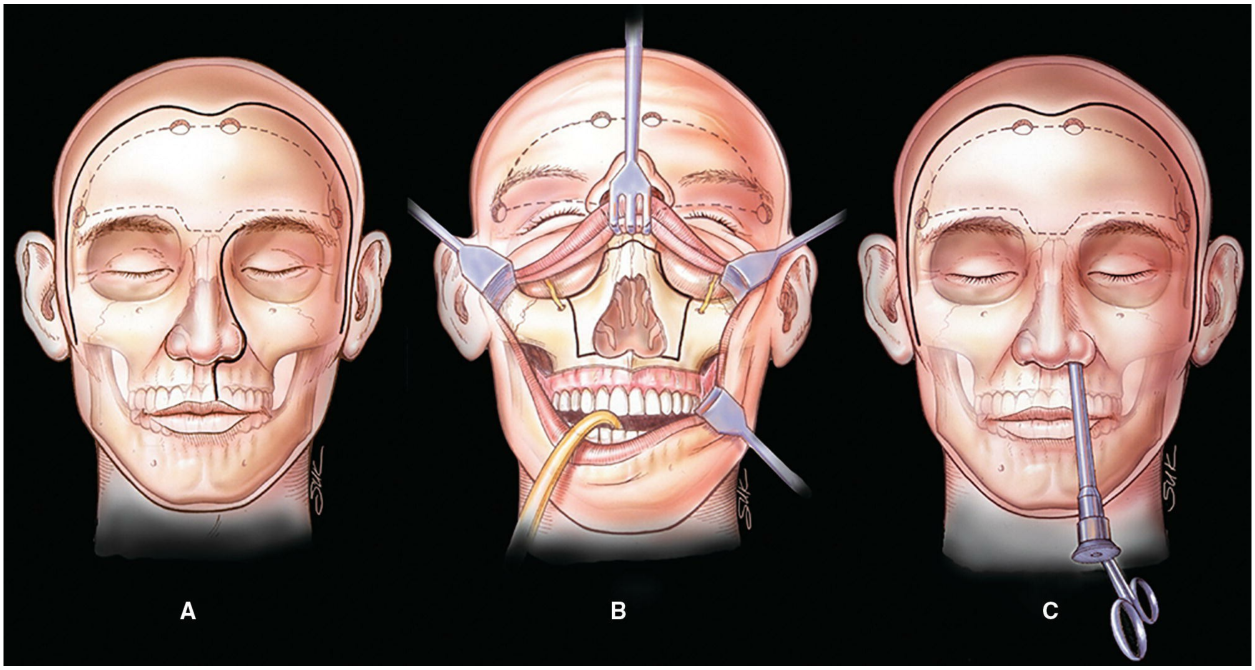

Figure 10.32. Anterior craniofacial resection: Extracranial approaches. In addition to the frontal craniotomy, the extracranial approach may be transfacial **(A)**, sublabial **(B)**, or endonasal **(C)**.

Craniofacial Resection.

Surgical resection of the *anterior* cranial base is commonly indicated for patients with sinonasal tumors involving the cribriform plate or fovea ethmoidalis. This is done, by definition, for most cases of ENB, as well as carcinoma of the ethmoid or maxillary sinuses approaching or involving the anterior cranial base (Fig. 10.16). Tumors transgress the cribriform plate either by direct bony invasion or by perineural spread along the filaments of the olfactory nerves. The dura of the anterior cranial fossa forms a barrier that delays, to a certain extent, brain invasion. Dural resection in patients with intracranial but extradural disease or patients with limited dural involvement often provides an adequate oncologic margin. However, malignant tumors that transgress the dural barrier and involve the underlying brain parenchyma are usually associated with poor prognosis.[53] However, even in some cases with limited frontal lobe involvement, anterior craniofacial resection may still be indicated for local control of the disease.

Resection of the floor of the *middle* cranial fossa is sometimes performed in patients with sinonasal tumors to achieve tumor-free surgical margins for

lesions extending to the roof of the infratemporal fossa or for those tumors that exhibit perineural spread along the branches of the trigeminal nerve to the gasserian ganglion, most commonly ACC.[44]

Craniofacial approaches combine extra- and intracranial access to the anterior and lateral skull base. Extracranial approaches may include transfacial, sublabial, or endonasal approaches as previously described[44] (Fig. 10.32).

The *bicoronal incision* starts in a preauricular crease anterior to the tragus. Careful dissection and preservation of the superficial temporal artery should be done. The scalp incision is extended in the coronal plane, staying behind the hairline along its entire course, to the contralateral preauricular region. We prefer to gently curve the incision anteriorly at the midline (**Fig.** 10.33**A and B**). The scalp flap is elevated in a subgaleal plane superficial to the pericranium between the superior temporal lines bilaterally. Lateral and inferior to the superior temporal lines, an incision is made through the superficial layer of the temporalis fascia 1 to 1.5 cm. posterior to the superior orbital rim and extends posteriorly parallel to the course of the zygomatic arch (**Fig. 10.33C**). Dissection proceeds at the plane of the deep layer of the temporalis fascia to preserve the frontal branch of the facial nerve, which is superficial to the fascia. The scalp flap is elevated anteriorly toward the superior orbital rims and posteriorly toward the vertex.

E

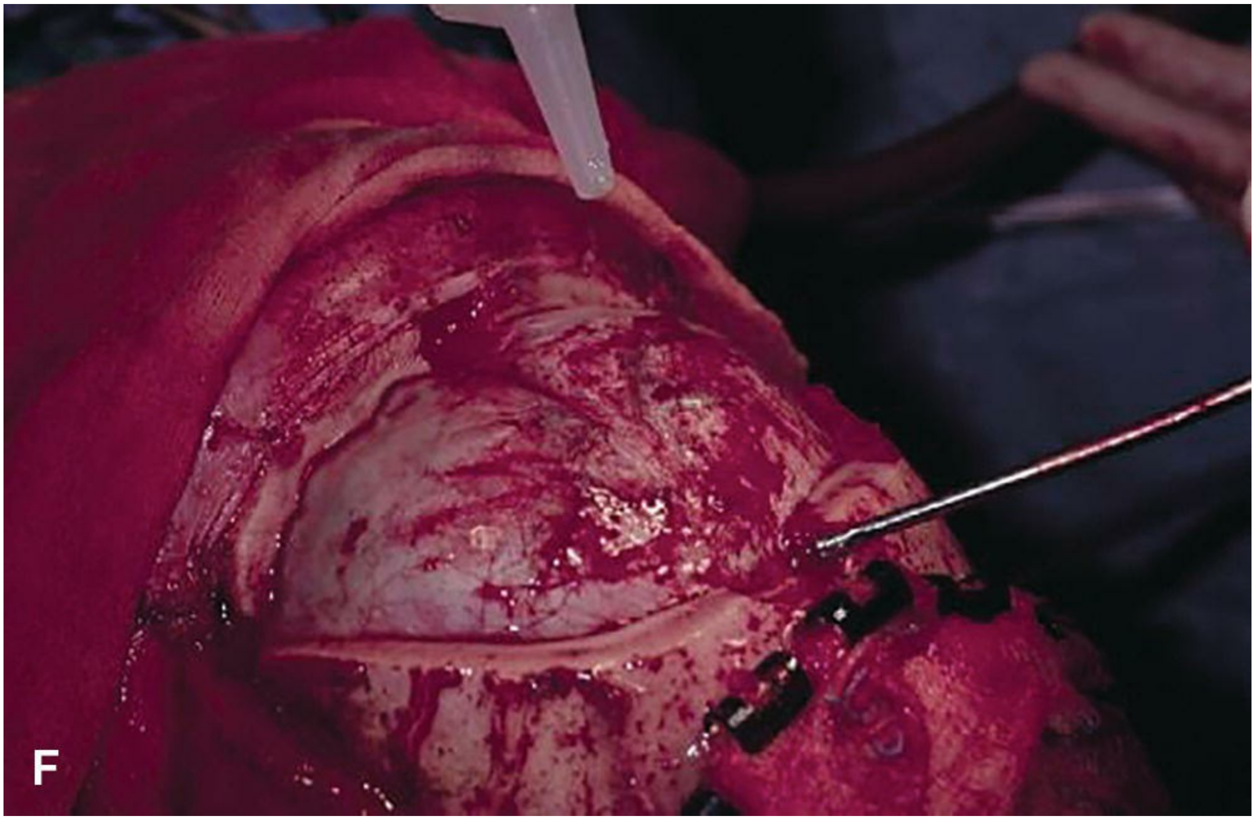

Figure 10.33. Frontal craniotomy. **A, B:** Bicoronal incision. **C:**Incision of the superficial layer of the deep temporalis fascia. Further dissection is done deep to this plane to preserve the frontal branch of the facial nerve. **D:** The pericranial flap. Adequate length and good vascular supply of the flap are prerequisites for effective reconstruction of the skull base defect. **E:**Frontal craniotomy (schematic). **F:** Frontal craniotomy (intraoperative photograph).

Pericranial incisions are made as far posteriorly as necessary to provide adequate length for the pericranial flap and along the superior temporal lines bilaterally. The pericranial flap is dissected free from the underlying bone and reflected anteriorly (**Fig. 10.33D**). Careful dissection and preservation of the supraorbital neurovascular pedicles are necessary in providing a well-vascularized pericranial flap for reconstruction of the cranial base defect. The supraorbital nerves and vessels are located along the medial one-third of the superior orbital rim. Elevation of the supraorbital rim periosteum begins laterally and proceeds medially, until the margin of the supraorbital groove is carefully exposed with a fine elevator. The nerve and vessels may exit the skull either through a notch or a true foramen. If a notch is present, then the nerve can be dissected free without difficulty. If a foramen rather than a notch

is found, the floor of the foramen is removed with a fine osteotome. This liberates the pedicle, and further elevation of the superior periorbita is then achieved. The periorbita is dissected free from both the superior and medial orbital walls bilaterally. The anterior ethmoidal vessels may by electrocoagulated by bipolar diathermy.

Frontal, temporal, or frontotemporal craniotomy is then performed to allow access to the floor of the anterior or middle cranial fossa or both, respectively. For a *frontal craniotomy*, bilateral burr holes are then placed in the depression posterior to the frontal-zygomatic sutures, after reflection of the temporalis muscle leaving a cuff of muscle at the superior temporal line for reattaching the muscle during closure (**Fig. 10.33E**). These anatomic keyholes provide access to the anterior fossa dura and periorbita, separated by the bony orbital roof. Burr holes are then placed on either side of the SSS, well anterior to the coronal suture. The bifrontal craniotomy is performed between the burr holes, with the burr holes straddling the SSS connected last. The dura of the anterior fossa is dissected from the orbital roofs. Under direct vision, orbital roof osteotomies are performed using a small osteotome.

Compared to frontal craniotomy, *subfrontal approaches* have the advantage of minimizing brain retraction by providing wider and more direct exposure of the floor of the anterior cranial fossa[44] (**Fig. 10.34**). This is especially helpful in more posteriorly located lesions such as those involving the planum sphenoidale, clivus, orbital apex, and optic chiasm (**Fig. 10.35**). The subfrontal approach is done by adding osteotomies that allow incorporation of the superior orbit and/or nasal bone to the craniotomy. These skeletal elements may be removed in several subunits or as a single bone flap (**Fig. 10.36**). Bilateral *nasal osteotomies* are done along the lower border of the nasal bones and then along the suture line between the nasal and lacrimal bones (Fig. 10.36C). The osteotomies are connected across the midline below the frontoethmoid suture line and in front of the anterior ethmoidal vessels. This avoids injury to the cribriform plate and olfactory nerves. After the dura and periorbita have been carefully dissected from the bone, the lateral wall and roof of each orbit are removed in separate *orbital osteotomies* (Fig. 10.36C). Under direct visualization, taking care to protect the periorbita and dura, an anteroposterior cut is made at the medial aspect of the orbital roof staying lateral to the ethmoid sinus. A second anteroposterior cut is made at the inferior aspect of the lateral orbital wall. These cuts are connected

posteriorly taking care to avoid the SOF. The bone flap consisting of the frontal bone, orbital roof, superior–lateral orbital rims, and nasal bones can be removed for wide exposure (Fig. 10.36D and E).

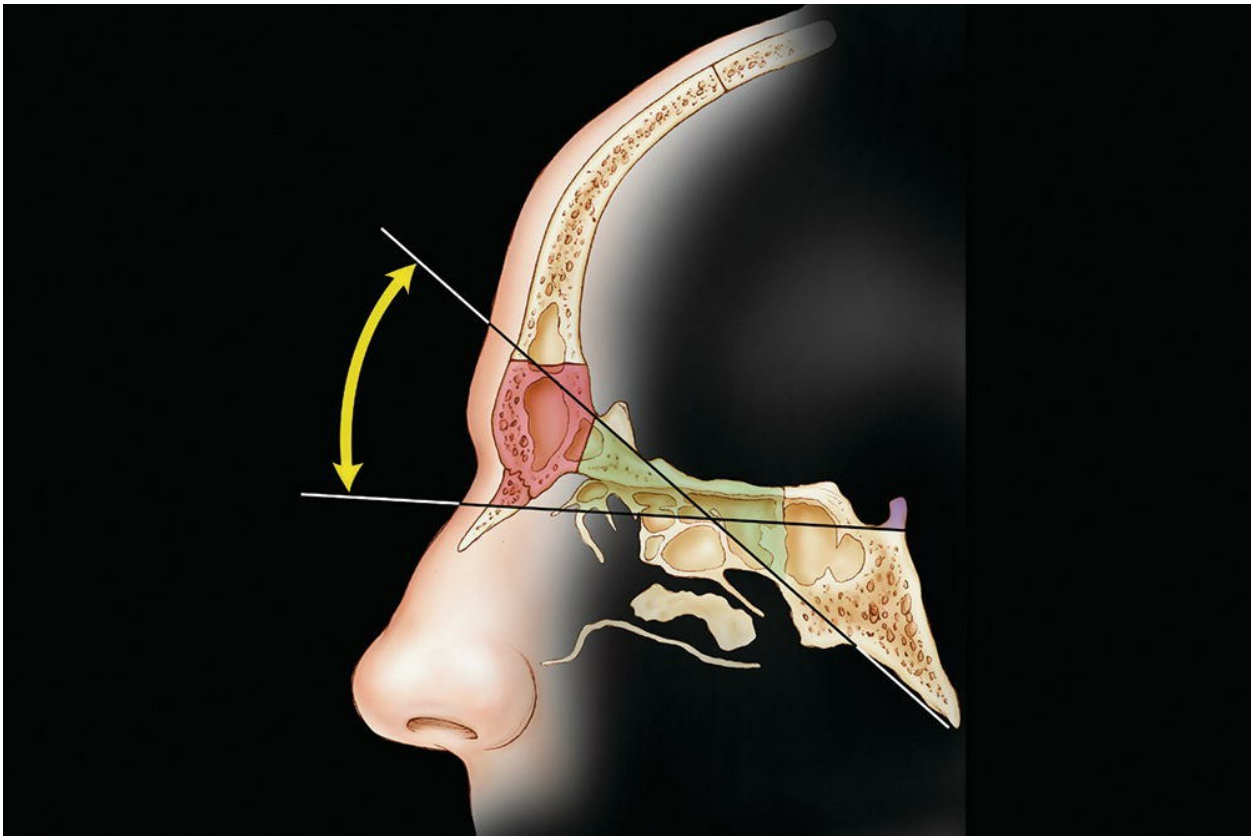

Figure 10.34. Subfrontal approach. Note the increased basal exposure provided by the subfrontal approach by incorporating the supraorbital rim, glabella, and nasal bone with the frontal craniotomy.

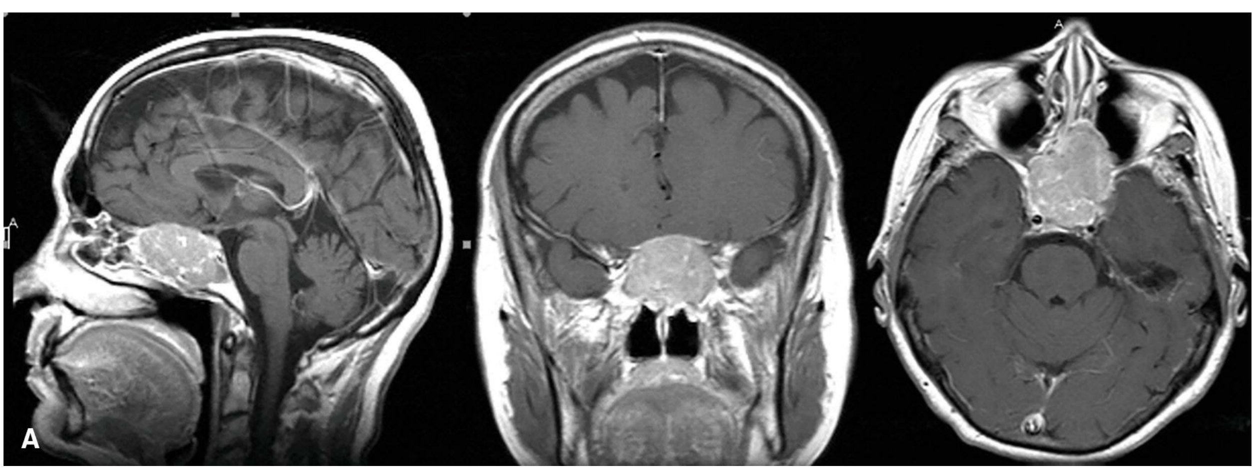

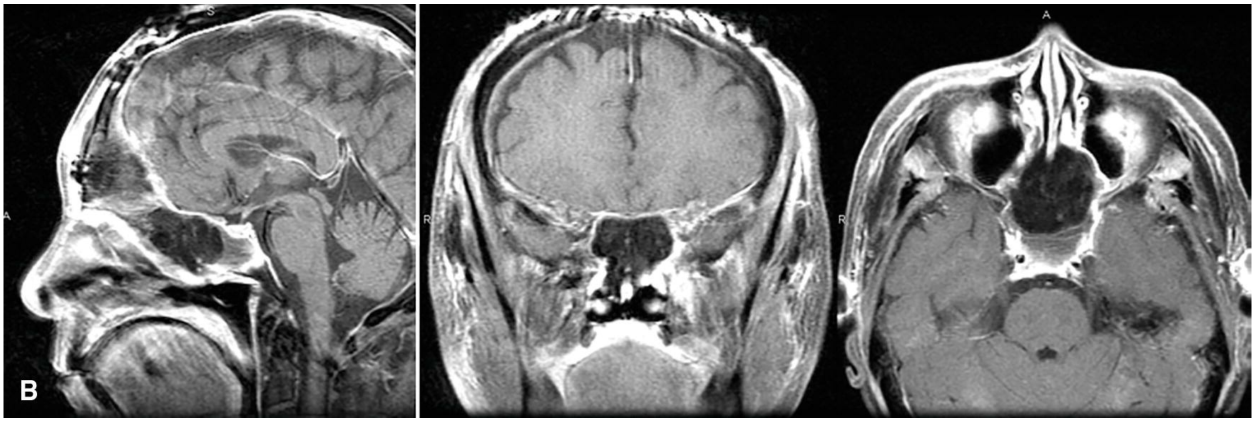

Figure 10.35. Pre- **(A)** and postoperative **(B)** MRI of tumor involving the planum sphenoidale and upper two-thirds of the clivus removed via a subfrontal approach.

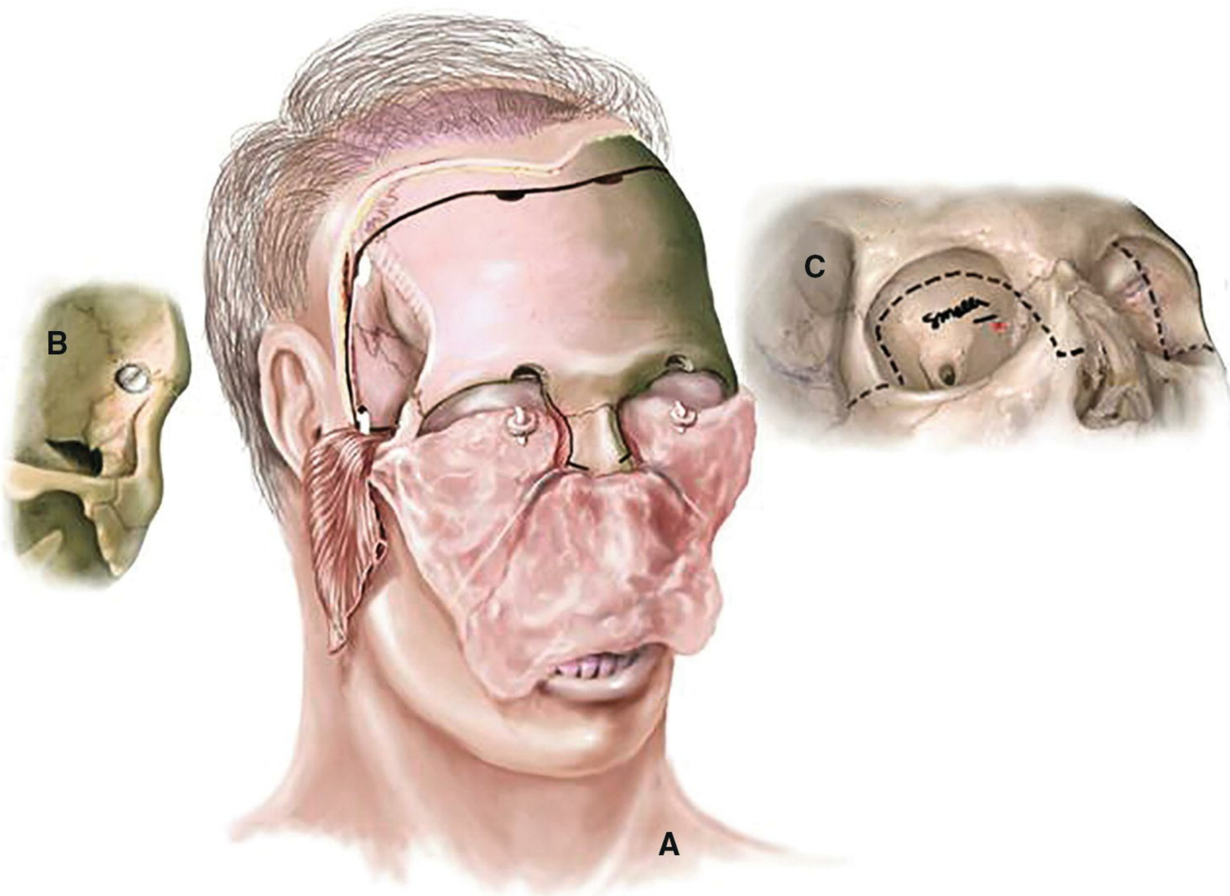

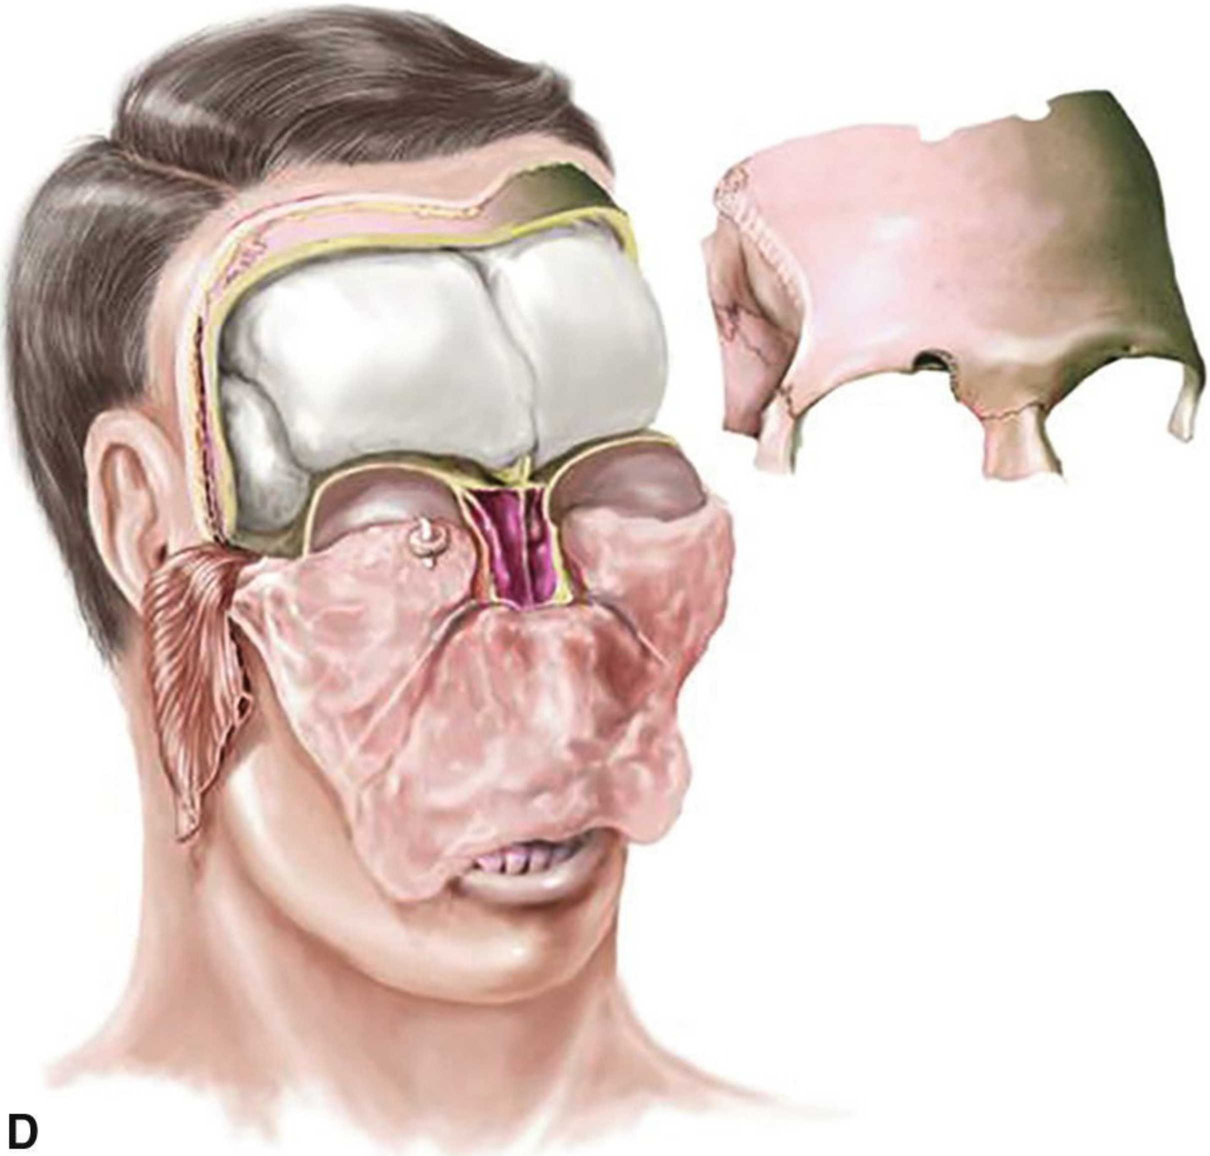

D

Figure 10.36. Subfrontal approach. **A:** Bicoronal incision and soft tissue dissection. The scalp flap is reflected anteriorly down to the level of the nasal bones. The supraorbital nerves were surrounded by complete foramina rather than a notch. Osteotomies around the foramina allow downward reflection of the nerves with the soft tissue flap. Burr holes are placed on either side of the SSS, anterior to the coronal suture. **B:** Bilateral burr holes are placed posterior to the frontal–zygomatic sutures. These anatomic keyholes provide access to the anterior fossa dura and periorbita, separated by the bony orbital roof. **C:** Orbital and nasal osteotomies. **D and E:** The cranio-orbital-nasal bone flap is removed as a single unit as illustrated by the diagram **(D)**, and intraoperative photograph **(E)**.

After completing the craniotomy, brain "relaxation" is achieved by withdrawing 25 to 50 mL of CSF from the lumbar subarachnoid drain, hypocapnia through controlled hyperventilation, mannitol diuresis, or steroids. This also lessens the need for brain retraction, which minimizes postoperative brain edema.[44] Next, the *dura* is carefully dissected along the floor of the anterior cranial fossa to expose the crista galli and olfactory grooves. The *olfactory nerves* are transected to expose the cribriform plate.

Dural elevation is continued to expose the fovea ethmoidalis and orbital roofs. Posteriorly, the planum sphenoidale and the base of the anterior clinoid process may be exposed as dictated by the extent of the tumor. If the dura is involved by the tumor, dura incisions are made around the tumor, and the dissection proceeds in a subdural plane, and the dura and even brain tissue if involved are resected along with the tumor.

With simultaneous exposure provided superiorly through the intracranial approach and inferiorly through the extracranial approach, osteotomies of the cranial floor around the tumor can be safely completed. Malleable retractors are used to protect the brain and the orbit as osteotomies are made. The placement of osteotomies and the extent of resection are dictated by the extent of tumor involvement and tailored in each case. Typically, however, osteotomies are made from the planum sphenoidale, along the roof of the ethmoid, and forward to the front of the cribriform plate (**Fig. 10.37**). Frozen section control of the margins should be done to ensure the adequacy of resection.

Management of the Orbit.

Every effort should be made to preserve the eye as long as preservation does not compromise the adequacy of oncologic resection. Attempts at orbital preservation in the face of gross residual disease however usually result in poor disease control and ultimate loss of orbital function. Most studies have shown that if orbital invasion is limited to the bony orbit or the periorbita, orbital preservation is possible without compromising oncologic outcome.[44,76] Orbital exenteration is usually indicated when there is gross invasion of the periocular fat, extraocular muscles, or optic nerve. The presence of proptosis or diplopia may be due to displacement rather than invasion of the intraorbital contents. Decreased visual acuity or visual fields,

or the presence of an afferent pupillary defect, usually indicates gross invasion of the orbit. Orbital invasion by perineural spread rather than direct extension may be missed unless careful examination of the cranial nerves especially V1 and V2 is done. Detailed neuro-ophthalmologic examination should be conducted on all patients with suspected or confirmed orbital involvement by sinonasal or other skull base tumors. If orbital exenteration is contemplated, always make sure that the patient has useful vision in the contralateral eye.

In the absence of any ocular signs or symptoms, however, evaluation of the extent of orbital involvement relies mainly on imaging. High-resolution CT and MRI are complimentary and provide critical information regarding the extent of orbital bony and soft tissue involvement, respectively. CT scans obtained at 1- to 3-mm slices with detailed bone windows are best for evaluating bony involvement of the orbital walls. MRI is best used to evaluate the extent of soft tissue invasion beyond the periorbita (**Fig. 10.38**). MRI is also useful in detecting perineural spread proximally beyond the orbital apex and into the CS or optic chiasm, which compromises surgical margins, local disease control, and survival and as such is a contraindication for surgical resection.[34] Even with the best imaging techniques, the definitive and most accurate assessment of the extent of orbital invasion and whether the eye could be preserved has to be made intraoperatively. This needs to be clearly discussed with the patient and family, and an informed consent for possible exenteration needs to be obtained in high-risk cases.

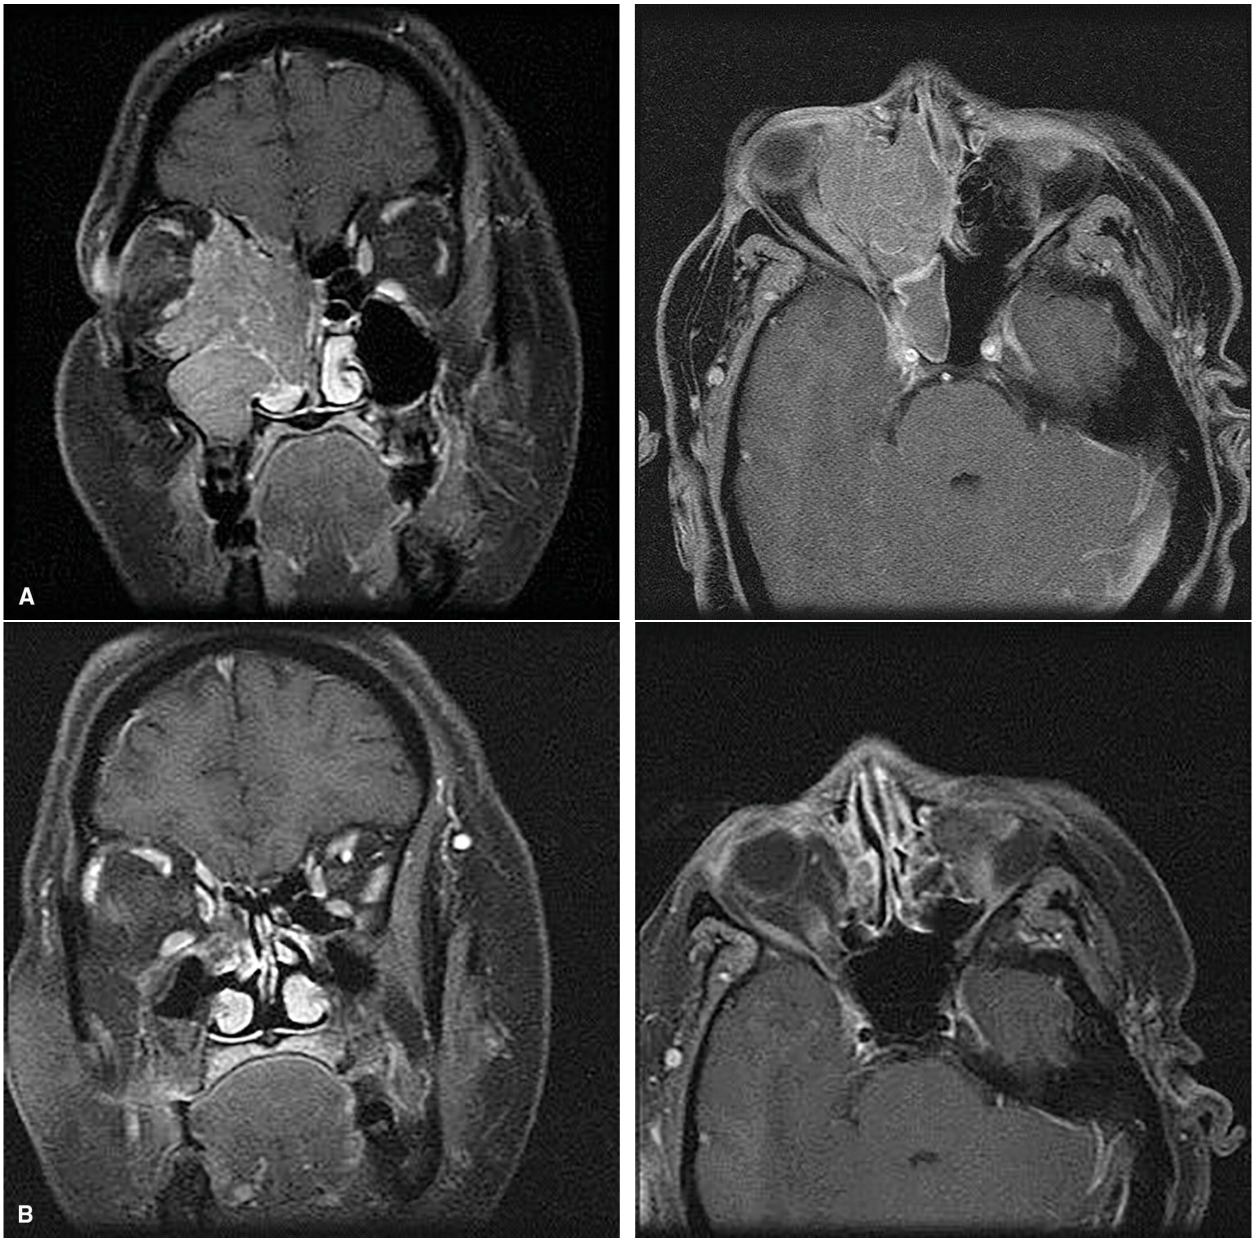

Figure 10.38. Sinonasal undifferentiated carcinoma with orbital invasion. **A:** MRI showing tumor of the right sinonasal region with gross invasion of the medial and inferior orbital contents. The tumor also invades the anterior skull base with limited intracranial extension. **B:** MRI of the same patient 3 years after completing treatment with induction chemotherapy followed by concurrent chemoradiation. Imaging shows no evidence of residual disease. Surgery was avoided, and the orbit was preserved.

There is an evolving role for induction chemotherapy and concurrent chemoradiation in the management of patients with orbital invasion by

advanced sinonasal cancers (Fig. 10.38). The role of such neoadjuvant treatment in enhancing the chances of orbital preservation continues to be investigated.[77] In a recent study, Hanna et al.[78] reported on the results of induction chemotherapy prior to local therapy in 46 patients with advanced SCC of the paranasal sinuses. Despite the relatively high number (37 of 46) of T4 tumors, with high prevalence of orbital (n = 31) and skull base (n = 14) invasion, orbital preservation was feasible in all but six patients, local recurrence rate was low, and local disease control was high.

If a decision is made to exenterate the orbit, supra- and subciliary incisions are made around the upper and lower eyelids, respectively. This allows for preservation of the eyelids, which can be used to line the orbit. If the eyelids are involved with cancer, they must be included in the resection (**Fig. 10.39**). The periorbita is incised over the superior and lateral orbital rims. Dissection continues along the roof of the orbit and lateral walls, until the SOF and the optic foramen are exposed. Lidocaine is injected around these structures to block any autonomic-induced cardiac arrhythmias. To prevent troublesome bleeding, the neurovascular structures in the SOF are slowly and carefully isolated, ligated or clipped, and transected. The optic nerve and the ophthalmic artery are then managed in a similar fashion. The extraocular muscles are transected at their origin in the orbital apex. The medial and inferior orbit may be left attached to the specimen if en bloc resection of the eye in patients with sinonasal cancer is indicated. Osteotomies are done as previously described for total maxillectomy, except that the orbital bony cuts are connected at the orbital apex, rather than the inferior orbital fissure.

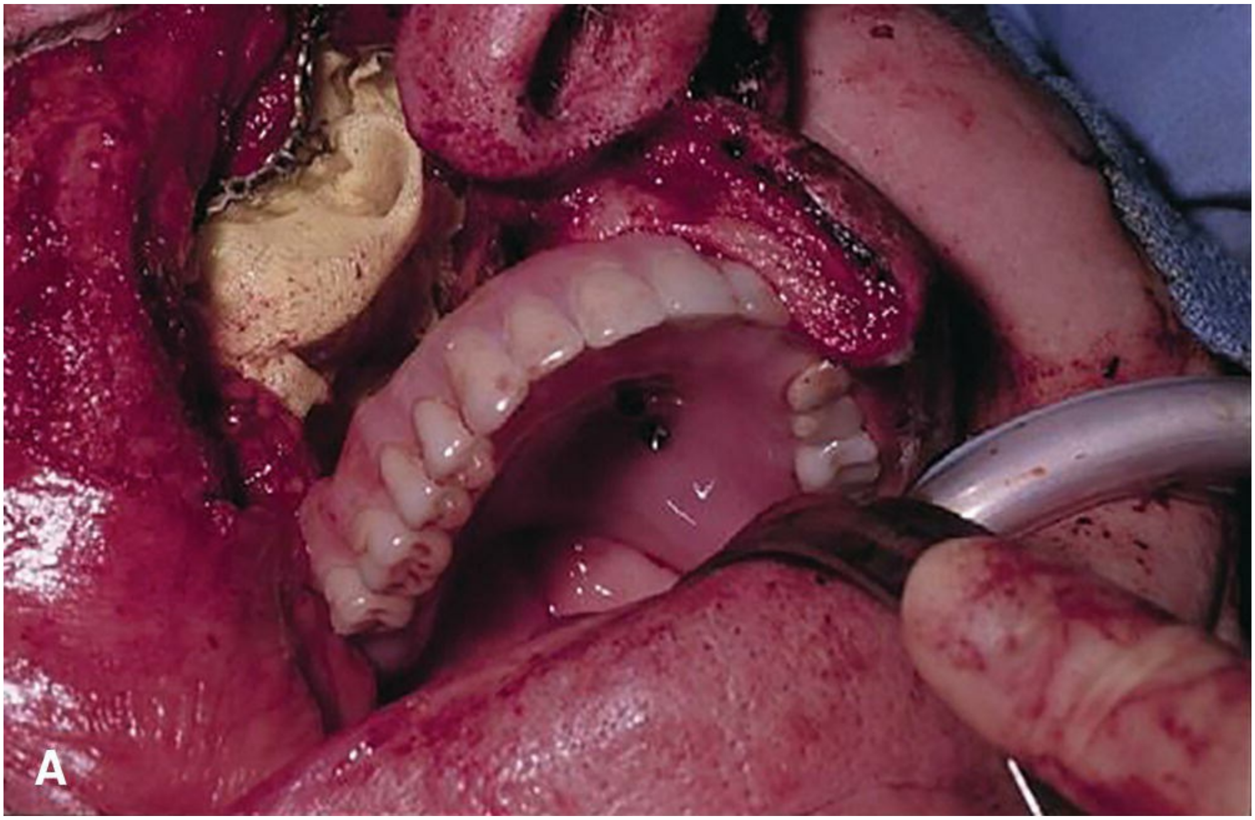
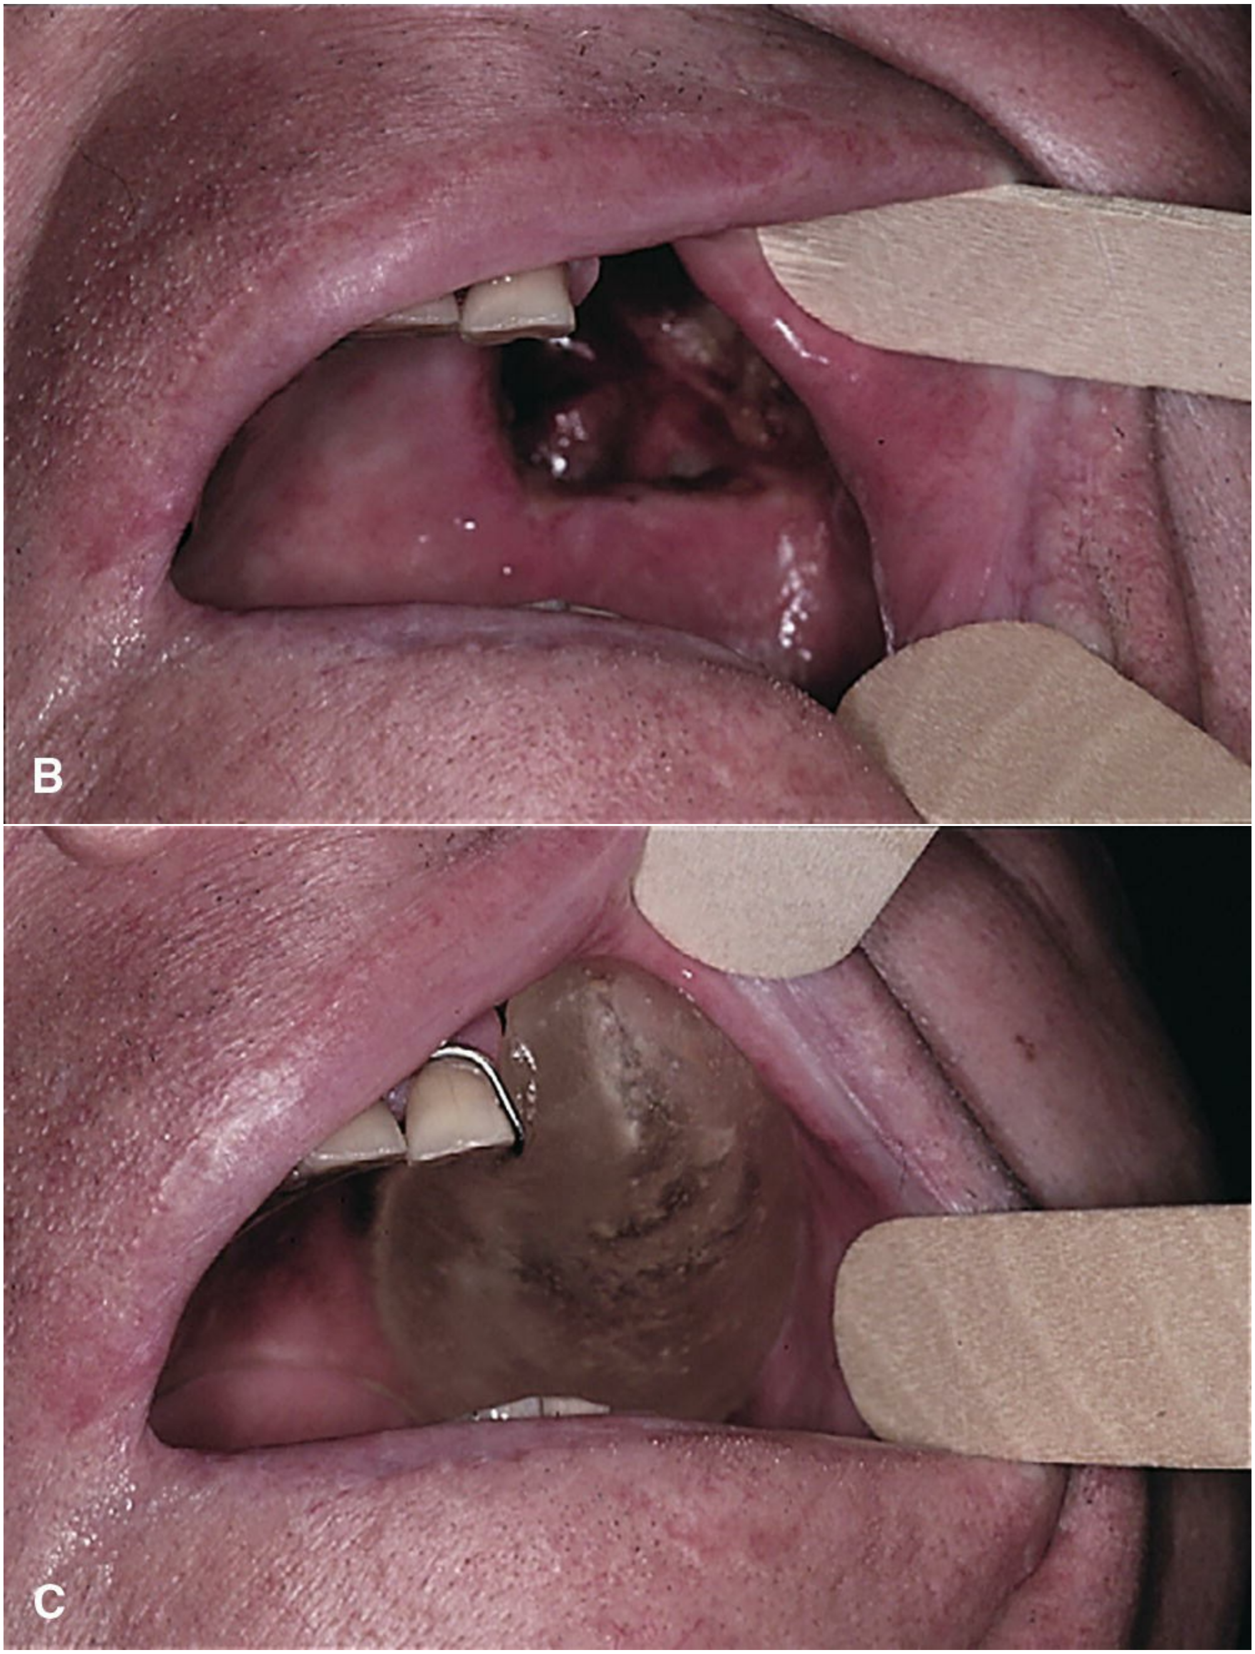
Surgical Reconstruction

Oronasal Separation.

Effective separation between the oral and nasal cavities is essential for effective speech and deglutition. Palatal defects resulting from a maxillectomy are simply and effectively sealed using a prosthetic obturator. Preoperatively, the oromaxillofacial prosthodontist takes dental impressions and designs a *surgical* obturator, which is used at the end of surgery to seal the palatal defect (**Fig.** 10.40**A**). The surgical obturator can be slightly modified intraoperatively to custom-fit the defect. The advantages of this immediate reconstruction are early postoperative restoration of normal speech and oral feeding.[79] This minimizes the early postoperative morbidity of surgery and obviates the need for enteral feeding. Preoperatively, a clear communication between the head and neck surgeon and the maxillofacial prosthodontist concerning the anticipated maxillary defect is required for optimal results. An additional advantage of the surgical obturator is its ability to support the surgical packing used to immobilize the skin graft lining the cheek flap (Fig. 10.40A). This epithelial lining, when completely healed, minimizes granulation tissue formation, provides a smooth mucosal lining, reduces scar contracture of the cheek, provides a scar band to support the obturator, and facilitates cavity hygiene (**Fig. 10.41**). At the end of the first postoperative week, and after removal of the surgical packing, the surgical obturator is replaced with an *interim* obturator (Fig. 10.40B and C). This is used for several weeks after discharging the patient from the hospital and after completion of adjuvant therapy, allowing the surgical cavity to heal completely. Patients are instructed to remove the obturator periodically and clean the cavity with saline irrigation. At follow-up visits, the obturator is removed and cleaned of any crusts or debris. Finally, a *permanent* obturator is designed to custom-fit the cavity after it matures to its final shape and dimensions. The acrylic dome incorporated into its design provides some cheek support (Fig. 10.40D). In addition to being a simple and effective method of reconstruction of palatal defects, permanent obturators can also

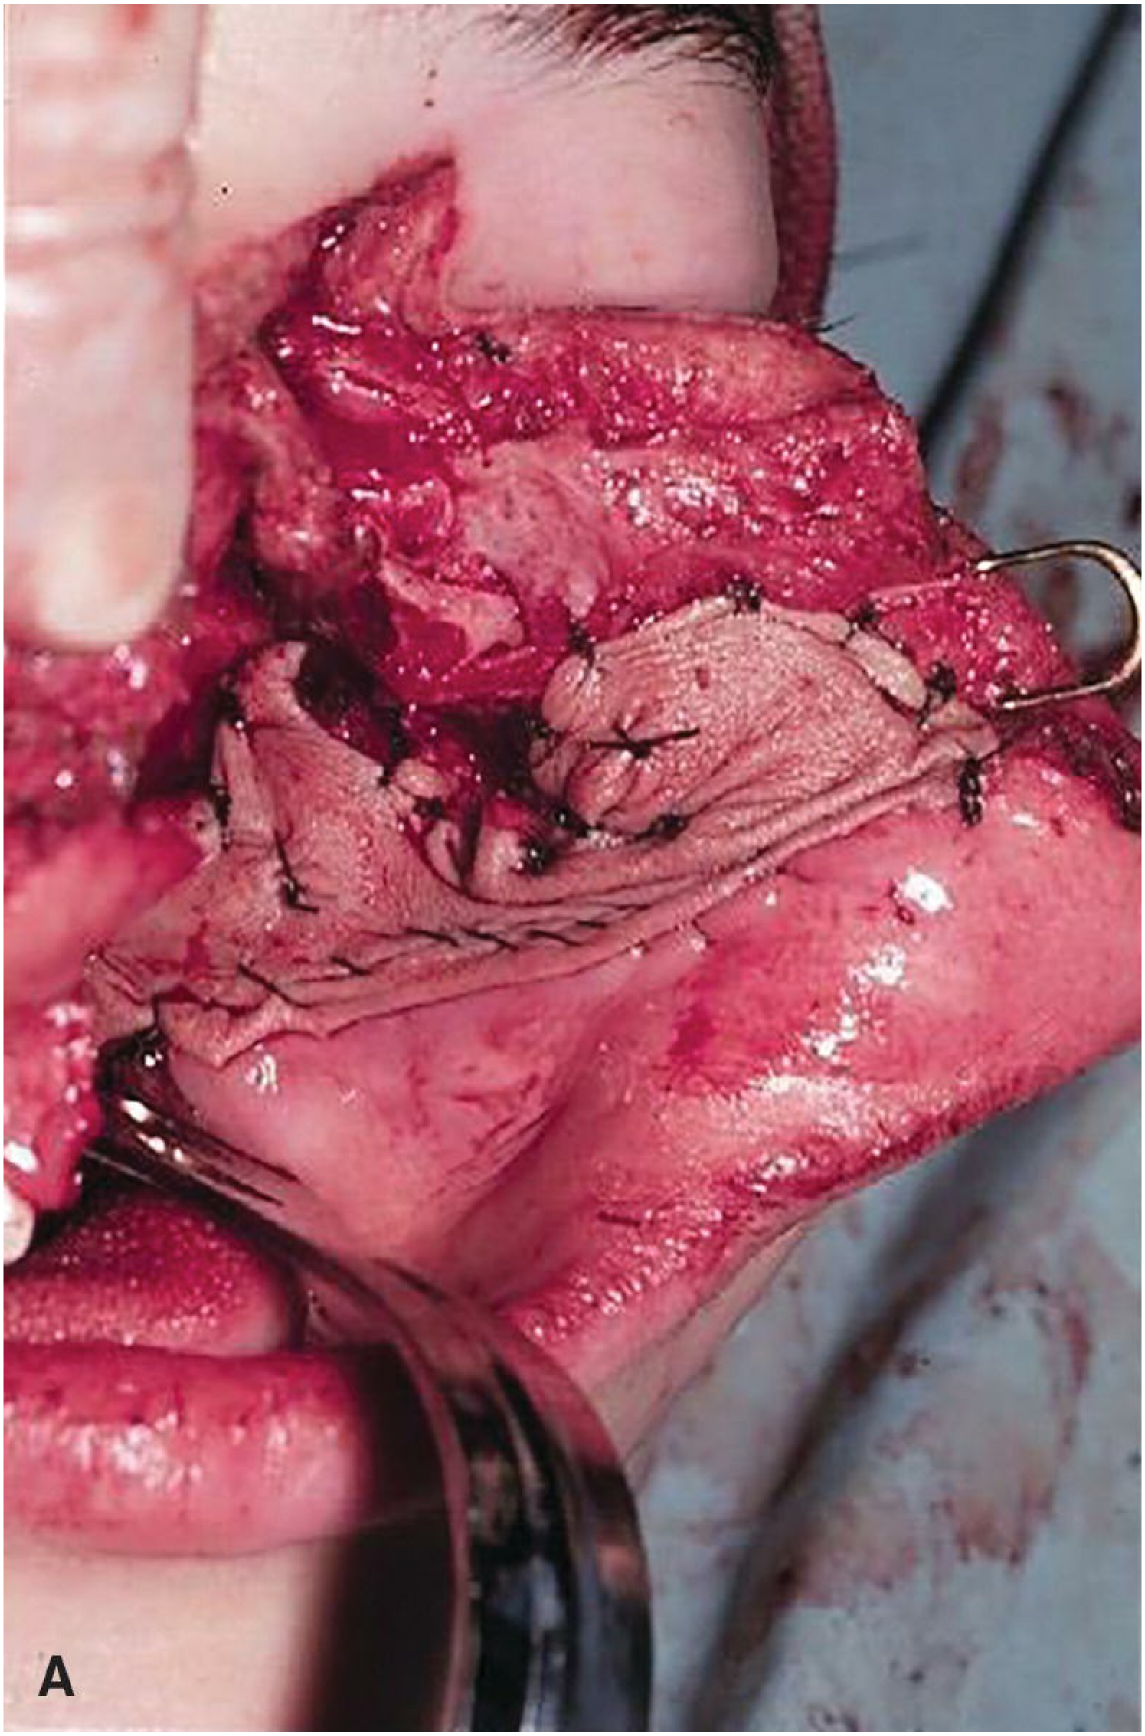
provide full dental restoration (Fig. 10.40E). At follow-up visits, removal of the obturator allows for easy inspection of the cavity for any evidence of recurrent disease.



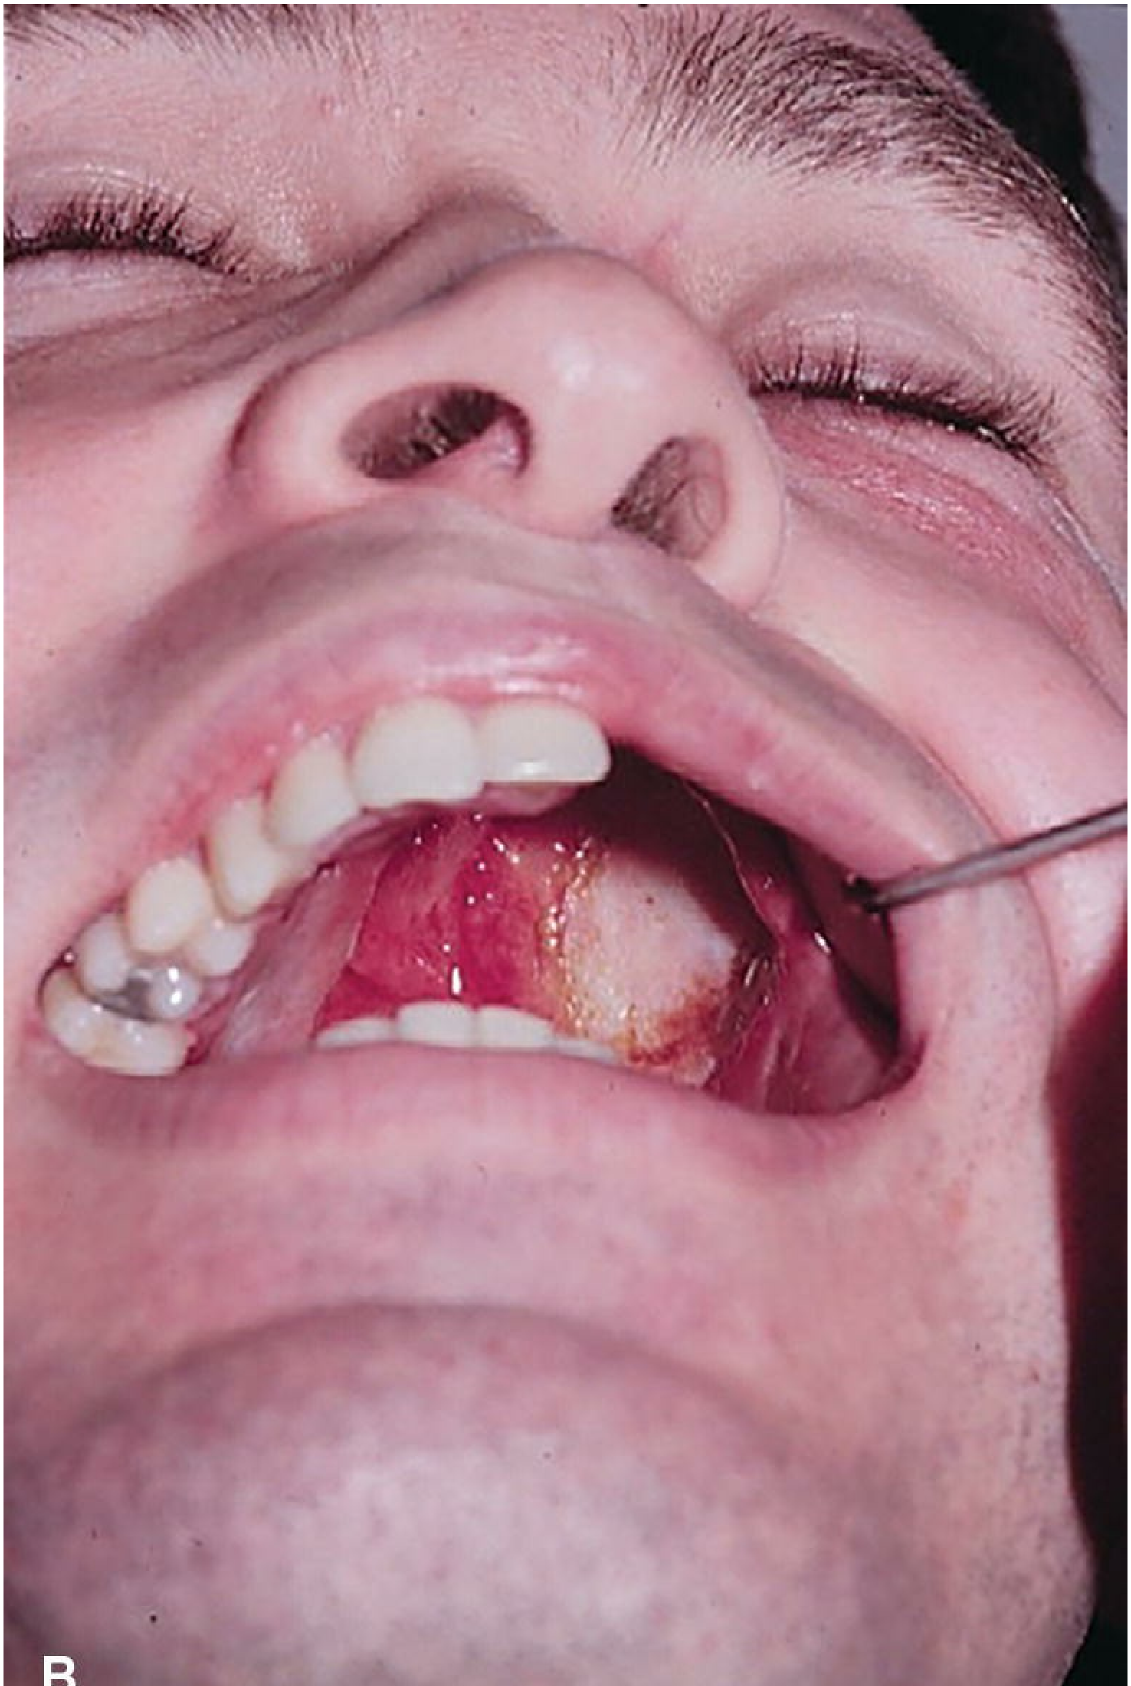


B
C

Figure 10.40. Prosthetic rehabilitation of postmaxillectomy palatal defect. **A:** Surgical obturator fixed to the palate with a lag screw providing immediate rehabilitation and supports the surgical packing. **B and C:** Interim obturator is used for several weeks until the cavity is completely healed. **D and E:** Permanent obturator has an acrylic dome to provide some cheek support. It also provides adequate dental restoration.



A



B

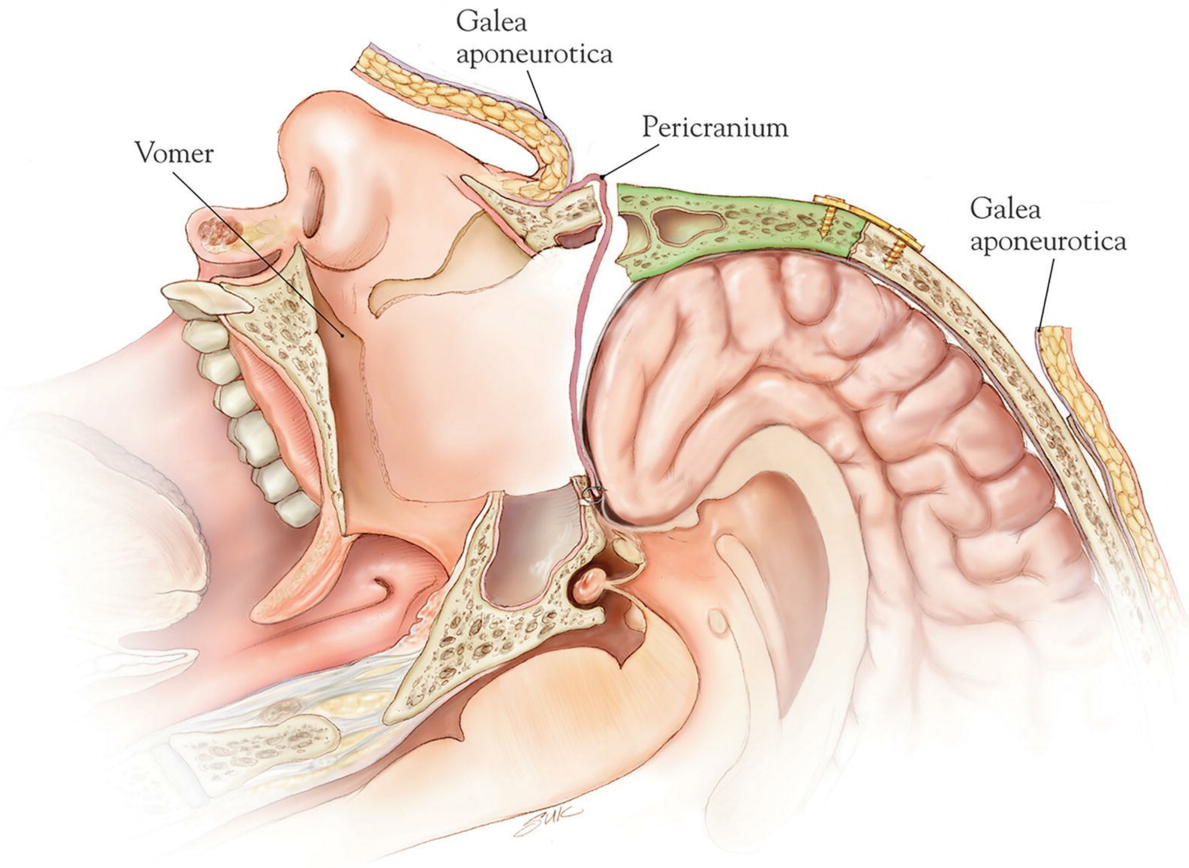
Figure 10.41. A STSG is used to line the surgical cavity and the deep aspect of the cheek flap **(A)**. Once healed, the STSG minimizes granulation tissue formation in the surgical cavity, prepares the surgical defect to receive an obturator, and reduces soft tissue contracture of the overlying cheek **(B)**.

Surgical reconstruction of palatal defects with tissue flaps has the advantage of eliminating the need for regular hygiene of the surgical cavity. Flap reconstruction however requires more extensive surgery, adds donor site morbidity, does not allow rapid dental restoration, and conceals the surgical cavity from inspection for recurrent tumor. These disadvantages make prosthetic obturators the method of choice for reconstruction of surgical defects of the palate. The use of tissue flaps is usually reserved to patients who need additional reconstruction to the maxillary skeleton, orbital floor, or cranial base. In a recent study from MDACC, analysis of the functional outcomes of 113 patients undergoing maxillectomy for cancer was performed.[79] Seventy-three patients received an obturator, and 40 patients were reconstructed with a free flap. They concluded that moderate-sized maxillectomy defects involving the palate can be successfully treated with either an obturator or free flap reconstruction. Extensive defects (more than 50% of the palate) have a better functional outcome (speech intelligibility and postoperative diet) with free flaps. Evidence does not suggest that free flap reconstructions delay diagnosis of local recurrences.

Cranionasal Separation.

Whenever the cranial and nasal cavities are joined by a surgical defect, as is the case with anterior craniofacial resection, watertight cranionasal separation is mandatory to reduce the risk of CSF leak, meningitis, and pneumocephalus. Meticulous closure of all dural tears should be done. Larger defects of the dura should be repaired using temporalis fascia, pericranium, or fascia lata grafts. Although bony reconstruction of the anterior skull base has been described using vascularized and nonvascularized bone grafts as well as bone cement, reconstruction of the bone defect is not routinely necessary in most patients.[44] The vascularized galeal–pericranial flap is currently the most frequently used flap for reconstructing defects of the floor of the anterior cranial fossa (Figs. 10.33D and **10.42**). Flap handling and suturing should be meticulous in order to achieve a watertight seal. Fibrin glue and tissue adhesives do not compensate for an imperfect closure. Lumbar subarachnoid

drainage for several days postoperatively helps to reduce CSF pressure and the possibility of a leak. However, aggressive lumbar drainage should be avoided because it may encourage the development of pneumocephalus.



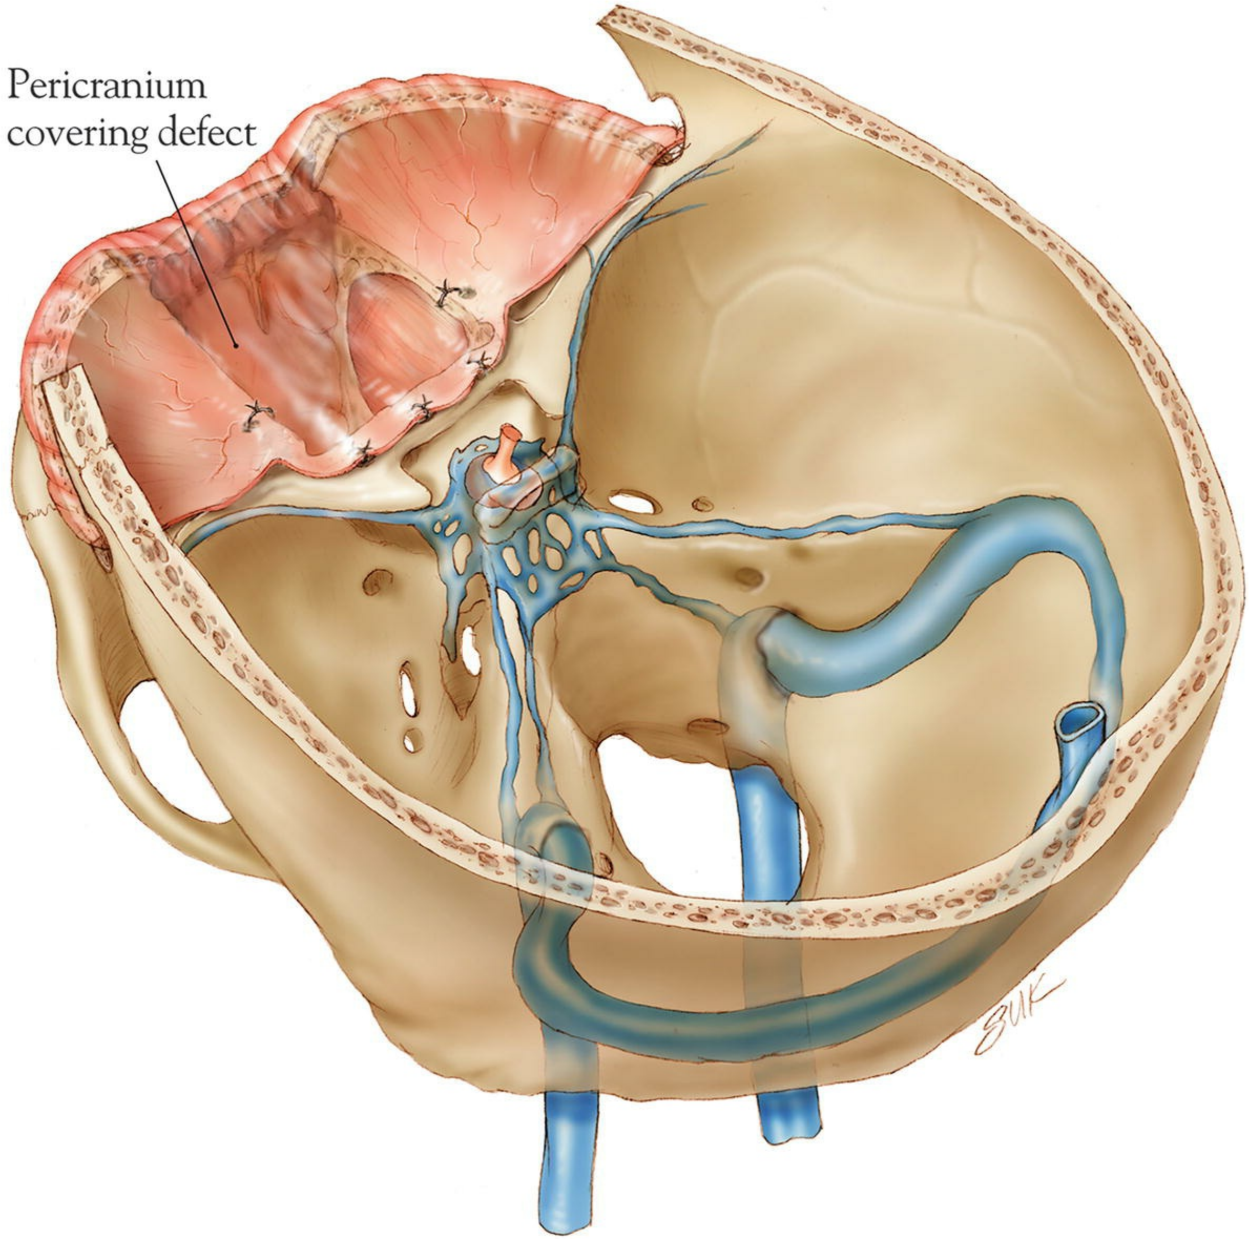


Figure 10.42. Schematic showing reconstruction of the floor of the anterior cranial base with pericranial flap.

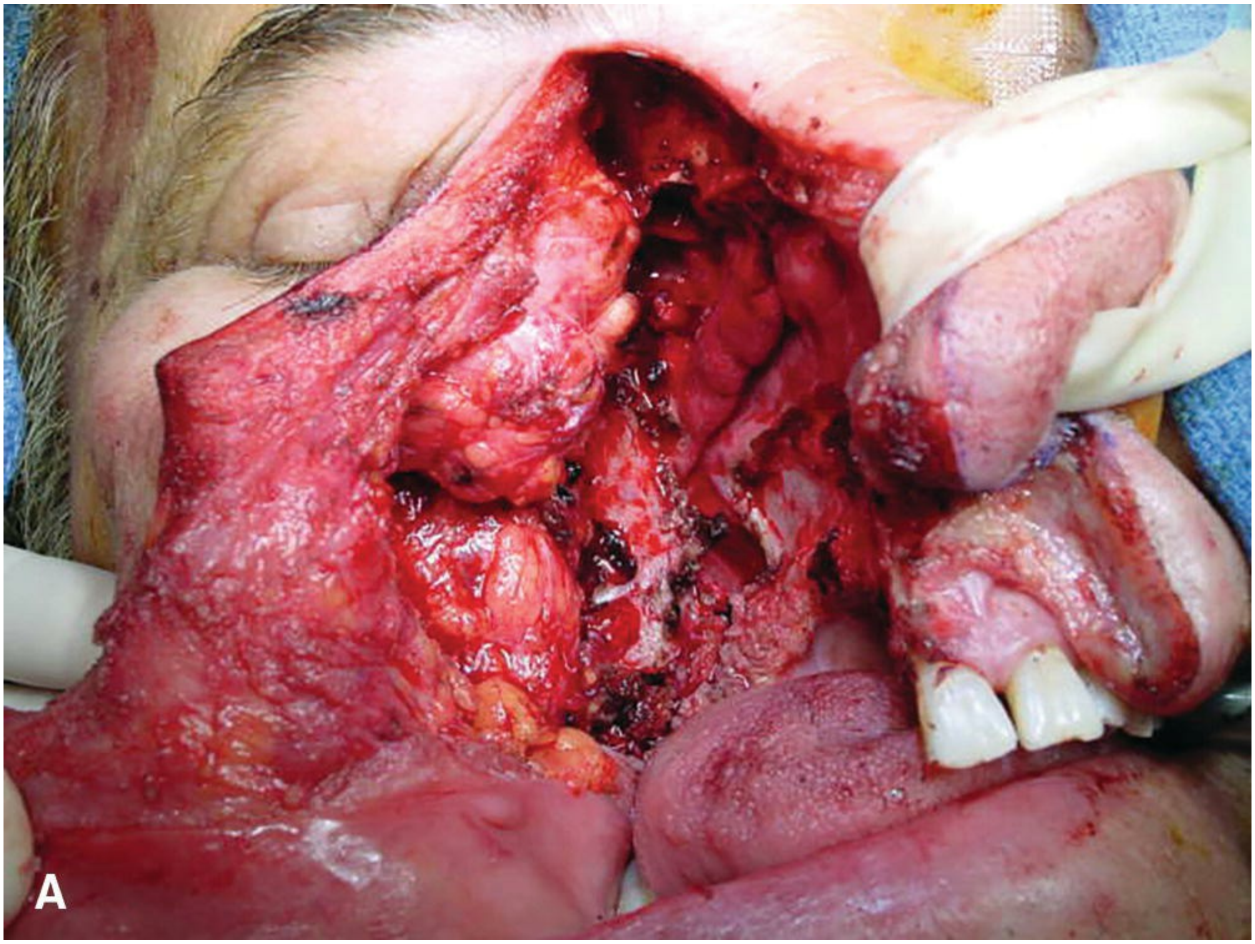
Occasionally, more bulk is needed to reconstruct the surgical cavity and reduce dead space, such as with extensive defects of the cranial base. Regional flaps, such as the temporalis muscle, are usually adequate for this purpose. If the muscle bulk is inadequate, or if its blood supply has been sacrificed, then a microvascular free flap is used. Vascularized tissue may also be needed to protect the carotid artery if it is exposed to the surgical defect. This is done to prevent desiccation of the arterial wall and carotid

artery blowout. This is particularly important if the patient received prior radiation therapy or will receive postoperative adjuvant radiation.[48]

Orbital Reconstruction and Cheek Support.

The maxilla has three bony buttresses, the nasomaxillary, zygomaticomaxillary, and pterygomaxillary. In addition to a palatal defect, total maxillectomy results in resection of all three buttresses and loss of adequate skeletal support to the soft tissues of the cheek. Loss of the zygomaticomaxillary buttress results in inferior displacement of the orbit and flattening of the malar eminence. Loss of the nasomaxillary buttress results in superior and posterior deviation of the alar base of the nose. Loss of the pterygomaxillary buttress results in superior and posterior deviation of the upper lip. Resection of the inferior orbital rim and floor leads to loss of skeletal supports to the eyelid and globe. Lack of adequate orbital support results in unacceptable esthetic and functional outcome of the preserved eye due to enophthalmos, ectropion, hypoglobus, and diplopia. The combined effects of loss of support of the eye and cheek result in the “typical” postmaxillary deformity (**Fig.** 10.43**A and B**). Although a split thickness skin graft (STSG) and a palatal obturator are commonly used in reconstruction after maxillectomy, these methods of reconstruction do not provide adequate support for the cheek and eye.[79] In such cases, bony reconstruction is needed to provide adequate support for the cheek and eye and enhance postoperative appearance and function.



B

Figure 10.43. Orbital reconstruction. **A:** Post total maxillectomy surgical defect showing total loss of the orbital floor and periorbita. **B:** Without bony reconstruction, the result is “typical” postmaxillectomy deformity due to lack of support of the orbit and cheek. There is downward displacement of the orbit and medial canthus. Note the presence of enophthalmos as evidenced by a prominent upper eyelid sulcus. There is flattening of the cheek and deviation of the nasal tip. The patient had significant diplopia. These deformities can be avoided with adequate bony reconstruction. **C:** Postoperative appearance showing good position of the eye, cheek, and nose in a patient with bony reconstruction of the orbital floor and cheek.

The function of the preserved orbit will be greatly enhanced by meticulous orbital reconstruction.[80] Careful reattachment of the medial canthal ligament will prevent telecanthus. If the lacrimal apparatus is transected, marsupialization of the lacrimal sac into the surgical cavity or a dacryocystorhinostomy should be performed to avoid postoperative epiphora.

If the orbital rim or a significant portion (more than one-third) of the orbital floor is removed particularly if the periorbita is resected, then bony support is needed to prevent enophthalmos, ectropion, hypoglobus, and diplopia. Bone reconstruction is best done using vascularized bone flaps. If nonvascularized bone grafts or alloplastic implants (e.g., titanium mesh) are used, then they should be adequately covered with well-vascularized soft tissue to minimize resorption of bone grafts and infection and extrusion of alloplastic implants (**Fig. 10.43A and C**).

The pedicled temporalis muscle flap, temporoparietal fascial flap, or septal mucosal flap are most commonly used for this purpose. Microvascular free flaps may be used to either provide soft tissue coverage of bone grafts or implants, or composite vascularized bone flaps may be used for full reconstruction of both soft tissue and bone defects.[48]

Primary reconstruction of defects of the maxilla and orbit at the time of maxillectomy is easier and results in better esthetic and functional outcome than delayed reconstruction. Although secondary reconstruction after globe-sparing maxillectomy is feasible, it is often difficult and the results are limited by excessive scarring and soft tissue contracture, especially in patients who underwent adjuvant radiation therapy. These patients may benefit more from free-tissue transfer reconstruction.[48]

The function of the preserved eye will also be greatly influenced by precise dosimetry of postoperative radiation. The use of IMRT and more recently proton therapy is particularly helpful in delivering effective radiation doses to the tumor bed while sparing ocular contents. In a report from MDACC, the use of IMRT improved the dose distributions within the target volume, reducing the late grade 3 to 4 complication rates (particularly ocular) from 34% to 8% ($p = 0.014$).[37]

Dental Restoration.

Prosthetic rehabilitation using partial or full upper dentures is the easiest method of dental restoration in patients who have undergone maxillectomy (Fig. 10.40). Remaining contralateral teeth facilitate retention of partial dentures. In edentulous patients, dental fixatives can be used, but denture retention is more difficult. A soft palate “band” at the posterior edge of the defect may provide enough of a ledge for retaining the prosthesis. Retention of the prosthesis in edentulous patients who underwent an extended resection

to include the soft palate may be extremely difficult. In such cases, the use of osseointegrated implants facilitates prosthetic dental restoration.[79]

Another important aspect in the rehabilitation of patients after maxillectomy is the prevention of trismus. Patients who have undergone resection of the pterygoid plates or muscles of mastication are particularly prone to develop trismus. This may be severe enough to interfere with inserting and wearing a denture-bearing obturator. Early postoperative jaw opening exercises using "stacked" wooden tongue blades, or commercially available devices (e.g., Therabite), are extremely important in preventing or minimizing postoperative trismus (**Fig. 10.44**).

A

Figure 10.44. A and B: This 15-year-old boy underwent a resection of a nasopharyngeal angiofibroma, which involved the pterygoid plates. Postoperatively, he had significant trismus, which resolved with mouth-opening exercises.

Restoration of Facial Defects.

Smaller defects of the face are optimally reconstructed using local flaps. Local skin flaps provide the best thickness and color match for facial defects. Reconstruction of more extensive facial defects may require regional or microvascular free flaps, but suffer from less optimal esthetic outcome due to color or thickness mismatch between the donor and defect sites (**Fig. 10.45**). Facial defects resulting from orbital exenteration or total rhinectomy are best managed with prosthetic restoration[48,81] (**Fig. 10.46**).

Cervical Metastasis.

The incidence of lymph nodal metastasis at presentation ranges from 3% to 26%, and several authors have reported high rates of neck recurrences in untreated necks that can reach up to 30%.[82,83] Although the most frequently reported sites of lymphatic metastasis are level I and II, a significant part of the lymphatic drainage of the paranasal sinuses and the nasal cavity is directed to the retropharyngeal lymph nodes, which are inaccessible for palpation and are frequently overlooked. It is possible, therefore, that the true incidence of lymphatic spread of sinonasal malignancy is underestimated. The retropharyngeal lymph nodes are best evaluated with high-resolution imaging (CT or MRI) or PET–CT.

The overall risk of nodal involvement at either diagnosis or as regional recurrence may depend on the histology and the stage and extent of the primary tumor. High-grade tumors such as SCC and SNUC and advanced stage (T3 to T4) tumors have a relatively higher rate of nodal involvement.[37] Tumor extension into the oral cavity and nasopharynx is also associated with increased risk of nodal metastasis.[82,83]

Lymphatic metastasis to the cervical lymph nodes carries with it a poor prognosis in patients with cancer of the SNT. In a study of 146 patients with maxillary sinus cancer treated at MDACC,[37] patients presenting with node-negative versus node-positive disease had an estimated 5-year OS rate of 56% versus 44%, respectively ($p = 0.06$) (**Fig. 10.47**).

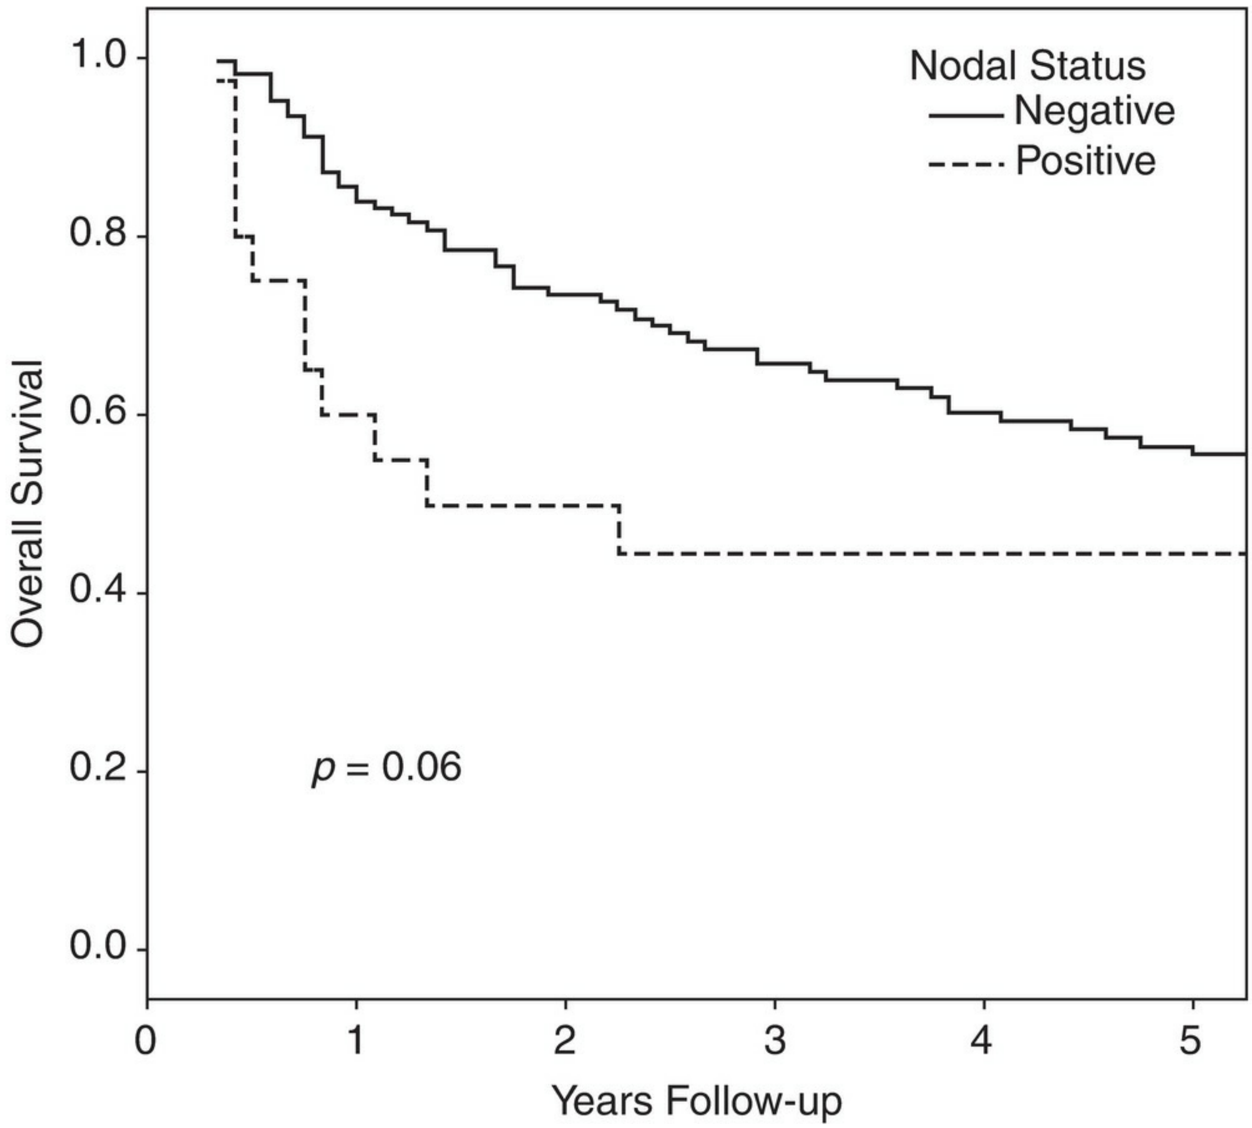

Figure 10.47. Overall survival in patients with sinonasal cancer stratified by presenting T stage and nodal status.

Obviously, patients with clinically positive lymph nodes require treatment of the neck, but prophylactic treatment of N0 patients remains controversial.[83] Because the risk of nodal metastasis is higher in patients with high-grade and advanced stage disease, it is generally recommended that the neck is electively treated in such patients. This policy of elective neck irradiation (ENI) of patients with advanced stage and high-grade tumors was adopted at MDACC in 1991.[37] **Figure 10.48A** shows the effect of elective neck RT on nodal control for node-negative (N0) patients with squamous cell or undifferentiated carcinoma. Of the 36 patients in whom the ipsilateral neck

was left untreated, 13 (36%) developed nodal recurrence versus only 3 (7%) of the 45 patients in whom ENI was administered ($p < 0.001$). The use of elective neck treatment in these patients translated into a significant reduction in distant metastases (3% in treated vs. 20% in untreated at 5 years; $p = 0.045$) and an increase in recurrence-free survival (67% in treated vs. 45% in untreated at 5 years; $p = 0.025$) (**Fig. 10.48B and C**).

RADIATION THERAPY

Radiation therapy is frequently incorporated in the overall management of patients with cancer of the nasal cavity and paranasal sinuses. Radiation therapy may be given with curative intent, or as an adjuvant therapy before,

or after surgery. Radiation therapy may also be combined with chemotherapy either as definitive treatment or as an adjunct to planned surgical resection. Radiation therapy may also be used in the palliation of recurrent or unresectable tumors. Regardless of the treatment strategy, there is almost a universal agreement that patients with advanced stage tumors are best treated with multimodal therapy including surgery, radiation, and in some cases chemotherapy.[84,85]

Surgery followed by postoperative radiation therapy has been the accepted gold standard for most tumors of the sinonasal cavity. Hoppe et al.[86] published an 18-year experience at Memorial Sloane-Kettering Cancer Center with 85 patients treated with surgical resection and postoperative radiation for sinonasal cancers. Most patients had SCC, T4 tumors, and tumors involving the maxillary sinus. Their 5-year estimates of local progression-free, disease-free, and overall survival (OS) rates were 62%, 55%, and 67%, respectively. The authors noted that squamous cell histology and cribriform plate involvement were independent predictors for local recurrence.

There is strong evidence that the use of combined surgery and adjuvant radiation therapy results in better tumor control and survival compared to radiation alone in patients with cancer of the paranasal sinuses.[87] In 2009, Mendenhall et al.[85] reported the results of 109 patients with sinonasal cancer treated between 1964 and 2005. Within this group, 56 patients were treated with definitive radiation therapy, whereas 53 patients received surgery and postoperative radiation. Although the 5-year local control rate was 82% in patients with T1 to T3 lesions, those patients with T4 disease had a lower local control rate of 50%. Local control at 5 years was 43% after definitive radiation therapy versus 84% with primary surgery and adjuvant radiation therapy ($p < 0.0001$). Cause-specific survival rates were 81% and 54% for stages I to III and stage IV disease, respectively. This group concluded that the probability of local control and cause-specific survival is better after surgery and radiation therapy compared with definitive radiation therapy. However, selection bias may have influenced the poor results of radiation therapy given that surgery was likely performed only for patients who had resectable disease. Similarly, in 2009, Snyers et al.[88] reported a series of 168 patients treated between 1986 and 2006. In all, 130 patients were treated with curative intent by surgery followed by postoperative radiotherapy, and 38 were considered inoperable and received radiotherapy alone ($n = 21$) or

radiotherapy and chemotherapy (n = 17). For the entire population, the 5-year local control rate was 62% and regional control was 79%. Distant metastasis–free survival was 79%. Of the cases with SCC or adenocarcinoma, patients with stages I to III versus stage IV disease had a local control rate at 5 years of 79% and 54%, respectively, comparable with the series reported by Mendenhall and colleagues.[85]

External beam radiation or brachytherapy or both may be used as definitive local therapy in selected patients with early-stage cancers of the nasal cavity.[89] Primary radiation therapy however has not been a well-accepted approach for definitive treatment of more advanced sinonasal cancers. This conclusion was partly based on the poor outcomes for patients with advanced lesions and concerns that radiation therapy does not adequately treat bony invasion, which is a frequent finding in patients with sinonasal malignancies. In additions, several publications have reported increased incidence of radiation-associated optic nerve injury and osteoradionecrosis when radiation therapy is administer as primary treatment.[85,88] Although some authors propose primary concurrent chemoradiation therapy for this site,[38,90] the majority of the published data on primary radiation therapy have been for tumor deemed not surgically resectable and with a selection bias toward advanced disease.[85,88,91] In a study from Memorial Sloane-Kettering Cancer Center, the 5-year disease-free survival (DFS) and OS were 14% and 15%, respectively, for 39 patients with unresectable stage IVB paranasal sinus carcinomas treated with RT, with or without chemotherapy.[92] The majority of the recurrence (64%) was within the irradiated field. The investigators report that the only significant factor for improved local progression–free survival (LPFS) and OS was a biologically equivalent dose of radiation of >65 Gy and that treatment outcomes for patients with unresectable sinonasal malignancies remain poor.

Delivering effective doses of radiation (60 to 70 Gy) for treatment of advanced sinonasal cancer using conventional radiotherapy is associated with serious morbidity, including blindness, brain necrosis, radiation-induced endocrinopathy attributed to hypothalamic–pituitary radiation damage, and osteoradionecrosis.[85,88] The use of 3-dimensional conformal radiotherapy (3D-CRT) and IMRT increases treatment accuracy by delivering tumoricidal doses to the tumor bed while reducing radiation doses to nearby critical structures such as the optic nerves and the brain. Duprez et al.[93] examined the

ocular complications of IMRT. They reported on 130 patients treated with IMRT up to 70 Gy, of which 101 patients were in the postoperative setting. The 5-year local control and OS were 59% and 52%, respectively. There was no radiation-induced blindness in 86 patients available for the 6-month follow-up. Ten patients reported grade 3 tearing and one patient with grade 3 visual impairment from ipsilateral retinopathy and neovascular glaucoma. Brain necrosis and osteoradionecrosis occurred in six patients and one patient, respectively. Chen et al.[94] analyzed 127 patients treated between 1960 and 2005. The cohort was treated with conventional RT in 59, 3-D conformation in 45 and IMRT in 23 patients. The 5-year OS, LC, and DFS were not significantly different when analyzed by decade. However, the incidence of grade 3 to 4 toxicity was 53%, 45%, 39%, 28%, and 16% for patients treated in 60s, 70s, 80s, 90s, and 2000s. The authors conclude that improvements in therapeutic ratio were responsible for decreasing incidence of complications for patients treated throughout these decades.

More recently charged particle radiation using beams of protons, carbon ions, helium ions, or other charged particles holds promise of further enhancing high-dose delivery to tumor targets while limiting toxicity to normal tissue. The unique physical properties of charged particle therapy—with rapid fall-off of dose beyond the Bragg peak (a sharp deposition of dose at a specific depth in tissue)—and its greater relative biologic effectiveness compared with photon therapy might further augment treatment outcomes, not only by reducing the incidence and severity of complications but also by allowing an escalation in radiation dose to improve tumor control and survival, which cannot be achieved with photon therapy. A recent systematic review and meta-analysis compared the clinical outcomes of patients treated with charged particle therapy with those of individuals receiving photon therapy.[95] The study included 43 cohorts from 41 noncomparative observational studies of which 30 cohorts were treated with photon therapy (1,186 patients), whereas 13 received charged particle therapy (286 patients). Median follow-up for the charged particle therapy group was 38 months (range 5 to 73) and for the photon therapy group was 40 months (14 to 97). The pooled event rate of OS for charged particle therapy was significantly higher than that for photon therapy at the longest duration of follow-up (relative risk 1.27, 95% CI, 1.01 to 1.59; $p = 0.037$) and at 5 years (1.51, 1.14 to 1.99; $p = 0.0038$; **Table 10.5**). Locoregional control was also significantly better at the longest duration of follow-up for patients treated with charged

particle therapy than for those receiving photon therapy (1.18, 1.01 to 1.37; $p = 0.031$), but not at 5 years (1.06, 0.68 to 1.67; $p = 0.79$). The pooled 5-year DFS event rate was significantly higher for charged particle therapy than for photon therapy (1.93, 1.36 to 2.75; $p = 0.0003$) but not at longest follow-up (1.51, 1.00 to 2.30; $p = 0.052$). **Table 10.6** shows the comparison of primary outcomes for cohorts receiving proton beam therapy versus those given IMRT. DFS at 5 years and locoregional control at longest follow-up were significantly higher in the proton beam therapy group. However, no other difference was noted between proton beam therapy and IMRT.

I^2 ≥50% suggests high heterogeneity across studies. IMRT, intensity-modulated radiation therapy; PBT, photon beam therapy.

[a]At longest duration of complete follow-up.

CHEMOTHERAPY

In an effort to improve local control and survival rates, chemotherapy is being increasingly incorporated in the management of patients with cancer of the SNT and cranial base. Chemotherapy has been included in the treatment of SCC, SNUC, NEC, ENB, and SG carcinoma of the paranasal sinuses. Chemotherapy may be given as induction (neoadjuvant), adjuvant, maintenance, or palliative treatment. It may be combined with radiation in a sequential or concurrent fashion. Routes of administration include systemic (intravenous or oral), regional (intra-arterial), and local (topical).

The incorporation of chemotherapy with radiation in a multimodality treatment approach seems to further enhance local control and perhaps DSS in patients with advanced- or high-grade cancer of the SNT. In the neoadjuvant setting, the most frequently used agents are cisplatin based, as a

single agent or in combination with one of the following agents: docetaxel, etoposide, ifosfamide, 5-fluorouracil, and cetuximab. (For pathology-specific regimens, please refer to next section in this chapter.) Potential benefits of induction chemotherapy are that it improves distant control, provide prognostic information, can cytoreduce tumors, and improve radiotherapy and surgical feasibility and tolerability.[78,96,97] Excellent long-term local control, OS, and DFS were achieved in locoregionally advanced paranasal sinus cancer treated with induction chemotherapy, followed by surgery and postoperative concomitant chemoradiotherapy.[96] Induction chemotherapy achieved a clinical response in 87% of patients, and a complete histologic response was documented at the time of surgery in half of these patients. The 10-year OS, DFS, and local control rates were 56%, 73%, and 79%, respectively. These results are encouraging and may be superior to those achieved with surgery and radiation therapy. Further investigation of incorporating chemotherapy with radiation and surgery in a multimodal approach is warranted.[96] More recently, Hanna et al.[78] reviewed the oncologic outcomes of patients with advanced SCC of the paranasal sinuses treated with induction chemotherapy prior to definitive local therapy at MDACC. All patients had T3 or T4 tumors, and 12 (26%) patients had clinical evidence of nodal metastasis, with an overall stage of III (20%) or IV (80%). More than two-thirds (67%) of the patients achieved at least a partial response to induction chemotherapy, 24% had progressive disease, and 9% had stable disease. Subsequent treatment after induction chemotherapy consisted of surgery usually followed by radiation or chemoradiation or by definitive radiation or chemoradiation with surgical salvage of any residual disease. Overall, surgical resection was performed in only 24 of 46 patients (52%) treated with induction chemotherapy. The 2-year survival for patients with at least a partial response or stable disease after induction chemotherapy was 77% in contrast to only 36% for patients with progressive disease (**Fig. 10.49**). The authors concluded that tumor response to induction chemotherapy in patients with advanced SCC of the paranasal sinuses may be predictive of treatment outcome and prognosis. Favorable response to induction chemotherapy is associated with better survival and a reasonable chance of organ preservation.[78]

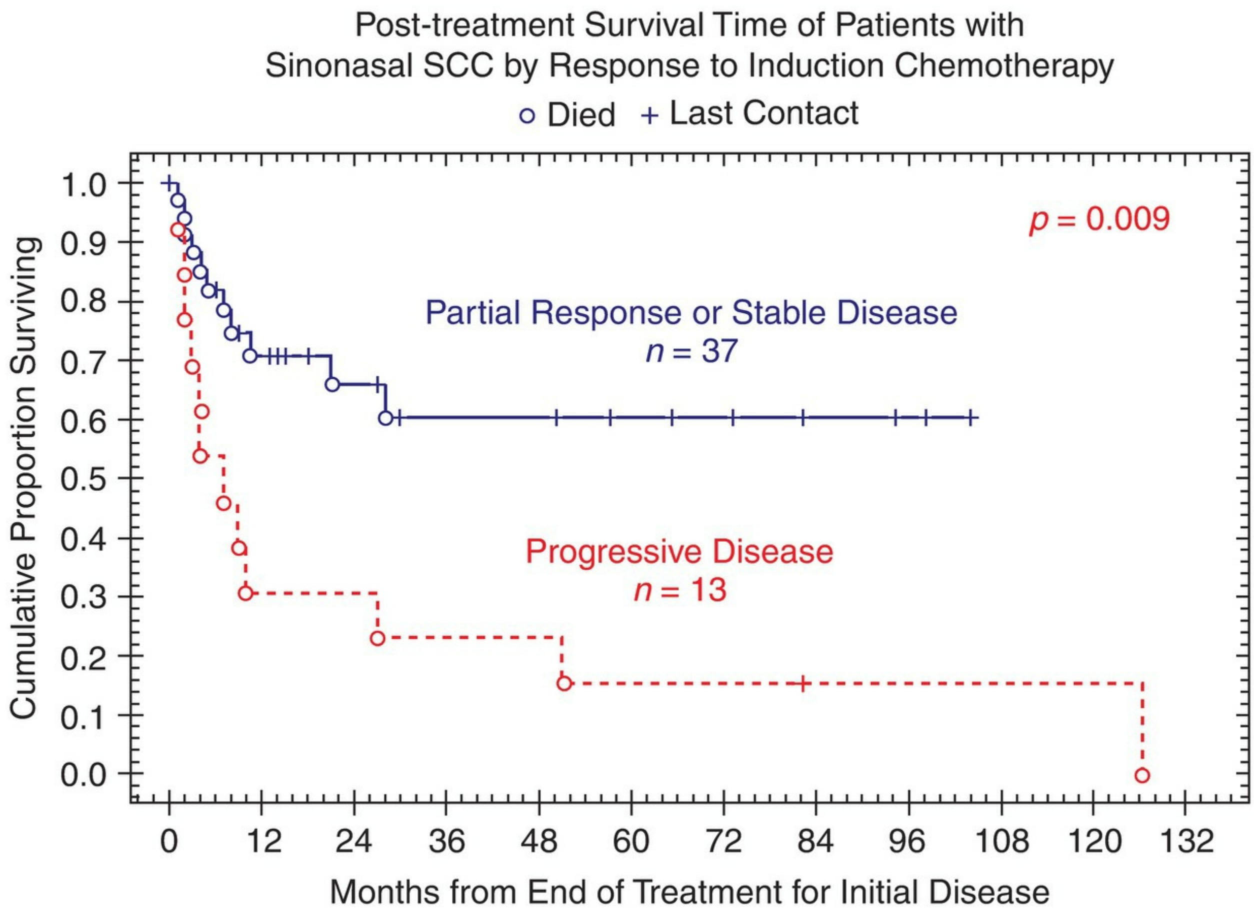

Figure 10.49. Survival in patients with sinonasal SCC by response to induction chemotherapy. (Hanna EY, et al. Induction chemotherapy for advanced squamous cell carcinoma of the paranasal sinuses. Arch Otolaryngol Head Neck Surg. 2011;137(1):78–81, Ref. 78.)

Intra-arterial chemotherapy has been proposed with the intention of limiting radiation doses to critical structures and organ preservation. The University of Tennessee reported on 19 patients with advanced stage tumors (84% with T4 disease) treated by intra-arterial high-dose cisplatin with concurrent radiation therapy followed by organ-sparing surgery.[90] The OS at 2 and 5 years was 68% and 53%, respectively. Ten patients developed grade 3 mucosal toxic effect, three patients with hematologic toxic effect, and one patient developed confusion. One patient developed a treatment-limiting toxic effect (died of myocardial infarction). Homma et al.[98] reported similar favorable oncologic results in 47 patients treated with intra-arterial cisplatin and conventional external-beam radiotherapy (65 to 70 Gy). The 5-year OS rate was 69.3% for the cohort. 74.5% experienced grade 3 to 4 toxicity. There

were 25 late adverse reactions: osteonecrosis (*n* = 7), brain necrosis (*n* = 2), and ocular/visual problems (*n* = 16). The authors concluded that this regimen can cure the majority of patients with advanced tumors and facilitate organ preservation, but late adverse reactions need to be monitored in future studies.

Topical chemotherapy has been reported to have favorable results in the treatment of adenocarcinomas of the ethmoid sinuses. The regimen usually involves surgical debulking followed by a combination of repeated topical chemotherapy (5-fluorouracil) and necrotomy. The 5-year DFS has been reported in the range of 85%, comparable to surgery with postoperative radiation therapy.[99,100] Several reports from Japan described the use of regional or local chemotherapy in addition to radiation to reduce the extent of surgical resection of maxillary sinus cancer and demonstrated equal (and sometimes better) cure rates compared to conventional treatment consisting of radical surgery followed by radiation therapy. For example, a report described the outcome of 75 patients with cancer of the maxillary sinus treated with surgery through a sublabial incision and tumor debridement, radiotherapy, and regional chemotherapy.[101] All 23 patients with orbital involvement retained the orbital contents, and the majority demonstrated adequate ocular function. The authors concluded that combined therapy with conservative surgery, radiotherapy, and regional chemotherapy appears to be an effective method for local control and the preservation of ocular function.[101]

Tumor-Specific Considerations

Squamous Cell Carcinoma.

SNSCC is the most common histologic subtype and accounts for almost half of all cancer in the sinonasal region. Of the 2,698 patients with sinonasal cancers treated at MDACC, 45% had SNCC (Fig. 10.12D). A recent comprehensive analysis using the United States National Cancer Institute’s Surveillance, Epidemiology, and End Results (SEER) database registry reported the trends in the epidemiology of SNSCC.[102] A total of 4,994 cases of SNSCC were identified, composed of 65% males and 35% females amounting to a 1.81:1 male-to-female prevalence ratio. The majority of SNSCC tends to occur in people 55 years and older, with 3,954 (79%) cases

reported in patients older than 55. Dividing the data by race showed that 4,120 (82.50%) patients were white, 436 (8.73%) were “others,” and 438 (8.77%) were black. The majority of cases reported the paranasal sinuses (2,693 cases, 53.92%) as the primary sites with the remainder of cases being in the nasal cavity (2,301 cases, 46.08%). Incidence trend analysis revealed a significant decrease in yearly rates from 1973 to 2009 for the overall population, females, whites, blacks, and “others” ($p < 0.05$). This decrease may be partially attributable to decreased exposure to textile dust and heightened awareness and better regulation of the exposure to the carcinogenic effect of industrial substances. Another variable that may have contributed to the decrease in overall incidence of SNSCC is the decline in tobacco smoking.[102]

The majority of SCC of the paranasal sinuses is keratinizing, but tends to be only moderately differentiated. Nonkeratinizing and poorly differentiated carcinomas are less common, and the latter show a more rapid course of growth. Variants of SCC make up 15% of all cases of SCC of the upper aerodigestive tract. There are five main histologic variants of SCC in the head and neck region: verrucous (VSCC), papillary (PSCC), spindle cell (sarcomatoid) (SCSC), basaloid (BSCC), and adenosquamous (ASC). Conventional sinonasal SCC has been studied extensively, but far less is known about its major variants. In a recent SEER database analysis, a total of 4,382 cases of conventional sinonasal SCC and 328 cases of its major variants were found.[103] Sinonasal BSCC was diagnosed at a significantly lower mean age than sinonasal SCC. Sinonasal SCSC significantly affected the maxillary sinus more commonly than SCC. In the setting of advanced stage disease, sinonasal VSCC, PSCC, and BSCC appear to be associated with a better prognosis than conventional sinonasal SCC, whereas the impact of histologic subtype on prognosis in early-stage disease appears to be more limited. Survival for SCSC and ASC, both regarded as more lethal variants, was statistically similar to conventional SCC. This study highlights the importance of distinguishing between conventional sinonasal SCC and its major histologic variants, because histologic subtype appears to carry important prognostic implications.[103]

Another distinct entity is schneiderian carcinoma, which commonly represents malignant transformation in a preexisting schneiderian papilloma (SP). Carcinomas arising from SP are rare, with more carcinomas identified

in the inverted type and oncocytic types, with only isolated reports describing carcinomas arising from the exophytic type. Carcinoma ex-SP ranges from 2% to 27% in the literature, but in a recent systematic review, without referral or academic institution bias, the 1.9% rate may be a more accurate rate.[104] In general, the male to female ratio of patients with schneiderian carcinoma ranges from 1.2 up to 6.7, with an overall average of about 3.4:1. Patients range in age from 32 to 86 years, with an overall mean around 61 years. Most patients experienced a mixed anatomic site presentation: nasal cavity combined with maxillary, ethmoid, sphenoid, and/or frontal sinus, with possible involvement of the nasopharynx and ear. SCC is the most common carcinoma type (85%), with other carcinoma types (mucoepidermoid, SNUC, and carcinoma, not otherwise specified [NOS]) less frequent. The role of human papilloma virus (HPV) in the oncogenesis of SP and malignant transformation remains to be defined, but some studies have demonstrated that high-risk HPV is more prevalent in dysplastic SP and in those with malignant transformation.[105,106] The majority of schneiderian carcinomas are synchronous (carcinoma present at primary presentation of SP) with 36% metachronous (carcinoma developing after initial treatment of SP). This highlights the importance of complete excision and careful histopathologic assessment of all SP, which minimizes the risk of recurrence and allows comprehensive evaluation of the specimen for the presence of any coexisting malignancy.[107] The recurrence rates of SP quoted in the literature vary from <5% to as high as 75% and may depend on the surgical approach and the completeness of the surgical excision. Although multicentricity of the tumor has been suggested to be responsible for the high rate of recurrence, inadequate removal of the tumor during the initial resection seems to be the most important predictive factor of local recurrence. This was well demonstrated by Myers et al.[108] who reported <5% recurrence rate of adequately resected SP.

The majority of patients with SNSCC (85%) present with advanced stage (T3 to T4) cancer. Although the reported incidence of clinically evident lymph node metastasis presentation is around 10% to 15%, the overall risk of nodal involvement from SCC of the paranasal sinuses is closer to 30%.[37,109] Regional spread to the lymph nodes is uncommon in cancer confined within the sinus walls. Once invasion into the overlying soft tissue and adjacent structures occurs (e.g., the oral cavity), nodal involvement and even

dissemination to distant sites are noted more frequently. Distant metastasis can be present in up to 10% of patients on initial diagnosis.[110]

Treatment of SNSCC depends on the stage and extent of disease. Early-stage (T1 to T2) tumors can be treated by single modality therapy more commonly surgery or in some selected cases radiation therapy. Patients with localized disease showed 5-year survival rates of 86%, 80%, and 78% when receiving surgery, radiation and surgery, and radiation alone, respectively.[102] Endoscopic sinus surgery may be applied in selected cases as discussed earlier with relatively good outcomes that are comparable to open surgery[54,69,111] (Fig. 10.24). The majority of patients with more advanced and resectable disease are treated with surgery and postoperative radiation. Extension to the skull base is common, and craniofacial resection has enhanced our ability to resect locally advanced tumors successfully.[45,46,112]

Lymph node metastases signify more advanced disease and carry worse prognosis. The reported incidence of lymph node metastasis at presentation varies from 10% to 15%, and nodal recurrence may occur in as much as 30% of patients.[83] The most common sites of involvement are the retropharyngeal and level II nodes. In cases where the primary disease can be addressed surgically and there is clinical evidence of nodal metastasis, a therapeutic nodal dissection should be performed. Management of the clinically N0 neck remains controversial, but elective nodal irradiation may be warranted in patients with locally advanced disease.[36,37,82,109]

Locally advanced disease that is not surgically resectable can be managed with radiation or chemoradiation therapy. Radiation therapy alone in this setting yielded poor results, and more promising outcomes have been reported by the use of intensive regimens of chemotherapy followed by concurrent chemoradiation.[96] In a review of 46 patients with locally advanced SNSCC treated with neoadjuvant chemotherapy at MDACC, more than two-thirds (67%) of the patients achieved at least a partial response to induction chemotherapy, and an additional 9% had stable disease.[78] The 2-year survival for patients with at least a partial response or stable disease after induction chemotherapy was 77% in contrast to only 36% for patients with progressive disease (Fig. 10.49).

Several recent reviews report an improvement in 5-year OS between 30% and 60%.[102,110,111] The most significant predictor of survival remains disease

stage with 5-year OS for localized, regional, and distant disease being 83%, 41%, and 29%, respectively.[102] Recurrence after treatment occurs most frequently locally (36% to 69%), followed by regional (27% to 33%) and distant (15% to 35%).

To improve our understanding of the biologic features of SNSCC and to promote development of novel therapeutic strategies for this disease, identification of new molecular markers is essential. Because of the rarity of this tumor, however, few molecular studies have been done.[35] We recently reported a comprehensive study of molecular markers in tumor specimens from 70 patients treated at MDACC for SNSCC, by using tissue microarrays to explore new useful prognostic markers or novel therapeutic targets.[20] The markers we evaluated included HR-HPV and its surrogate marker p16, the well-known cyclin-dependent kinase inhibitor p16Ink4A; cyclin D1, a key factor for cell cycle G1/S transition; 3 receptor tyrosine kinases, epidermal growth factor receptor (EGFR), human epidermal growth factor receptor 2 (HER2), and c-Kit; tumor suppressor p53 and its downstream proapoptotic protein Bax; matrix metalloproteinases (MMP)-2 and MMP-9, which are known to be associated with tumor invasion and metastasis; vascular endothelial growth factor (VEGF), which stimulates vasculogenesis and angiogenesis; and DNA repair proteins Ku70 and excision repair cross-complementing 1 (ERCC1). EGFR, cyclin D1, MMP-2, MMP-9, Ku70, and ERCC1 were positive in more than half of the specimens. p16 Ink4A, VEGF, p53, and Bax were expressed in 10% to 40% of cases. For all of the markers except HR-HPV, HER2, and c-kit, differences in expression between normal and tumor tissues were significant by two-tailed Fisher exact test. The most significant finding in this study was that patients with EGFR-positive SNSCC had a significantly poorer rate of DFS than patients with EGFR-negative disease (p = 0.01307) (**Fig. 10.50A**). Their OS rate was worse as well, but the difference was not statistically significant (p = 0.06398) (**Fig. 10.50B**). The rate of local recurrence was significantly worse for patients with EGFR-positive disease (p = 0.0144). In summary, this study showed that EGFR protein expression may be a prognostic indicator for SNSCC. If this finding is confirmed by further studies, targeted inhibition of EGFR may be a new approach to treating patients with SNSCC.[20]

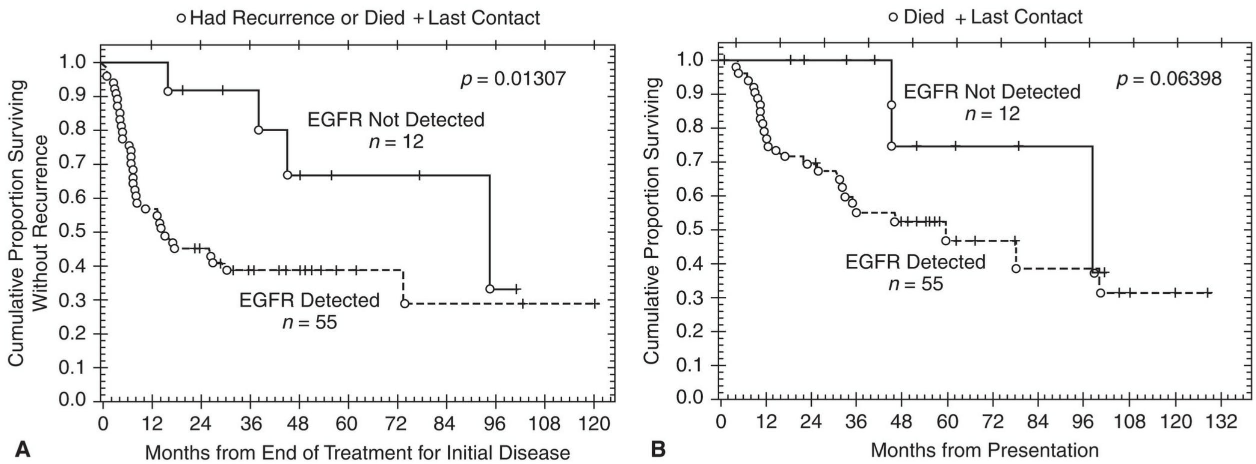

Figure 10.50. Kaplan-Meier analyses of survival of patients with sinonasal SCC according to EGFR expression. **A:** Patients with an EGFR-positive tumor had significantly shorter DFS than patients whose tumor did not express EGFR ($p = 0.01307$). **B:** Patients with an EGFR-positive tumor had a poorer OS rate than patient whose tumor did not express EGFR, but the difference was not statistically significant ($p = 0.06398$). (Takahashi Y, et al. Comprehensive assessment of prognostic markers for sinonasal squamous cell carcinoma. Head Neck. 2014;36(8):1094–1102, Ref. 20.)

Adenocarcinoma.

The World Health Organization classifies primary SNACs into salivary and nonsalivary types. Salivary types are usually well-defined myoepithelial neoplasms, which closely resemble their salivary counterparts. The most common type is ACC, and other types of salivary adenocarcinomas are rare in the SNT, but cases of acinic cell carcinoma, MEC, epithelial–myoepithelial carcinoma, basal cell adenocarcinoma, salivary duct carcinoma, polymorphous low-grade adenocarcinoma (terminal tubulus adenocarcinoma), and carcinoma-ex-pleomorphic adenoma have been reported.[114] Nonsalivary types are separated into intestinal-type SNAC (ITAC) and non-ITAC, and both have low- and high-grade categories.[115] ITACs are aggressive tumors and often arise in the ethmoid sinus. The lesions closely resemble adenocarcinomas of the large intestine with papillae and infiltrating glands lined by tall, columnar epithelial cells with hyperchromatic elongated nuclei. Goblet cells, Paneth cells, and endocrine cells are sometimes present, and a variable amount of extracellular mucus is seen. They are divided into well differentiated (papillary, tubular, and

papillary–tubular type), moderately differentiated (papillary–mucinous and papillary–tubular–mucinous type), and poorly differentiated (mucinous, alveolar goblet cell, signet-ring type).[9] Non-ITACs are somewhat poorly characterized and have been less reported.[116] They are of presumed seromucous gland origin, have marked morphologic heterogeneity, and can arise anywhere in the SNT. Moreover, ITACs typically demonstrate an intestinal-type immunohistochemical profile (CK20+, CK7−, CDX2+, and villin+), whereas non-ITACs reveal a respiratory-type profile (CK20−, CK7+, CDX2−, and villin−).[115]

SNAC is the second most common malignant tumor of the SNT after SCC. It accounts for ~10% to 20% of all sinonasal cancers.[117] However, SNACs have been reported to be the most common pathology in European series. The reason for this is unclear but may be related to increased occupational exposure particularly in the wood industry.[6,8] There is a strong association with wood dust exposure and leather tanning; between 45% and 90% of cases demonstrate prolonged exposure with a mean duration of ~22 to 32 years.[99,113,118–120] Recent studies suggest that this increased risk is specifically linked to the development of ITACs of the ethmoid sinuses rather than other types of SNACs.[9–11] One of the largest series from Italy involved 646 consecutive patients with malignant tumors of the paranasal sinuses that were surgically treated at the Fondazione I.R.C.C.S. Istituto Nazionale dei Tumori of Milan, between January 1987 and November 2007.[9] Among the 345 patients with ethmoid cancer, exposure to organic dusts was found in 148 of 153 patients with ITAC, in 3 of 16 patients with non-ITAC adenocarcinoma, and in 10 of 176 patients with other tumors. The authors concluded that only ethmoid ITACs have an indisputable relationship with the exposure to organic dusts.[9]

The first dedicated large-scale, retrospective analysis of a North American SNAC population reported in 2014 the demographics and survival of patients diagnosed within the time period of 1973 to 2009 using the SEER database.[121] Of the total 1,270 cases of SNAC analyzed, males accounted for 52% of cases, whereas females accounted for 48% of cases, amounting to a male-to-female ratio of 1.06:1.00. This is in great contrast to the striking male-to-female ratio of 21:1 for patients with ITACs reported from Italy by Cantu et al.[9] Age ranges from 9 to 90 years, although the average age of

presentation is between 50 and 60 years. The most common site for nonsalivary SNACs is the ethmoid sinuses (40%), followed by nasal cavity (27%) and maxillary sinus (20%).[114] Patients tend to present with nonspecific symptoms, with nasal obstruction, epistaxis, and headache being the most common complaints.[99,113,120] Presentation is usually similar to that of inflammatory sinonasal pathology, so diagnosis may be delayed.[117] The majority of patients present with advanced disease (T3 or greater).[113]

The mainstay of treatment of SNAC is surgical resection, which can be performed through an endoscopic or open approach such as lateral rhinotomy, midfacial degloving, Caldwell-Luc, or, if the there is skull base invasion, craniofacial resection.[117] Whatever approach is used, the goal of surgery should be complete removal of the tumor with negative margins to maximize local disease control. Postoperative radiation therapy is usually used in most patients with advanced disease (T3 and T4) and can probably be avoided in smaller lesions (T1 to T2) when resection margins are wide, although the exact indications for adding radiation are not well defined and have not been studied in randomized trials. In one of the largest studies reported by the French GETTEC (Groupe d'Etude des Tumeurs de la Tête et du Cou) group, 418 patients who had presented with ethmoid adenocarcinoma at 11 French hospitals from 1976 to 2001 were analyzed to determine the clinical characteristics and treatment of the disease.[119] Treatment consisted of surgery alone in 55 cases (13.2%), radiotherapy alone in 33 cases (7.9%), and combined treatment (surgery and radiotherapy) in 324 cases (77.7%). Five (1.2%) patients received no treatment due to their poor medical status. The survival of these four groups of patients showed a higher rate of survival in groups who had been treated with surgery ($p < 0.0001$). The surgical approach was transfacial in 274 cases (72.5%), combined in 77 (20%), neurosurgical in 22 (6%), and endoscopic in 6 (1.5%). The OS rates of the population for 1, 3, 5, and 10 years were 88%, 72%, 64%, and 49%, respectively. The median survival was 120 months. A Kaplan Meier analysis showed factors that significantly negatively influenced the survival rate of this population were the size of the lesion (T4), lymph node involvement (N+), and invasion of the brain or dura, sphenoid, or orbit.

These findings were similar to studies from North America, where the distribution of non-ITACs is significantly higher than in Europe where ITACs are the predominant type. The recently published MDACC experience

with SNAC demonstrated 5-year OS of 66%, with a median survival of 83 months.[113] The 5-year DSS was 79% with median survival of 121 months (**Fig.** 10.51**A**). Histologic subtypes (ITAC 53% vs. non-ITAC 47%) did not show significant correlation with survival; however, poorly differentiated carcinomas had significantly worse survival compared with well- or moderately differentiated tumors (**Fig. 10.51B**). Similar to the GETTEC series, 5-year survival was found to be significantly worse in patients with T4 disease compared to lower T classifications (p < 0.05; **Fig. 10.51C**). Sphenoid sinus invasion also significantly correlated with worse prognosis (p = 0.013, **Fig. 10.51D**), but unlike the GETTEC series, in the MDACC study prognosis was not affected by patients who presented with skull base invasion or dural invasion (p = 0.162). Multimodality treatment regimens showed significant association with improved survival versus unimodality therapy.

Figure 10.51. Outcomes of patients with SNAC. **A:** OS and DSS of patients with SNAC. **B:** Survival is significantly reduced in patients who have poorly differentiated pathology ($p = 0.002$). **C:** Survival distribution by T classification reveals T4 disease to have significantly lower survival ($p < 0.001$). **D:** Survival is significantly reduced in patients who have sphenoid sinus invasion ($p = 0.013$). (Bhayani MK, et al. Sinonasal adenocarcinoma: a 16-year experience at a single institution. Head Neck. 2014;36(10):1490–1496, Ref. 113.)

More recently, as with other types of sinonasal tumors, endoscopic resection has gained increasing popularity, and several series have reported comparable outcomes to those obtained by open approaches in well-selected patients and with appropriate use of adjuvant therapy.[54,67–69,120,122–125] In 2014, Vergez et al.[120] published a retrospective, multicenter study of nine French tertiary referral centers, of 159 patients with SNAC treated by an endoscopic approach. Histologic margins were positive in 17%. In total, 130 patients received adjuvant radiotherapy on the primary tumor site (58 Gy), 24 cases were not irradiated, and 5 refused treatment. The mean follow-up was

32.5 ± 24 months. The recurrence rate was 17.6% (28 cases) within 23 ± 21 months. Eleven patients underwent a second surgical procedure. Nine patients died of their disease (3T2, 2T3, 4T4b). The overall and disease-specific rate at 3 years was 74% and 84%, respectively. In the MDACC study of patients surgically treated for SNAC, open surgical resections did not offer a greater survival benefit compared with endoscopic procedures across all T classifications.[113] Moreover, open procedures did not significantly improve survival compared with endoscopic surgical resections when outcomes were matched for T1 to T2 (p = 0.52) and T3 to T4 (p = 0.82).

For patients with unresectable SNAC, radiation therapy alone has been used, but to date, the effectiveness of radiotherapy alone for SNAC has not been extensively studied.[126] Generally, radiotherapy as a single-modality treatment has less efficacy than that of surgery or combined therapy; however, it should be noted that patients treated with radiotherapy alone are more likely to have locally advanced incompletely resectable tumors and are not comparable to those treated with surgery. This selection bias is inherent in the literature concerning the efficacy of radiation alone as definitive treatment of patients with SNAC.[117] Promising results are evolving though from newer radiation therapy techniques. For example, a recent study by Koto et al.[126] evaluated the safety and efficacy of carbon ion radiotherapy (CIRT) for patients with locally advanced SNAC. Of the 22 patients with SNAC who were treated with CIRT, 16 patients had CIRT as primary treatment. The majority had T4 disease (5 patients had T4a and 14 patients had T4b). The median follow-up period was 43 months for all patients. The 3-year local control and locoregional control rates for all patients were 77% [95% CI, 56.7% to 97.1%] and 61% (95% CI, 38.5% to 84.1%), respectively. The 3-year OS and DSS rates were 59% (95% CI, 38.6% to 79.6%) and 66% (95% CI, 44.9% to 86.3%), respectively. The authors concluded that CIRT is effective and safe for patients with inoperable SNAC, but further studies on larger numbers of patients and long-term follow-up are needed to define the usefulness of CIRT for locally advanced SNAC.

Another approach that has been less reported for inoperable disease is surgical debulking and the use of adjuvant topical chemotherapy. Although not widely popular, there are two reports of this technique, but results are encouraging.[99,100] Knegt et al.[99] reported their strategy of surgical debulking of SNAC followed by application of topical fluorouracil (5-FU). The 5-FU

application was repeated 8 times with debridement of necrotic tissue at that time. They reported a 79% overall 5-year survival and 87% 5-year DSS. More recently, Almeyda and Capper[100] reported the outcome of 25 consecutive patients with locoregionally advanced SNAC of whom 14 patients were treated with primary radiotherapy and 11 with surgery and topical 5FU. Five-year DFS improved was 50% with primary radiotherapy and 86% with debulking surgery and topical 5FU ($p = 0.03$).

Systemic chemotherapy has also been in used in the management of advanced or metastatic SNAC. There are several reports of metastatic SNAC responding to docetaxel, cisplatin, and 5-FU.[127] Brasnu et al.[128] reported an overall response rate to neoadjuvant cisplatin and 5-FU of 36% ($n = 8$), 23% showed a complete clinical response, and 13% showed complete histologic response. In the series reported by Roux et al.[129] of 54 patients with ethmoid SNACs given neoadjuvant cisplatin and 5-FU, 8 showed complete response (15%), 12 had a >50% reduction in tumor volume (22%), and 34 had no response (63%) or <50% reduction in tumor volume. Patients who did respond fared better with 100% 10-year survival if a complete response was achieved with chemotherapy.

Adenoid Cystic Carcinoma.

ACC accounts for ~10% of all nonsquamous carcinomas in the head and neck and 15% of all tumors of the SGs. It is the second most common cancer of SGs, after MEC. ACC arises more commonly in the minor SGs than in all the major glands combined. It accounts for over 35% of all tumors involving the minor SGs. The oral cavity, including the palate, and the SNT are the most common sites representing 50% and 18% of all ACC in the minor SGs, respectively. ACC represents 3% to 15% of malignant tumors arising in the paranasal sinuses (Fig. 10.12D). It is slightly more common in females, and ~90% of patients are between 30 and 70 years of age, with a peak incidence in the fifth and sixth decades of life.[130–135]

Lupinetti et al.[25] reported a study of 105 patients with sinonasal ACC seen at MDACC from 1990 to 2004. The mean patient age at presentation was 50.8 years (range, 18 to 81 years). Most patients were Caucasians (72.4%), nonsmokers (48.4), and nondrinkers (74.4%). Common presenting symptoms included nasal obstruction, facial pain, epistaxis, nasal drainage, and facial numbness in the distribution of the second division of the

trigeminal nerve. Forty-eight percent of patients presented to MDACC after initial diagnosis of their disease, whereas 19% presented with residual disease after prior treatment, and 33% presented with recurrent disease. The site of origin of the tumor was the maxillary sinus in 46.7% of patients, the nasal cavity in 29.5%, the ethmoid sinus in 11.4%, and the sphenoid sinus in 4.8%. ACC has a propensity for perineural spread and bony invasion and at the time of initial diagnosis, 27.6% of tumors extended to the skull base, and 23.8% invaded the skull base. The majority of patients presented with T3/T4 (76.7%), N0 (98%), and M0 (97%) disease.

ACC exhibits three histologic subtypes based on tumor architecture: cribriform, tubular, and solid. The *cribriform* pattern, which is the most common subtype, has the classic “Swiss cheese appearance” in which the cells are arranged in nests separated by round or oval spaces. The *tubular* (or trabecular) pattern has a more glandular architecture, whereas the *solid* (or basaloid) pattern shows sheets of cells with little or no luminal spaces. The tubular variety has the best prognosis, the solid variety has the worst prognosis, and the cribriform pattern has an intermediate prognosis.[25] Most ACCs usually exhibit a mixed architecture of more than one pattern, and their classification in such cases depends on the predominant histologic subtype.[136]

ACC exhibits a slow growing, locally aggressive, relentless progression of disease. Patients may have symptoms from 10 weeks to 15 years prior to diagnosis, with an average of 5 years. Recurrence can occur 10 to 20 years after the initial treatment, and 5-year “survival” rates may give an erroneous indication of absolute survival. Perineural spread—the hallmark of ACC—is usually evident and provides avenues of spread to the cranial base and the central nervous system.[34] In a recent international collaborative study of 495 patients with ACC of the head and neck, of 239 patients (48%) who had nerve invasion, 174 (73%) had PNI, 65 (27%) had intraneural invasion, and 37 had (15%) perineural inflammation.[137] The maxillary, mandibular, and vidian nerves are the most frequently involved and allow perineural spread of sinonasal ACC through the foramina rotundum and ovale and the vidian canal (Fig. 10.17). Retrograde spread intracranially, or alternatively, and antegrade spread from the gasserian ganglion to the nerve branches in the infratemporal and pterygopalatine fossae can then occur. Achievement of negative surgical margins in such cases is difficult.[75] Perhaps this is one of

the reasons why ACC of the SNT has the worst prognosis of all sites in the head and neck.[137,138] The mechanism of perineural spread of cancer is poorly understood. Neural cell adhesion molecules (NCAMs) may have a role in the pathogenesis of perineural spread of malignant tumors including ACC and SCC.[32,33]

Lymphatic spread of ACC is uncommon. The incidence of lymph node metastasis from ACC detected at presentation or developing later in the course of the disease ranges from 10% to 30%.[139] Metastasis to the regional lymphatics is more common in tumors originating from the oral cavity (37%) than the parotid gland (19%). The rate of occult metastasis in patients undergoing elective neck dissection for the clinically negative neck is 17%, and the role of elective neck dissection remains unclear.[140,141] The development of lymph node metastasis was associated with poor outcome despite aggressive therapy.

Distant hematogenous dissemination is common cause of treatment failure in patients with ACC. In a recent international retrospective review of 489 patients with ACC of the head and neck treated between 1985 and 2011 in nine cancer centers worldwide, 111 patients (22%) developed distant metastases during follow-up.[138] Twenty-nine of them (26%) also had locoregional failure, whereas distant disease was the only site of recurrence in the remaining 82 patients (74%). The most common site of distant metastases was the lung (20%), followed by bone (4%), liver (3%), and brain (1%). Median interval to the diagnosis of distant metastasis was 30 months (range, 2 to 192 months). Multivariate analysis revealed that age ≥70 years, primary site, orbital invasion, and N classification were independent predictors of distant metastases. Most importantly, the metastasis site had a significant impact on both overall (p = 0.04) and disease-specific (p = 0.03) survival. Analysis of outcome according to the site of distant metastasis showed that patients with bone and brain metastases had the poorest outcome, with 31% and 25% median survival, respectively. In contrast, patients with lung and liver metastases had significantly better survival, with 66% and 84% median survival, respectively (p = 0.04).

ACC is an indolent cancer, and late recurrences are common. Survival continues to decline well beyond 5 years and up to 20 years after treatment. Therefore, evaluation of reported outcomes of treatment should carefully examine the length of follow-up. A meta-analysis of sinonasal ACC

demonstrated a 1-year survival probability with treatment of 95%, a 5-year survival probability of 63%, and a 10-year survival probability of 32%.[133] This highlights the importance of lifelong follow-up and cancer surveillance for patients treated for sinonasal ACC.

Although surgery remains to be the mainstay of treatment of sinonasal ACC, multimodality treatment is warranted for the majority of sinonasal ACC. Surgery followed by postoperative radiation therapy is the standard treatment approach[25,142] and has been shown to provide the better survival outcomes than single-modality therapy.[25,143,144] A recent systematic review of studies for sinonasal ACC from 1960 to 2012 demonstrated that surgery with postoperative radiotherapy is the most commonly used and may possibly be the most effective therapy, and aggregate patient data meta-analysis revealed a 5-year survival rate of 62.5%.[133] The largest single institution experience of patients with sinonasal ACC was published by MDACC in 2007 and reported similar findings.[25] Of the 105 consecutive patients reviewed, the majority of patients presented with T3/T4 (77%), N0 (98%), and M0 (97%) disease. Surgery was the initial therapy in 70% of patients and the majority (85%) of patients treated with surgery received postoperative radiation therapy. The mean follow-up after the end of original treatment to the date of last contact was 76.6 months. Surgery with postoperative adjuvant radiation provided the best overall and DSS compared with other treatment modalities ($p = 0.018$ and $p = 0.05$, respectively). The local recurrence rate was 30%, and the distant metastases rate was 38%. The 5-year OS and DSS rates were 63% and 71%, respectively[25] (**Fig. 10.52A**). When the OS and DSS of patients were compared according to the epicenter of the original tumor, patients with nasal cavity tumors had the best survival, and patients with sphenoid tumors had the worst survival ($p = 0.003$ and $p = 0.031$, respectively) (**Fig. 10.52B**). Skull base invasion also was identified as a significant factor for overall and DSS compared with no skull base invasion ($p = 0.029$ and $p = 0.031$, respectively). Patients with stage IV disease had worse OS than patients with stage I, II, and III disease ($p = 0.018$) (**Fig. 10.52C**). In addition, when patients were grouped according to T classification, patients who had T4 disease had a worse OS compared with patients who had T1, T2, or T3 disease ($p = 0.013$). When the histopathologic types of ACC were compared, there was a significant difference in overall and DSS. Patients with cribriform tumors had the best survival, and patients

with solid tumors had the worst outcome ($p = 0.002$ and $p = 0.019$, respectively) (**Fig. 10.52D**).[25]

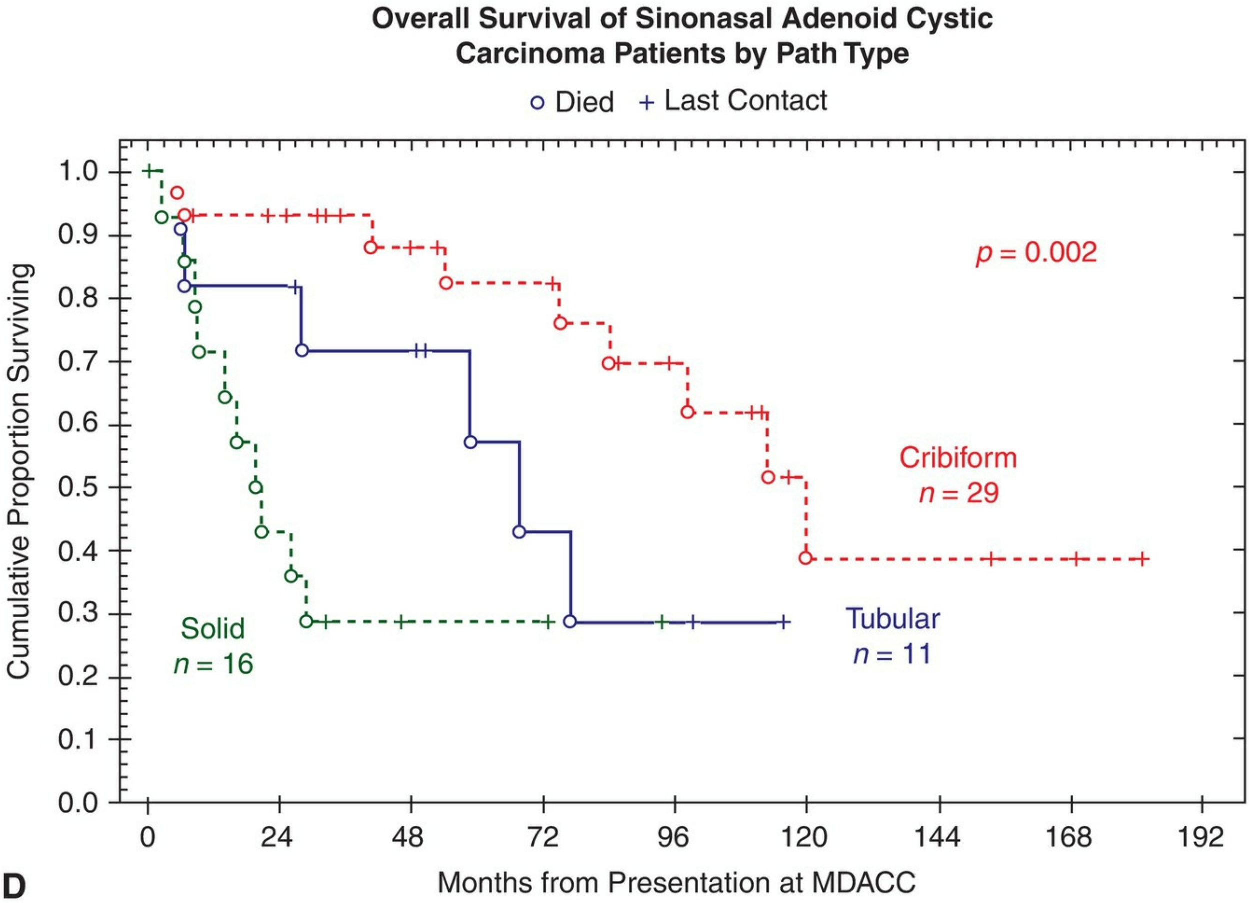

Figure 10.52. A–D: Survival of patients with ACC.

Several studies suggested that fast-neutron radiation therapy provides higher rates of locoregional control of unresectable or recurrent ACC compared to photon or electron radiation therapy and perhaps should be considered the initial treatment of choice in some cases.[145–147] In one study of patients treated with fast neutron for gross inoperable, residual unresectable, or recurrent disease, the 5-year locoregional control rates were 92% for patients treated definitively (without a prior surgical procedure), 63% for those treated postoperatively for gross residual disease, and 51% for those treated for recurrent disease after a surgical procedure.[148] This study suggested that neutron irradiation alone may be the therapy of choice in the treatment of some patients with unresectable advanced stage ACC and that surgery should be limited to those patients in whom disease-free margins can be obtained. The potential morbidity of a “debulking” surgical procedure before neutron irradiation is not warranted because no improvement in locoregional control can be demonstrated over that achievable with neutron

therapy alone.

A study of 75 patients with inoperable, recurrent, or incompletely resected ACC showed that fast-neutron radiotherapy provides higher local control rates than a mixed beam and photons. This advantage for neutrons in local control however was not transferred to significant differences in survival because of a high incidence of distant metastasis, which occurred in 40% of these patients.[146] In another recent study of 72 patients with recurrent or gross residual ACC after surgery treated with fast-neutron therapy, the RFS was 83% after 1 year, 71% after 2 years, and 45% after 5 years.[147] These impressive results are encouraging; however, the use of fast-neutron radiation therapy is hampered by the lack of its widespread availability. Currently, only a few facilities are equipped with the technology and expertise of delivering fast-neutron radiation therapy.

More recently, proton therapy has been reported to have promising initial outcomes for the treatment of advanced unresectable or recurrent ACC of the head and neck.[149] In a study of 23 patients with ACC of the skull base by Pommier et al.[150] from the Mass Eye and Ear Hospital, the 5-year overall and DSS were 56% and 77%, respectively. Twelve patients had been treated with prior surgery with gross residual disease or positive resection margins. At 5 years, the local control was 93%, and the freedom from distant metastasis was 62%. The development of multifield optimization (MFO) through intensity-modulated proton therapy (IMPT) may further enhance the efficacy of proton therapy for patients with head and neck tumors. Frank et al.[151] from MDACC reported the first clinical report of MFO-IMPT for head and neck tumors. Early clinical outcomes are encouraging and warrant further investigation of proton therapy in prospective clinical trials.

Another emerging approach in treating unresectable ACC is the use of concurrent chemoradiation. In a recent report of 16 patients with unresectable head and neck ACC treated with concurrent chemoradiation, 13 patients were alive and 7 without signs of disease with a median follow-up of 61 months.[152] Tumor progression was noted in eight patients (50%) (distant metastasis in five patients and local tumor progression in three patients) with a median time to progression of 25 months (range, 4 to 52 months). OS, PFS, and LPFS rates at 5 years were 87%, 39%, and 61%, respectively. This study suggested that concurrent chemoradiation is a feasible treatment option and may lead to sustained locoregional tumor control in patients with nonresected

ACC of the head and neck.

Systemic therapy including chemotherapy and targeted therapy is generally reserved for the palliative treatment of symptomatic locally recurrent or metastatic disease that is not amenable to further surgery or radiation.[153,154] Prospective trials of chemotherapy in advanced ACC are limited, and the optimum regimen is unclear. A recent systematic review summarized and rated the quality of trials assessing chemotherapy for treatment of ACC. Endpoints evaluated include tumor response and rates of symptomatic improvement in 34 trials involving 441 patients.[155] Single-agent mitoxantrone, cisplatin, epirubicin, vinorelbine, paclitaxel, and gemcitabine were studied in 141 patients. Objective major responses were uncommon (18 of 141), with none observed in the 14 patients who received paclitaxel or the 21 patients who received gemcitabine. No responses were seen in previously treated patients. Reported response durations ranged from 5 to 20 months. Stable disease was more common than objective responses and was reported in 64 of 111 patients. Disease stabilization might be a marker of antitumor activity, but this is difficult to interpret unless clear evidence of progression is documented before the start of therapy. Notable rates of disease stabilization (in 39 of 66 patients) were also seen in trials that required progressive or symptomatic disease for study entry.[155]

The activity of standard cytotoxic drugs given in combination was studied in 143 patients enrolled in 17 trials.[155] Less than 15% of patients had prior systemic therapy. By contrast with single-agent studies, most patients had distant metastases. Cisplatin and doxorubicin were the most common drugs given in combination regimens and were given with cyclophosphamide (CAP regimen) in four trials. Although the trials assessing CAP regimen used slightly different doses and schedules, major objective responses were noted in nine of 36 patients (response rate 25%; 95% CI, 11% to 39%). Regimens containing both cisplatin and an anthracycline other than doxorubicin also showed modest activity, as did other platinum-based regimens. In 14 studies, cisplatin-based regimens led to objective responses in 29 of 118 patients (response rate 25%, 17% to 33%). Response duration ranged widely, from 6 to 77 months. Experience with carboplatin-based regimens has been even more limited: a study of carboplatin plus paclitaxel reported a response rate of 20% (2 of 10 patients), and two studies reported that all seven patients who received carboplatin instead of planned cisplatin did not respond to therapy.

Disease stabilization in patients who had been progressing was reported in trials of cisplatin-based therapy. Duration of disease stabilization for patients with ACC given any regimen was reported in only two trials. In two studies, none of the previously treated patients responded to trial therapy.[155]

Because chemotherapy has been of only limited palliative benefit in patients with advanced disease, and there has been little exploration of its use in definitive management, recent investigation has focused on identification of the characteristic molecular signatures and genomic alterations in ACC and other SG cancers.[153] These efforts have suggested the potential for molecularly targeted therapies, and clinical trials exploring this approach are currently underway.[154] A good example is the imatinib experience in c-kit–positive ACC. High expression of c-kit has been noted in up to 90% of ACC tumors. In a systematic review by Laurie et al.,[155] six studies have assessed imatinib activity in ACC, with only two objective responses reported in 71 evaluable patients. Both responses were stable (durations of 14 months and at least 15 months) and occurred in the only study that required high c-kit expression and progressive disease for study entry. Stable disease was reported more commonly than objective responses; however, evidence of disease progression at study entry was either not required or not stated in most trials. One trial did explore the efficacy of imatinib in combination with cisplatin: patients received imatinib alone for 2 months, and those who did not respond or progressed were also given cisplatin. Of 17 evaluable patients, 2 patients progressed, and no objective responses were observed during the imatinib-alone phase. With the addition of cisplatin, three partial responses were noted. Studies of other targeted agents in ACC are summarized in the meta-analysis by Laurie et al.[155] Phase 2 studies of the EGFR inhibitors gefitinib (19 patients) and cetuximab (23 patients) did not report any major objective responses. Disease stabilization was reported with both drugs; however, not all patients had progressive disease at the time of study entry. Lapatinib, a dual inhibitor of EGFR and HER2 (also called ERBB2), was studied in 19 patients who had documented radiologic progression, symptomatic deterioration, or both, within 6 months of study entry. Immunohistochemistry evidence of expression of either target was required. No objective responses were seen, although nine patients (47%) had disease stabilization for at least 6 months. The proteasome inhibitor bortezomib has been studied in 25 patients. Eligible patients had evidence of disease

progression within the previous 9 months. Bortezomib was given until disease progression, at which time doxorubicin was added, given weekly for 2 of 3 weeks. No objective responses were reported with single-agent bortezomib, but 17 patients had disease stabilization, with a median PFS of 8.5 months. One objective response was seen with the addition of doxorubicin. Overall, therapy was well tolerated. In summary, recent progress in our understanding of the molecular biology of ACC promises the possibility that more specific targeted therapies might prove useful. The careful design and conduct of prospective clinical trials will be critical to improving our treatments for this disease.[153,154]

Mucoepidermoid Carcinoma.

MEC is the most common SG malignancy. Primary sinonasal MEC (SN-MEC) is rare. It is most commonly located in the nasal cavity, followed by the maxillary sinus. There are few published studies reporting on the natural history of MEC.[156–158] In 2015, a report of the SEER database (1973 to 2010) identified 149 cases of SN-MEC and 4,234 cases of SG-MEC.[159] They analyzed the demographic, clinicopathologic, and survival characteristics of SN-MEC and established comparisons with primary major SG-MEC. Mean ± standard deviation (SD) age at diagnosis for SN-MEC was 58.6 ± 16.6 years. High histologic grade (i.e., grades 3 and 4) at the time of diagnosis was more common among SN-MEC than SG-MEC (42.3% vs. 25.5%, $p < 0.0001$). Overall 5-year DSS was 62% for SN-MEC and 84% for SG-MEC ($p < 0.001$). For SN-MEC, factors associated with poor prognosis were age [75+ years; hazard ratio (HR), 3.38; 95% CI, 1.25 to 9.51], higher tumor grade (grades 3 and 4; HR, 3.62; 95% CI, 1.75 to 8.22), larger tumor size (>4 cm; HR, 8.36, 95% CI, 1.59 to 153.74), and primary tumor site (ethmoid sinus; HR, 2.95; 95% CI, 1.28 to 6.23) (all $p < 0.05$). Survival was better among those treated with surgery [with (64.4% survival) or without (81.3% survival) adjuvant radiation therapy] than those treated with primary radiation therapy alone (25.6% survival) ($p < 0.05$). This report represents the largest series of SN-MEC to date and highlighted that although SN-MEC and SG-MEC share a common histology, there are important clinical differences between the two conditions.[159]

Esthesioneuroblastoma.

First described by Berger, Luc, and Richard in 1924, ENB, also known as

olfactory neuroblastoma, is a tumor of neural crest origin. It arises almost exclusively from the olfactory epithelium of the nasal cavity and paranasal sinuses. ENB represents 3% to 6% of all sinonasal cancers.[160]

Patients presenting with ENB are typically reported to have a slight male predominance and a bimodal age distribution, with one peak in the second decade of life and the second peak in the sixth decade of life.[161] However, a recent report from MDACC of 70 patients with ENB treated from 1992 to 2006, the median age at diagnosis was 51 years with a range 9 to 78 years.[162] The most common age group of presentation was the sixth decade (20%), followed by the fifth and seventh decades of life. This observation is confirmed by a population-based analysis of the SEER database, where patients in the second decade of life comprised <10% of the cohort.[163]

The most common site of origin is in the superior nasal vault in the region of the cribriform plate.[160,164] “Ectopic” origin in lower nasal cavity or within one of the paranasal sinuses (e.g., maxillary sinus) may occur.[160,164] ENB may on occasion present as an intracranial (frontal lobe) mass with involvement of the superior aspect of the cribriform plate or rarely occur intracranially with no intranasal component.[165]

Microscopically, the tumor is composed of round cells larger than lymphocytes, with round nuclei, dense chromatin, and inconspicuous cytoplasm. The hallmark of this tumor is the arrangement of these cells into rosettes, pseudorosettes, or sheets and clusters. In the absence of rosettes and pseudorosettes, the differential diagnosis includes peripheral neuroectodermal tumor (PNET), anaplastic carcinoma, malignant lymphoma, malignant melanoma, plasmacytoma, embryonal rhabdomyosarcoma, and metastatic small cell carcinoma (SmCC). ENB can be particularly confused histologically with several other “small blue round cell tumors” of the nasal cavity and paranasal sinuses, including SNUC, NEC, SmCC, pituitary adenoma, melanoma, lymphoma, and rhabdomyosarcoma. Expert histopathologic review is essential in confirming the diagnosis because a study demonstrated a significantly high misdiagnosis rate of patients referred to MDACC with presumed diagnosis of ENB.[43] Immunohistochemistry is usually needed to establish the diagnosis in such cases, and ENB usually expresses a variety of neuroendocrine markers such as neuron-specific enolase (NSE), chromogranin, and synaptophysin but usually does not

express cytokeratin.[42]

The distinction between ENB, NEC, SNUC, and SmCC is critical because it has a huge impact on the choice of initial therapy and prognosis. In 2004, Rosenthal et al.[23] reported the outcomes of 72 adults with pathologically proven, nonmetastatic, primary sinonasal neuroendocrine tumors treated at MDACC from 1982 to 2002. There were 31 patients with ENB, 16 patients with SNUC, 18 patients with NEC, and 7 patients with SmCC. Patients with ENB usually were treated with local therapy alone (surgery and/or radiotherapy); only 3 of 31 patients (9.7%) received treatment (radiation) to regional lymphatics, and only 5 of 31 patients (16.1%) received chemotherapy. In contrast, patients with non-ENB histologies usually received chemotherapy (10 of 16 patients with SNUC, 12 of 18 patients with NEC, and 5 of 7 patients with SmCC), and nonsurgical locoregional therapy was used more frequently (6 of 16 patients with SNUC, 4 of 18 patients with NEC, and 5 of 7 patients with SmCC). The median follow-up for surviving patients was 81.5 months (range, 6 to 266 months). OS and local, regional, and distant disease control at 5 years was best for ENB and declined significantly for NEC, SNUC, and SmCC in descending order (**Table 10.7**). Delayed regional lymph node metastasis was common in ENB and increased the regional failure rate from 8.7% at 5 years to 31.9% at 10 years.[23]

Table 10.7 Summary: Survival and Patterns of Failure in Patients with Sinonasal Carcinomas with Neuroendocrine Differentiation

Histology	5-Year Rates (%)			
	OS	LC	RF	DM
ENB	93.1	96.2	8.7	0.0
NEC	64.2	72.6	12.9	12.3
SNUC	62.5	78.6	15.6	25.4
SmCC	28.6	66.7	44.4	75.0

Rosenthal DI, et al. Sinonasal malignancies with neuroendocrine differentiation: patterns of failure according to histologic phenotype. *Cancer.* 2004;101(11):2567–2573.

The prognosis of ENB depends on the extent of disease at presentation. Several staging systems have been proposed, and no single one has become universally accepted. Kadish staging was the first classification system for ENB. Although it was initially described based on 17 patients only, it remains the most popular and simplified go-to staging system.[166] Its main limitation is that it only assesses local disease extent: Kadish A for tumors limited to the nasal cavity only, Kadish B for involvement of the paranasal sinuses, and Kadish C for extension outside the paranasal sinuses. Dulguerov[167] and Biller[168] then proposed more detailed TNM-type staging systems. Dulgerov's classification differentiates between intracranial and/or orbital extension, whereas Billers' separates resectable versus nonresectable parenchymal brain disease. More importantly, both of these staging systems take into account regional neck node involvement and distant metastasis. Lymph node metastasis was in fact shown to be in itself a major determinant of prognosis and to be associated with poorer outcome. In the Princess Margaret report, Dulguerov classification correlated most closely to survival and recurrence.[169] Zafereo et al.[170] also demonstrated that the TNM-based systems (Dulgerov and Biller) in contrast to Kadish staging could reliably identify worse DFS. Therefore, recognizing the poor prognostic implications of regional and distant disease, Morita and his colleagues[171] from the Mayo Clinic proposed a more accurate and practical modification to the Kadish system. Cervical lymphadenopathy and distant metastasis are incorporated as a fourth "D" category. In this scheme, Jethanamest et al.[163] in a SEER database review showed significant outcome differences among the four groups with a worse DFS for the D category. ENB has its own T and N designation in the most recent staging of Sinonasal Cancer According to the AJCC 7th edition that was modified in 2010 (Table 10.2). This staging system, which relies on high-resolution imaging prior to therapy, recognizes the early involvement of the cribriform plate, but it allows for tumors that arise below the cribriform plate and that can be treated in a more conservative fashion to be staged separately. Also, a stage is included at which a tumor is intracranial but remains extradural and is therefore likely to have a better prognosis than a tumor that has invaded the brain. Nodal disease in this classification is either absent (N0) or present (N1). Despite the efforts to better characterize ENB's clinical behavior, staging systems individually are far from ideal. Although some have used them as predictors of outcome, they remain, for many, questionable and suboptimal tools of stratification for

patients with ENB.[172]

There is evidence that the histologic grade of ENB influences biologic behavior, particularly as it relates to disease progression, local recurrence, and metastasis. Histologically, well-differentiated ENB forms nests or sheets of cells in a neurofibrillary stroma. Nuclei are small, round to ovoid with punctuate “salt and pepper” chromatin. The glandular architecture with true lumen rosette (Flexner-Wintersteiner) or pseudorosette (Homer-Wright) formations is characteristic.[172] The Hyams grading system, proposed back in the late 80s by the American Forces Institute of Pathology, is a scheme that captures the spectrum of ENB maturation, from indolent disease to more aggressive behavior.[173] A score from 1 to 4 is given based on the degree of expression of key adverse features: mitotic activity, nuclear pleomorphism, rosette formations, necrosis, disorganized architecture, and sparse fibrillary matrix (**Fig. 10.53**).

HYAM’s	Grade 1	Grade 2	Grade 3	Grade 4
Architecture	Lobular	Lobular	Variable	Variable
Mitotic Activity	Absent	Present	Prominent	Marked
Nuclear Pleomorphism	Absent	Moderate	Prominent	Marked
Fibrillary Matrix	Prominent	Present	Minimal	Absent
Rosette	HW	HW	FW	FW
Necrosis	Absent	Absent	+/– Present	Common
Hematoxylin & Eosin				
Figure 10.53. Key features and criteria for HYAM’s grades 1, 2, 3, and 4 and their corresponding histopathologic H&E slides.

Although the initial data supporting the value of the Hyams classification for prognostication has been critically received because of the subjective nature of the grading, a building body of evidence is trending toward validation of grade as an essential tool in prognostication and management. Three recent studies from the Mayo Clinic,[174] UCSF,[175] and The Institue Gustave Roussy in France[175] demonstrated that the Hyams grading system in

either an independent or a complimentary predictor of outcome and prognosis compared to the Kadish or AJCC staging systems. Bell et al.[173] from MDACC published the most recent and largest study comparing the effect of grade and stage on prognosis. Out of 124 ENB cases identified, 121 were assessed for Hyams grading and 109 for modified Kadish staging. Clinically, of the 109 cases that had been staged, 16% were stage A, 33% stage B, 43% stage C, and 8% stage D. Histologically, 62% of tumors were low grade (1/2), 21% were high grade (3/4), and 17% were metastasis. Although high-grade ENB had significantly worse DFS, the analysis revealed no statistically significant differences, for either modified Kadish stages or TNM stages, in terms of recurrence, distant metastasis, or 5-year survival rates. Briefly, in this large cohort of ENB, high grade was significantly associated with poor outcome, whereas advanced stage was not. The collective evidence of these studies suggests an important prognostic impact of histologic grade and perhaps the need for and intensity of adjuvant therapy in high-grade tumors.

Adequate surgical resection is the treatment of choice for olfactory neuroblastoma.[160] Early-stage, low-grade ENB, confined to the nasal cavity, may be treated with surgery alone provided resection margins are negative for tumor. For advanced disease and high-grade tumors, treatment involves multimodality therapy. In such cases, surgery combined with radiation is superior to surgery alone as definitive therapy.[163,165,176–179] In a recent study of 70 patients with ENB treated at MDACC, patients who were treated with surgery alone had a median DSS of 87.9 months, whereas those who were treated with surgery and postoperative radiation had a median DSS of 218.5 months ($p = 0.047$).[162] Radiation therapy followed by surgery may also be used. The University of Virginia group treats patients with Kadish A or B tumors with preoperative radiation therapy and those with Kadish C tumors with preoperative sequential chemotherapy and radiation therapy. The 5- and 15-year DFS were 86.5% and 82.6%, respectively. The local–regional recurrence was 24%, and distant recurrence was 10%.[180]

Several surgical approaches have been described. Whatever approach is used, the goal of surgery must be complete surgical resection with tumor-free margins. This offers the best chances of locoregional control as well as survival. Because the tumor originates from the olfactory epithelium, most tumors arise close to or within the nasal roof. In most cases, the cribriform plate will usually, by necessity, need to be resected en bloc with the tumor to

achieve adequate surgical margins. The most commonly used approach to adequately resect tumors in these locations is a combined anterior craniofacial resection. Over the past decade, endoscopic surgery has become an accepted treatment modality in early-stage ENB. Several small series have reported 3- to 5-year DFS of between 89% and 100%.[54,68,69,181–184] In a meta-analysis of 23 papers comparing endoscopic to open surgery, endoscopic surgery was most frequently used to treat Kadish A and B disease and resulted in a 10-year OS of 90%.[179] The incidence of local recurrence has been reported to be between 10% and 30%, and indications for postoperative radiation therapy or chemoradiation therapy include high Hyams grading, advanced stage disease, intracranial extension, and positive resection margins.[165,173,185,186]

Five to eight percent of patients will have neck disease at presentation and is a negative prognostic indicator.[165] These patients should be offered therapeutic nodal dissection with postoperative irradiation if indicated. Twenty-five percent of patients with untreated necks will develop nodal metastasis.[187] Delayed regional lymph node metastasis is common in ENB. In a study from MDACC, the regional failure rate was 8.7% at 5 years but rose to 31.9% at 10 years.[23] There are no reports that prophylactic neck dissection is beneficial, but there are limited data that ENI to the cervical nodal basin is associated with a reduction in relapse rates and should be considered in patient treated with advanced stage or high-grade disease.[188]

Despite promising 5-year outcomes, the results of long-term follow-up are not well reported. This is critical because recurrences continue to occur after 5 years. Ow et al.[160] from MDACC specifically reported long-term outcomes of ENB in a study with a median follow-up of 91.4 months (7.6 years). In their report, the median time to recurrence was 6.9 years, and the incidence of overall recurrence and distant metastasis (DM) was 46% and 15%, respectively. Recurrences have been reported beyond 10 years after the initial diagnosis, and patients treated for ENB warrant long-term follow-up.[49,180,189]

Sinonasal Undifferentiated Carcinoma.

The original definition for SNUC was reported by Frierson et al. as a “highly aggressive and clinicopathologically distinctive carcinoma of uncertain histogenesis with or without neuroendocrine differentiation but without

evidence of squamous or glandular differentiation” that typically presents with locally extensive disease.[190,191] SNUCs are rare tumors, with fewer than 200 reported cases. SNUCs can present from the third to ninth decade, with a median age in the sixth decade.[192] There is a slight male predominance.[192–194] The majority of SNUCs arise in the ethmoid and maxillary sinus.[194] Patients are symptomatic, presenting with nasal obstruction, epistaxis, proptosis, cranial nerve palsies, visual disturbances, or pain. Symptoms are of relatively short duration (from weeks to months) compared with other sinonasal neoplasms, which have a more gradual onset.[41] The majority of patients present with stage T4 disease,[194] and ~50% present with orbital involvement and/or skull base and brain involvement. The rate of lymph node metastasis is 10% to 30%, and distant metastasis occurs in 25% to 30% of patients, mostly to the lung and bone.[23,192–195]

The differential diagnosis of SNUC includes a variety of undifferentiated tumors that can be categorized as an epithelial or a nonepithelial neoplasm[41] (**Fig. 10.54**). Recently, we described a practical algorithm of immunophenotyping and genotyping for differentiating these neoplasms[41,42] (**Fig. 10.55**). A definitive diagnosis is important in making treatment recommendations that drive patient outcomes.

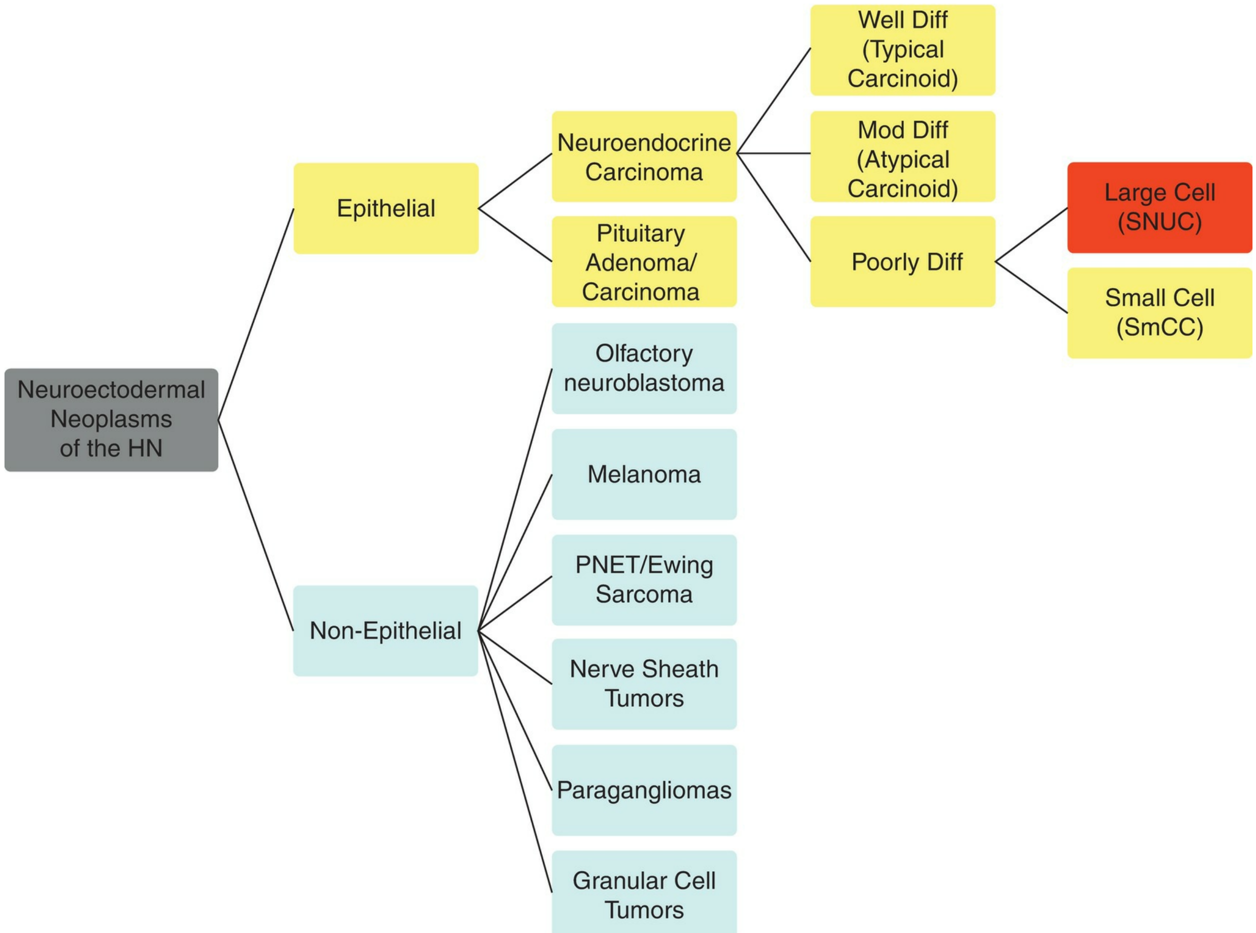

Figure 10.54. Neuroectodermal neoplasms of the head and neck.

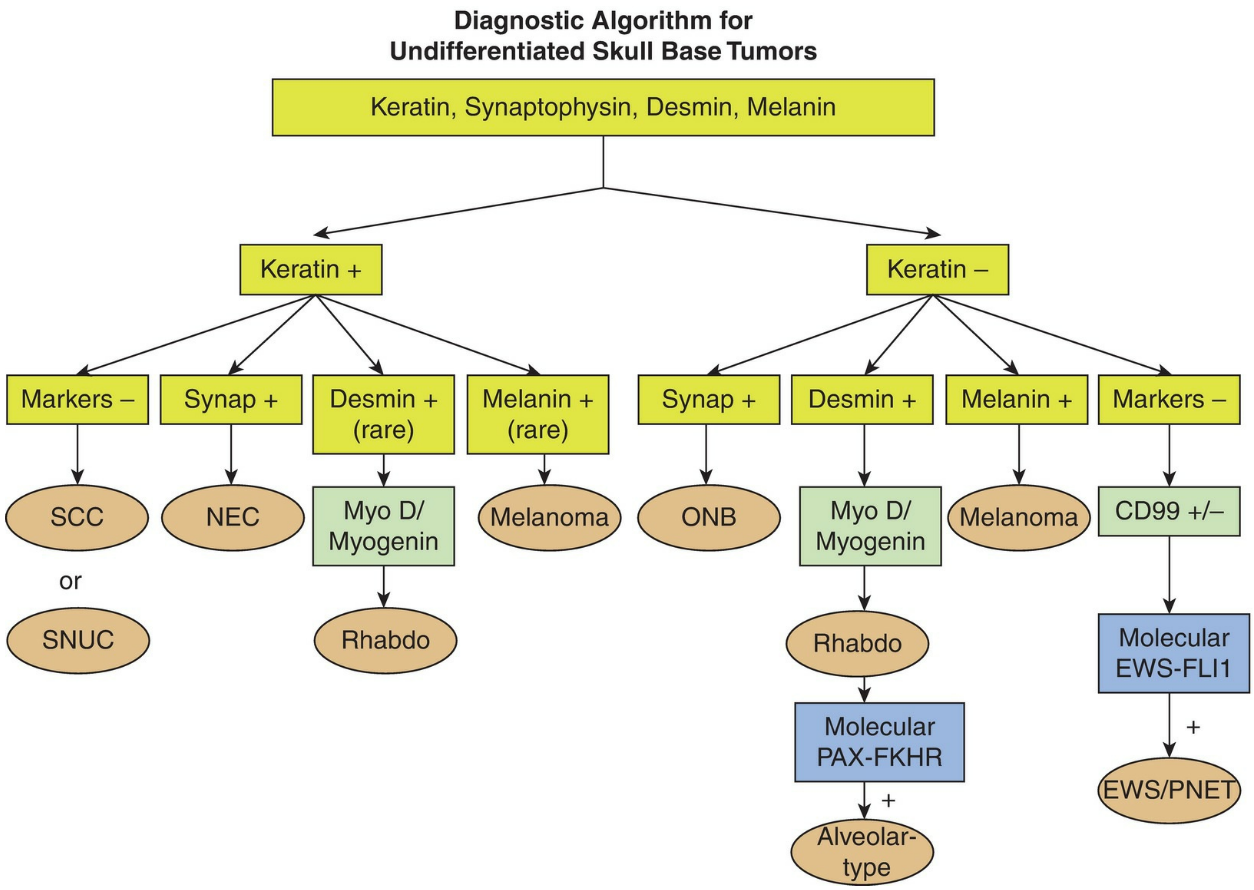

Figure 10.55. Diagnostic flow chart for immunohistochemical evaluation of poorly differentiated skull base tumors. An initial panel **(A)** of keratin, synaptophysin (Synap), desmin, and melanin markers allows for the classification of most neoplasms. Panel B includes confirmatory/ancillary markers and molecular studies for rhabdomyosarcoma (Rhabdo), MyoD or Myogenin, and PAX-FKHR for the alveolar type, and Ewing sarcoma/peripheral neuroectodermal tumor (EWS/PNET), CD99, and EWS-FLI1. ONB indicates olfactory neuroblastoma; NEC, neuroendocrine carcinoma; SCC, squamous carcinoma; SNUC, sinonasal undifferentiated carcinoma. (Cordes B, et al. Molecular and phenotypic analysis of poorly differentiated sinonasal neoplasms: an integrated approach for early diagnosis and classification. Hum Pathol. 2009;40(3):283–292, Ref. 42.)

The optimal treatment of SNUC is not well defined in the literature. The rarity of the disease combined with the inconsistent treatment strategies makes it difficult to draw any conclusions on the best treatment strategy for patients with SNUC. There is uniform adoption however of a multimodality approach given the advanced locoregional disease at presentation and the

propensity for distant dissemination.[23,192–204] In general, there are two major treatment strategies; the first is primary surgical resection followed by adjuvant radiation or chemoradiation, and the second is primary radiation or more often chemoradiation, with surgery reserved for salvage of persistent or recurrent disease. It is difficult to compare the outcomes of these two divergent strategies because the former (primary surgery) is more often reserved for "resectable" disease. This selection bias will preferentially include the less common but favorable disease for surgical treatment and assign patients with more advanced and less favorable disease to nonsurgical therapy. It is no surprise then that reported 5-year survival rates range from <10% to over 65%.[23,192–204]

Our preferred approach at MDACC for patients with SNUC is to start with induction or neoadjuvant chemotherapy. The rationale for this strategy is the relatively high risk of distant metastasis, which is a major component of treatment failure and death from disease. We treated 30 consecutive patients with this approach, and all but one patient had T4 (26 patients, 87%) or T3 (3 patients, 10%). The most common chemotherapy regimen used included platinum and etoposide. Response to chemotherapy was classified as complete in 4/30 (13%), partial in 14/30 (47%), stable in 6/30 (20%), and progressive disease in 6/30 (20%) of patients (**Fig. 10.56**). Patients with complete or partial response were more likely to receive chemoradiation (11/18, 61%) or radiation (5/18, 28%) than surgery (2/18, 11%) for their subsequent definitive locoregional therapy. By contrast, patients who showed no response to induction chemotherapy (stable or progressive disease) were more likely to receive surgery (8/11, 73%) than chemoradiation or radiation (4/11, 37%) for subsequent locoregional therapy. The survival outcomes of these 30 consecutive patients treated uniformly with this approach are shown in **Figure 10.57A**. These outcomes are better than those reported in the literature and may suggest an added advantage for incorporating neoadjuvant chemotherapy in the overall management of patients with SNUC. More importantly, response to chemotherapy was predictor of a more favorable survival regardless of subsequent locoregional therapy (**Fig. 10.57B**). We also continue to study the molecular characteristics of SNUC in an effort to either better predict response to therapy or provide novel targets for molecular therapy.[205] We were also able to establish and characterize a novel SNUC cell line in order to facilitate further research in the biology of this rare

disease.[206]

Neuroendocrine Carcinoma.

NEC are very rare in the nasal cavity, paranasal sinuses, or nasopharynx.[207] The recognizable types are typical carcinoid (well differentiated), atypical carcinoid (moderately differentiated), and SmCC neuroendocrine type (poorly differentiated).[208] There are also rare cases that do not fit these categories, and the diagnostic label "neuroendocrine carcinoma, not otherwise specified" may be applied. The limited number of cases published hampers evaluating the ideal treatment strategy.[209–211] A recent study from MDACC reviewed their experience of patients with NEC to determine prognostic factors, treatment strategies, and OS from this rare malignancy.[212] The median age at presentation was 56 years, with equal sex distribution. The majority of patients presented with T3 or T4 disease (78%) and was node

negative (82%). The most common sites of tumor origin were the ethmoid sinus (64%), the nasal cavity (32%), and the maxillary sinus (14%). Approximately half of the cohort received surgery as the primary treatment modality and one-third received chemoradiation therapy. The 5-year OS, DSS, and DFS were 67%, 79%, and 44%, respectively. The incidence of local, regional, and distant failure was 21%, 25%, and 18%, respectively. These results are better than generally reported.[209–211] Predictors of poor outcomes were patients with foveal or orbital involvement and tumor originating outside of the nasal cavity. A complete response to neoadjuvant chemotherapy correlated with improved survival at 3 years.[212] Given the high incidence of distant failure and the chemosensitivity of NEC, neoadjuvant chemotherapy followed by either chemoradiation or surgery and postoperative radiation therapy is a promising strategy. In an earlier report from our institution where eight of 18 patients were treated with neoadjuvant chemotherapy, the OS and local, regional, and distant recurrence were 64.2% and 27.4%, 12.9%, and 12.3%, respectively.[23]

Melanoma.

Malignant melanomas develop from melanocytes derived from the neural crest cells. Although cutaneous melanoma is by far the most common type, melanomas can arise in any organ in which melanin-containing cells are present. Overall, mucosal melanomas remain a rare entity that account for only 0.8% to 3.7% of all melanomas; however, more than half of these cases will arise in the head and neck region most commonly from the sinonasal respiratory mucosa or the oral squamous mucosa.[213] Sinonasal mucosal melanomas (SNMM) are infrequent and account for <1% of all melanomas and up to 4% of all sinonasal malignancies.[214] Epistaxis is the most common presenting symptom followed by nasal obstruction. The lateral nasal wall is the most often affected site, followed by the nasal septum, maxillary sinus, and ethmoid sinus.[213,215–218] Melanomas arising from the nasal cavity had a more favorable prognosis than those arising from other subsites probably related to earlier symptomatology and lower stage of disease at presentation compared to those arising from paranasal sinuses. Unlike cutaneous melanoma, SNMM can be nonpigmented in 35% to 40% of patients.[217,218]

The staging system for sinonasal melanoma has been in evolution. In 1970, Ballantyne introduced a clinical staging system for mucosal

melanomas of the head and neck.[219] This is a simple system that comprises three stages: stage I for local disease, stage II for regional disease, and stage III for distant disease. Although it was widely used, it could not be validated as an independent prognostic factor, mostly because the low percentage of patients who presented with stage II or III. According to Ballantyne's clinical staging system, 76% to 95% of patients with SNMM present with stage I disease.[220] Although the Ballantyne staging system is simple, unfortunately it could not provide prognostic classification because the majority of patients fall in a single category. To address this problem, others have proposed a microstaging system for patients with node-negative disease (Ballantyne stage I) based on histopathologic features such as depth of invasion and tumor architecture.[221,222] These systems have not yet been widely used or validated by others. More recently, Moreno et al.[214] compared the prognostic value of the Ballantyne system with the current AJCC sinonasal staging system in 58 patients with SNMM treated at MDACC. Compared to the Ballantyne system, the AJCC staging system provided an even distribution of the tumor stages (**Fig. 10.58**) and accurately reflected stage-specific prognostic information (**Fig. 10.59A**). The AJCC system has the advantage of being well known by oncologic surgeons and other specialists routinely involved in the care of head and neck cancer patients. Other authors have also described the prognostic value of this staging system in smaller series.[223] On the basis of these findings, we believe that the current AJCC sinonasal staging system should be the primary staging system for patients with SNMM.

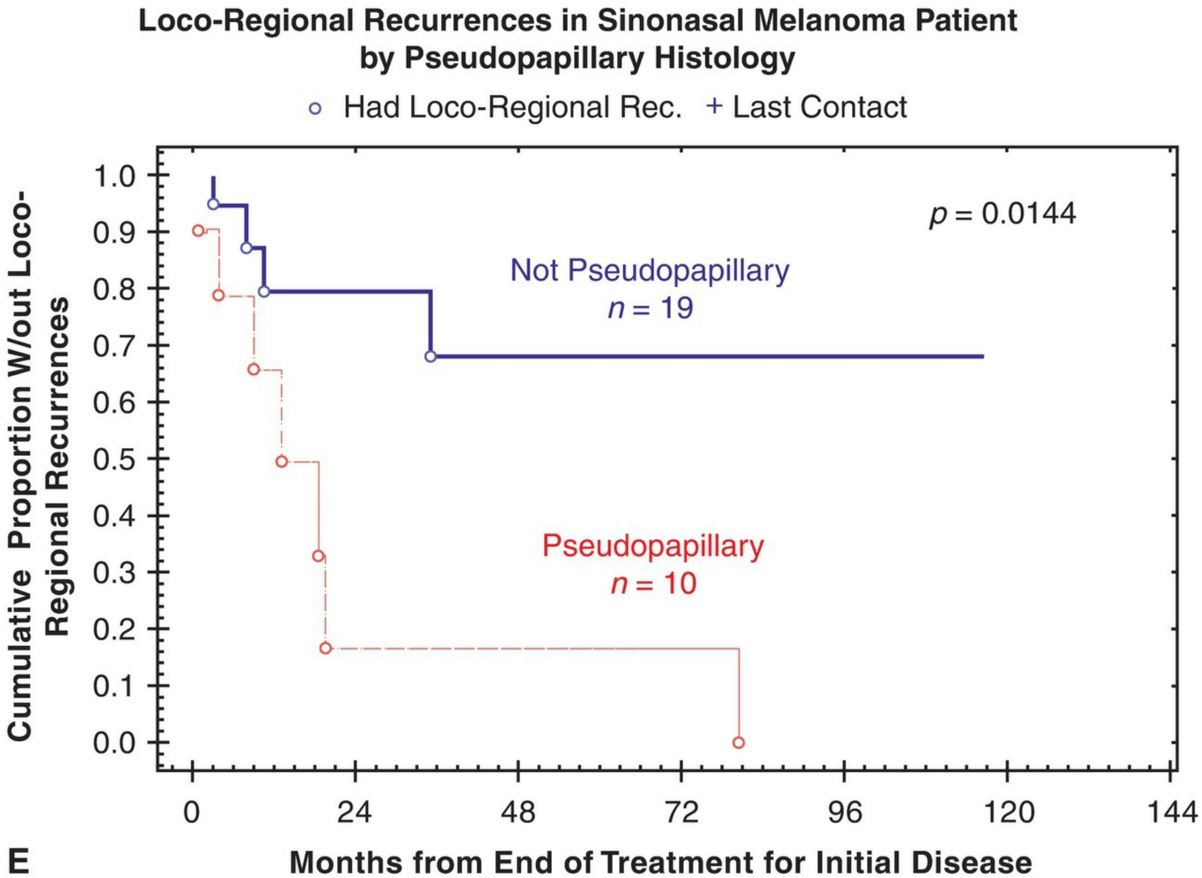

Figure 10.59. Outcomes of patients with sinonasal melanoma treated at MDACC. **A:** Survival by AJCC stage. **B:** Effect of distant metastasis on survival. **C:** Effect of radiation dose on disease recurrence. (Moreno MA, et al. Mucosal melanoma of the nose and paranasal sinuses, a contemporary experience from the M.D. Anderson Cancer Center. Cancer. 2010;116(9):2215–2223, Ref. 214.) **D:** Effect on level of pigmentation on survival. **E:** Effect of histologic pattern on survival.

Complete tumor excision is widely accepted as the standard of care for treatment of patients with SNMM. The invasive and locally advanced nature of these tumors coupled with the anatomical complexity of the sinonasal passages and proximity to vital structures makes a complete resection difficult in most cases. Surgical margins are described as microscopically positive or close (within 1 mm) in more than 20% of patients. Although negative margins are associated with better local disease control, the impact of surgical margins on survival is less clear. The potential benefits of negative margins of improved local control may be concealed by the development of distant metastasis in a significant number of patients with a

profound negative impact on survival (**Fig. 10.59B**).[214] In this context, the optimal surgical approach will depend on the location and extent of tumor. The surgeon's experience and thorough knowledge of the anatomy are key to achieve a successful oncologic resection with a minimum cosmetic and functional impact. Elective treatment of the neck is usually not performed, as the incidence of nodal disease at the time of presentation is relatively low, ranging from 6% to 25%.[213] The use of sentinel lymph node mapping and biopsy has proven beneficial in cutaneous melanoma but has only been minimally explored in mucosal melanomas.[224]

The available evidence suggests that the use of adjuvant radiation therapy improves locoregional control, although there is no evidence of benefit in OS.[220,223,225,226] To date, there is no consensus regarding the indications for postoperative radiation therapy, although most authors agree regarding its use in patients with positive and close margins, especially as these have been recently identified as negative prognostic factors. Radiobiologic studies show a high heterogeneity in behavior of irradiated melanoma cells, and to date, the optimal total dose and fractionation schemes for SNMM are also not well defined.[226] In cutaneous melanoma, there is evidence suggesting that hypofractionation schemes may improve tumor response rate and decrease treatment toxicity, but prospective randomized trials have failed to support these findings. In a recent study from MDACC, the use of postoperative radiation improved locoregional control but only when a total dose >54 Gy was used (**Fig. 10.59C**).[214] A similar improvement was observed when a standard fractionation schedule was used versus hypofractionation. It is difficult to determine whether the lack of improvement for the group that received a lower dose was determined by total RT dose, hypofractionation, or a combination of both. In contrast with these findings, other authors have reported that hypofractionation might improve local control and OS in head and neck mucosal melanomas.[227] In the future, a better understanding of the radiosensitivity of this rare tumor and the availability of new technical radiation modalities might allow for better incorporation of radiotherapy into a multimodality treatment strategy.

There is no standard systemic therapy recognized as optimal for the treatment of patients with SNMM, and studies of systemic therapy focused on SNMM are scarce. Bartell et al.[228] reported the experience of 15 patients treated with biochemotherapy for advanced head and neck mucosal

melanoma at the MDACC. In this study, 11 patients presented with distant metastasis and 4 had locoregional recurrence or bulky, unresectable disease. The overall response rate for the series was 47% with a complete response rate of 27% and a median OS of 22 months. Biochemotherapy was associated with severe but manageable toxicity including severe pancytopenia in all patients, but there were no treatment-related deaths. The authors concluded that biochemotherapy should be considered not only for metastatic disease but also as neoadjuvant therapy in patients with extensive locoregional disease.

The 5-year OS of patients with SNMM is poor and ranges from 20% to 35% among different reports and has not changed significantly over the last several decades.[213] Given the rarity of this tumor, most series extend retrospectively several decades to gather an adequate number of patients. For example, a recent review of the U.S. National Cancer Institute's SEER registry identified 567 patients with SNM between 1973 and 2009.[229] DSS at 5 years was 37% for patients diagnosed with nasal cavity disease, 24% for patients with maxillary sinus tumors, and 18% for patients with ethmoid sinus disease. Patients showing evidence of overlapping sinus involvement had approximate 1-year survival of 54%, and none survived beyond 49 months. Unfortunately, such survival analysis of patients who were treated over a time period that spans almost five decades may fail to reflect the advances in diagnosis and treatment that might have occurred in recent years. For this reason, investigators from MDACC sought a review of SNMM limited only to the most recent 15 years to capture contemporary data that more accurately reflect the current status of this disease.[214] For the 58 patients with SNMM, 2-year OS was 69% for T1, 67% for T2, 33% for T3, and 18% for T4 (Fig. 10.59A); these differences were statistically significant ($p = 0.0183$). Differences in 5-year survival between these groups did not reach statistical significance ($p = 0.2067$), except when combining T1/T2 versus T3/T4 ($p = 0.0096$). Patients with negative margins had a better 2-year survival (64% vs. 42%) and 5-year survival (44% vs. 25%), although this difference did not reach statistical significance ($p = 0.1534$ and $p = 0.2169$, respectively). Local recurrence developed in 42% of the patients with positive margins versus 20% of those with negative margins ($p = 0.2657$). The study also suggested that certain histopathologic features correlated with outcome. The presence of melanin pigment was a highly significant outcome

predictor (0% vs. 48% 5-year survival; $p = 0.0183$). Even more, the level of pigmentation of the lesion was correlated with a worse clinical outcome, as shown in Figure 10.59D. The presence of 10 or more mitosis per HPF appeared to be an outcome predictor. All except 1 of the 20 patients who had >10 mitoses per HPF died of disease or presented with locoregional recurrence. In contrast, all the patients who had a complete response to biochemotherapy were among those with 10 mitoses per HPF or less. As is shown on Figure 10.59E, the presence of a pseudopapillary architecture was associated with a higher rate of locoregional failure ($p = 0.0144$) but did not affect survival ($p = 0.4909$).

In recent years, several molecular markers have emerged as potential prognostic indicators. The Ki67 antigen is an indicator of proliferative activity that has been associated with prognosis in cutaneous melanoma among other tumors. Recently, Kim et al.[230] reported that patients with more than 35% for Ki67 staining had a survival advantage over those with scores of more than 35% in a series of 27 sinonasal melanomas. The abnormal expression of caspases and inhibitor of apoptosis proteins is thought to be the cause of apoptotic dysfunction in melanoma. The nuclear expression of survivin, an inhibitor of apoptosis protein, has been associated with higher recurrence rates and poor survival in cutaneous melanoma. In a recent review of 77 patients with melanoma, 25 of them of mucosal origin, Chen et al.[231] reported the prognostic value of nuclear expression of survivin-C and survivin-N. They found that this is an indicator independent of tumor stage and location (mucosal vs. cutaneous) and appears to be superior to Ki67 immunostaining in multivariate models. Genetic mutations involving the receptor tyrosine kinase KIT have been associated with some types of melanoma. Specifically, c kit, a protein encoded by the KIT proto-oncogene melanoma, is thought to play a role in early stages of oral mucosal melanoma tumorigenesis. There is emerging evidence indicating that melanomas with KIT activation may also respond to KIT inhibitors already in use such as imatinib or dasatinib.[228] The role of these therapeutic agents in SNMM needs to be investigated further, but, if confirmed, it would represent a paradigm-shifting entry into the era of personalized medicine in which therapy can be tailored to mechanistically relevant changes in cancer cells of this deadly disease.

Sarcomas.

Sarcomas account for 10% to 15% of SNT malignancies and comprise a wide array of tumors of mesenchymal origin.[232] The most common primary sites of origin are the maxillary sinus followed by the ethmoid sinus. Sarcomas of soft tissue origin account for ~80% of cases, whereas bony or cartilaginous sarcomas are less frequent.[233] Five-year OS for sinonasal sarcomas in large-group analyses ranges between 46% and 67%. However, survival is significantly dependent on histology and the histologic grade of tumor.[232,234–236] Rhabdomyosarcoma, osteosarcoma, and Ewing sarcoma are examples of high-grade tumors with 5-year OS reported between 33% and 70%. Low-grade tumors such as hemangiopericytoma, chondrosarcoma, and leiomyosarcoma have a more favorable reported 5-year OS of 64% to 94%.[232,233,235,237,238] High-grade lesions account for the majority of sinonasal sarcomas in both the pediatric and adult populations with rhabdomyosarcoma and osteosarcoma comprising between 47% and 73% of sinonasal sarcomas.[232–234,239]

In a recent study of the SEER database, 352 patients with sinonasal sarcomas, diagnosed from 1973 to 2008, were analyzed.[232] The influence of patient age, gender, race, and prior irradiation, as well as tumor histology and subsite, on outcome was reported. The mean age was 44 ± 28 years, and the patients were fairly evenly distributed among the age groupings. The majority (78%) of patients were identified as white, 12.5% were identified as black, and 10% were classified as other. The majority of tumors were located within the maxillary sinus (58%), followed in frequency by the ethmoid (22%) and sphenoid sinus (13%). Rhabdomyosarcoma was the single most common tumor histology (34%), followed by miscellaneous soft tissue malignancy (31%) and miscellaneous fibromatous malignancy (16%). Approximately half of the patients received radiation postoperatively. Median follow-up was 28 months (25th percentile = 12 months, 75th percentile = 83 months). Of the 352 total patients, 192 (55%) died over the follow-up period. The 1-, 5-, and 10-year survival probabilities were 78.8%, 47.4%, and 38.1%, respectively. Median survival time was 50 months. Males had a significantly lower median length of survival and 5-year survival (42.5% vs. 53.1%) than female sarcoma patients (35 vs. 74 months). Females had a roughly 32% decrease in the rate of mortality compared to males (HR = 0.68, $p = 0.0153$), controlling for the other factors. Neither race nor radiation therapy were significantly associated with mortality. Survival declined with increasing age. The 5-year

survival for patients younger than 10 years was 63.1%, whereas the 5-year survival for patients older than 80 years was 26.8%. In general, older age was associated with a significant decrease in the median survival time and 5-year survival rate. The HR became successively larger with each older age category. For example, patients aged 10 to 49 years had a 1.84 times greater rate of mortality compared to patients aged <10 years after controlling for the other factors, whereas patients aged 50 to 69 years had a 2.78 times greater rate, and patients >80 years had the highest HR with 10.8 times higher mortality rate. For histology, chondrosarcoma was associated with lowest mortality rates after controlling for the other factors and was therefore chosen as the reference group for the purpose of the analysis. Five-year survival for chondrosarcoma was 64.4%. Kaposi sarcoma patients had a 5.53 times greater rate of mortality (HR = 5.53, $p = 0.0051$, 5-year survival 20.0%), whereas rhabdomyosarcoma patients had a 3.62 times greater rate of mortality (HR = 3.62, $p = 0.0018$, 5-year survival 32.9%) compared to chondrosarcoma patients. Clearly, the natural history, treatment strategies, and prognosis are dependent primarily on the histopathologic type of sarcoma, and the reader is referred to the details of management and outcome discussed in the chapter dedicated to sarcomas of the head and neck.

Lymphoma.

Primary non-Hodgkin lymphoma (NHL) of the SNT accounts for <10% of all NHLs and comprises three main pathologies: diffuse large B-cell lymphoma (DLBCL), natural killer/T-cell lymphoma (NKTCL), and T-cell lymphoma (TCL).[240,241] Although DLBCL is the most common form of sinonasal NHLs in the Western population, NKTCL is the predominant variant in Asia, with both also demonstrating different epidemiologic patterns and symptomatology.[242] DLBCL most commonly affects patients over 60 years of age and has a predilection for paranasal sinus origination with between 37% and 75% arising from the maxillary sinus.[241–243] NKTCL, on the other hand, occurs in a younger subset of patients, median age of 45 years, with ~67% to 80% originating in the nasal cavity and <30% involving the paranasal sinuses.[240,243,244] The high rate of nasal cavity involvement in NKTCL, also known as lethal midline granuloma, is associated with the classic presentation of the disease characterized by destruction of the nose and midline facial structures. Other differences in presentation and diagnosis include the relative absence of B symptoms in DLBCL while present in up to

29% of cases of NKTCL, as well as the significant association of EBV with NKTCL (up to 92%).[240,243,244]

Treatment of NHL of the paranasal sinuses is chemotherapy and radiation therapy. The chemotherapeutic agents utilized between DLBCL and NKTCL differ, however, NKTCL expresses high levels of P-glycoprotein conferring multidrug resistance.[245] As such, CHOP-based chemotherapeutic regimens (cyclophosphamide, hydroxydaunorubicin, oncovin, prednisone) are generally utilized in DLBCL, whereas regimens containing agents unaffected by P-glycoprotein (L-asparaginase, vincristine, prednisone) are recommended for NKTCL.[240,242,245] Early-stage disease is most often treated with concurrent chemoradiation therapy or chemotherapy with sandwiched radiotherapy. Late-stage and disseminated disease may only be amenable to systemic therapy. Hematopoietic stem cell transplant is reserved for late-stage, nonnasal, disseminated, or relapsed lymphomas where remission has been achieved.[245] Five-year OS of sinonasal DLBCL ranges between 50% and 68%, whereas sinonasal NKTCL demonstrates 5-year OS of <40%.[240–244] Patients able to achieve a complete response after primary therapy show significantly improved OS compared to those who do not, even accounting for locoregional or distant disease on presentation.[240] In a recent study, the SEER database was searched for patients diagnosed with sinonasal NKTCL and DLBCL between 1973 and 2011. Data analyzed included patient demographics, incidence, treatment modality, and survival.[246] Three hundred and twenty-eight sinonasal NKTCL cases and 1,054 sinonasal DLBCL cases were identified. The mean ages at diagnosis for NKTCL and DLBCL were 51.7 and 67.8 years, respectively ($p = 0.0001$). Overall 1-, 5-, and 10-year DSS rates for DLBCL were 85.5%, 63.5%, and 44.0%, compared to 66.4%, 30.9%, and 9.2% for NKTCL, respectively ($p < 0.0001$). For patients matched for stage, age, and treatment modality, the 1-, 5-, and 10-year DSS for the DLBCL group were 94.4%, 72.8%, and 46.8%, respectively, whereas the respective survival rates for the NKTCL group were 77.6%, 38.4%, and 13.9%, respectively ($p < 0.0001$ at each time interval). This large population-based comparison between sinonasal DLBCL and NKTCL demonstrated that DLBCL has a better prognosis regardless of gender, stage, treatment modality, and age. For detailed discussion of the management and outcomes, the reader is referred to the chapter on Lymphomas of the Head and Neck.

Metastasis to the Sinonasal Tract.

Involvement of the SNT with metastatic deposits is a rare phenomenon with <200 reported cases in the literature. Hematogenous spread to the paranasal sinuses is the most common form of delivery. Renal cell carcinoma is the most common malignancy to metastasize to the SNT, followed by breast, lung, and prostate cancer. Tumors that rarely metastasize to the SNT including follicular thyroid carcinoma, hepatocellular carcinoma, and colorectal carcinoma have also been reported.[247] Metastasis to the sinonasal region may be the first clinical evidence of the primary tumor, or it might appear after treatment of the primary neoplasm. Although the maxillary antrum is the most frequent site for metastasis, any area of the SNT may be involved. Treatment is palliative and is indicated for the relief of pain, bleeding, or orbital complications.[248]

OUTCOME AND PROGNOSIS

Although the literature is replete with reports describing the outcome and prognosis of patients with sinonasal cancer, several confounding factors make meaningful interpretation of the results extremely difficult. Such factors include the diversity of histologic diagnoses, site of origin, extent of tumor invasion, prior therapy, extent of surgical resection, status of surgical margins, adjuvant therapy, and length of follow-up. The greatest factor influencing prognosis is the histopathologic type of sinonasal malignancy. This has a direct bearing on the biology and natural history of the disease and consequently the outcome of therapy. This is highlighted in **Figure 10.60** showing the 5-year survival by histology for 2,698 patients with sinonasal cancer seen at MDACC from 1944 to 2007. For example, ENB and adenocarcinoma have significantly better survival than melanoma and SNUC. As discussed in the section on tumor-specific consideration, even among patients with same tumor type, histopathologic grade has a significant impact on survival, for example, Hyams grade for ENB (Fig. 10.53), tumor pattern in ACC (tubular, cribriform, and solid) (Fig. 10.52D), tumor characteristics in melanoma such as pigmentation and psuedopapillary features (Fig. 10.59D and E), and tumor differentiation in NEC. These are examples of the need for accurate grading of sinonasal tumors within the same histopathologic type.

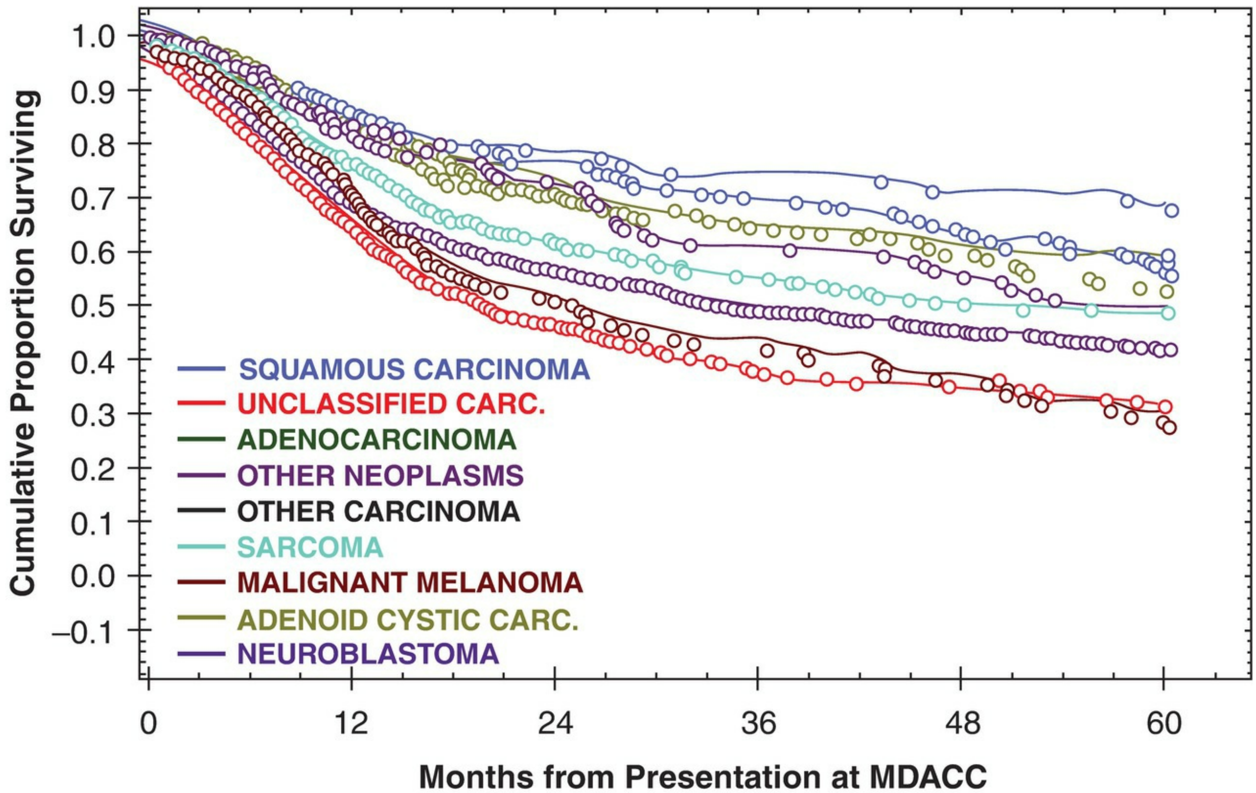

Figure 10.60. Overall 5-year survival by histology of 2,698 patients with sinonasal cancer seen at MDACC from 1944 to 2007.

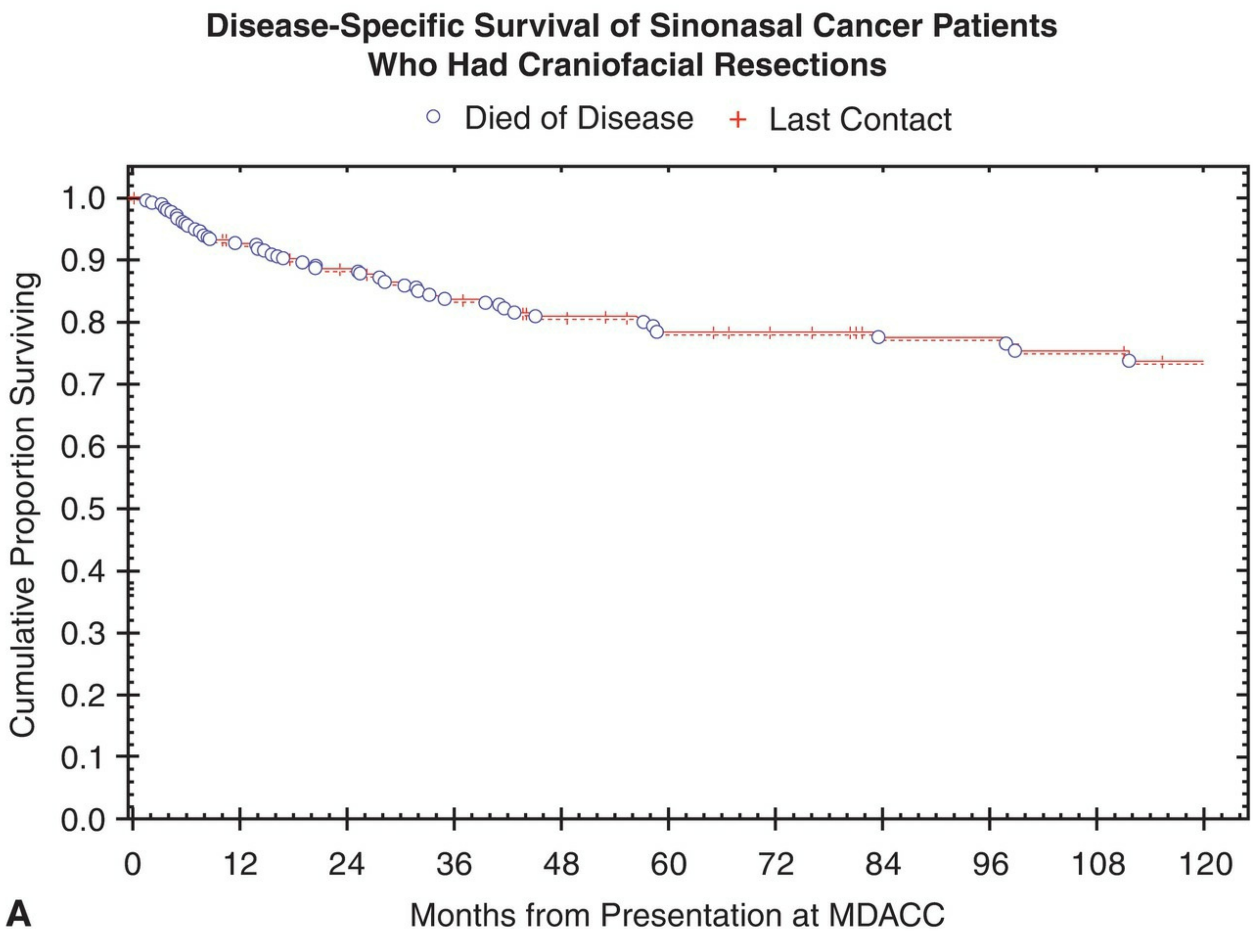
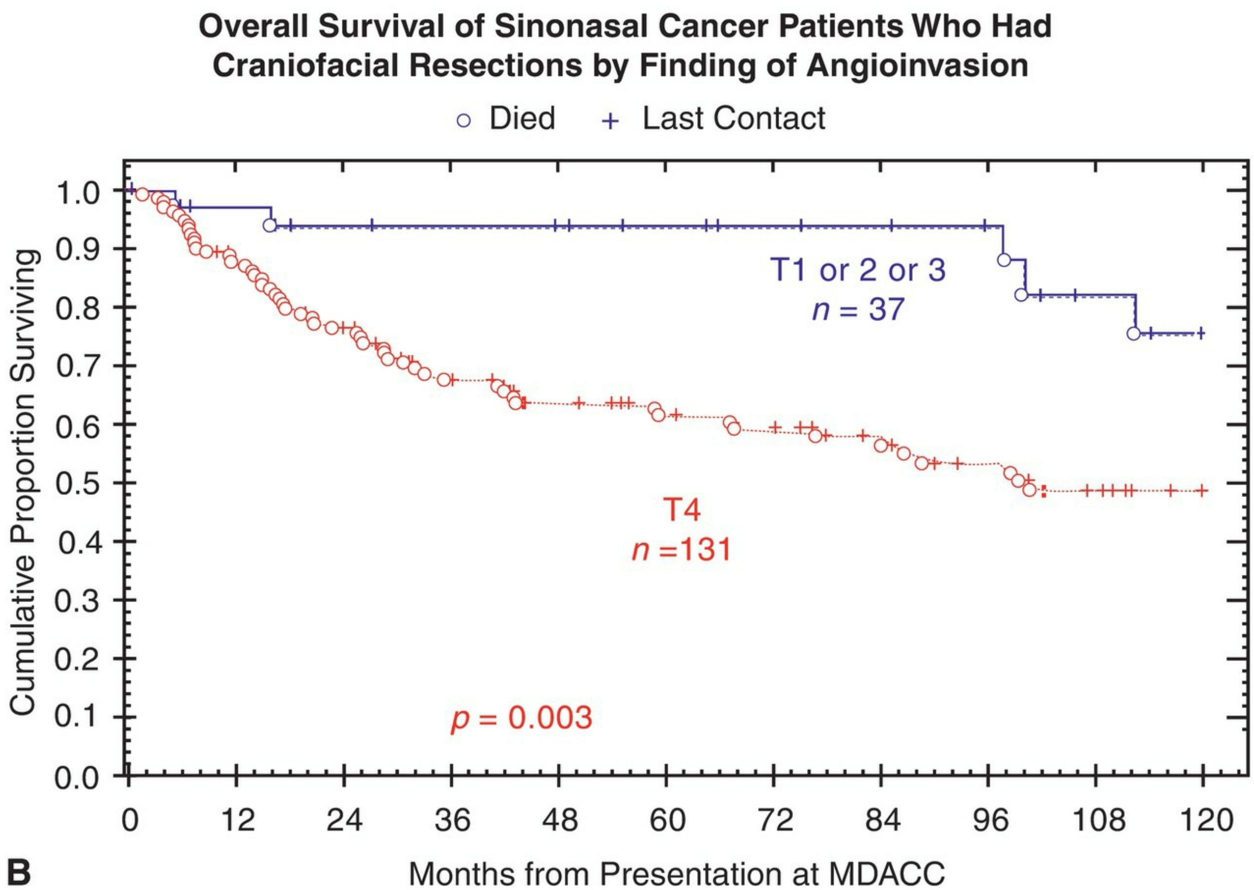
The multidisciplinary integration of modern techniques of skull base surgery, microvascular reconstruction, conformal radiation, and chemotherapy improved the overall outcome of patients with sinonasal malignancy (Fig. 10.1). The 10-year survival outcomes of patients undergoing anterior craniofacial resection for sinonasal cancer at MDACC in the last decade are shown in **Figure 10.61A**. Despite these excellent outcomes, patients with T4 tumors have a worse prognosis (**Fig. 10.61B**). The presence of PNI (**Fig. 10.61C**) and angioinvasion (**Fig. 10.61D**) also has negative impact on survival. Brain invasion has a particularly profound, and perhaps the most dramatic, impact on survival (**Fig. 10.62A**). This probably has to do with the difficulty achieving negative surgical margins, which is a major determinant of a favorable outcome in surgically treated patients (**Fig. 10.62B and C**). It is interesting to note that the effect of method of resection (en bloc vs. piece meal) did not affect the outcome as long as the margins were negative (**Fig. 10.62D**). Several molecular and genetic markers of prognosis have been already discussed in corresponding tumor-specific section. The presence of cervical lymph node metastasis from sinonasal

cancer is an uncommon event, but when it is present, survival is reduced by at least 50%. Finally, the presence of distant metastasis is usually an indication that the disease is incurable and treatment strategies should focus on palliation.





Overall Survival of Sinonasal Cancer Patients Who Had Craniofacial Resections by Finding of Angioinvasion

C

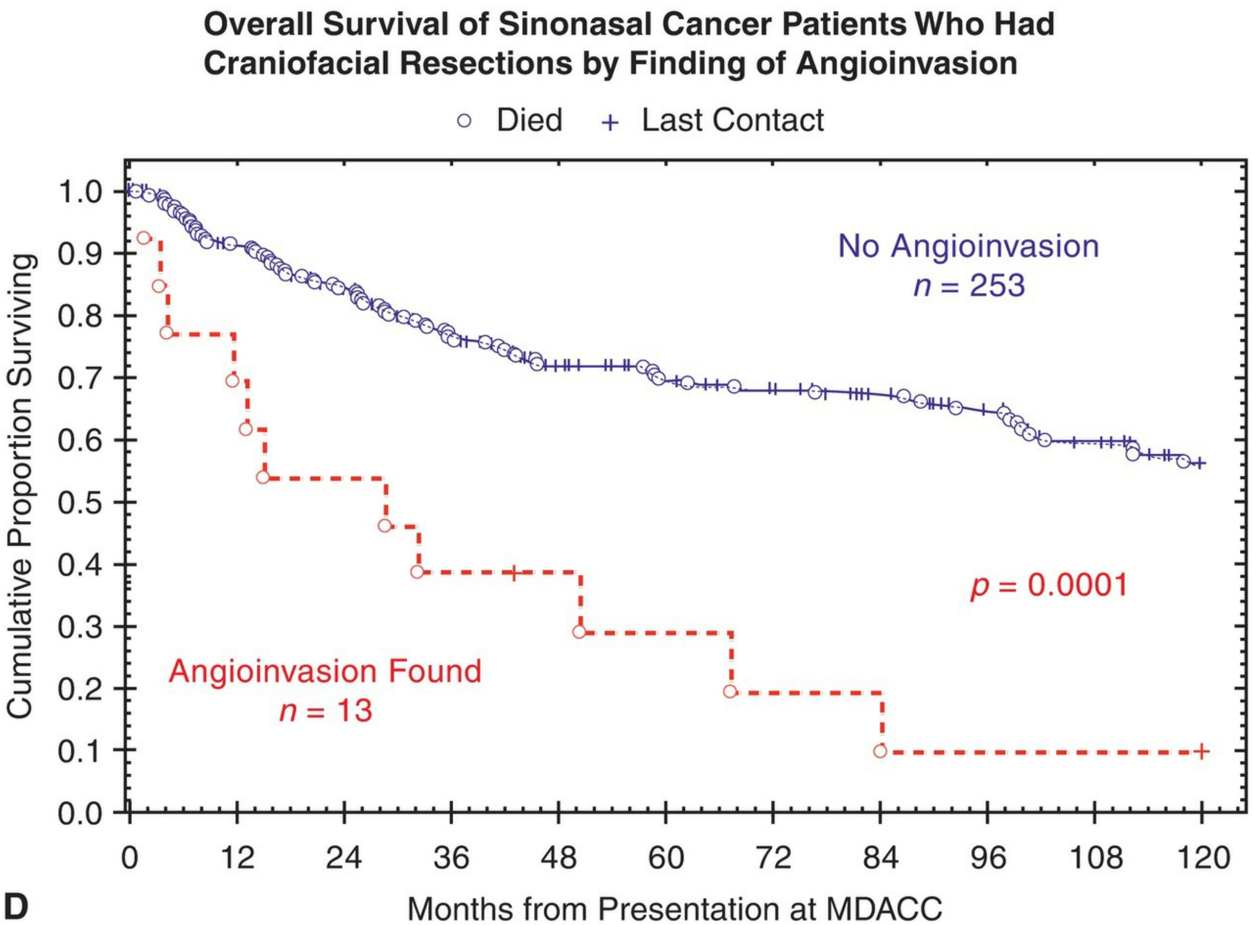

Figure 10.61. Survival outcomes of craniofacial resection in patients treated at MDACC in the last decade. **A:** Ten-year disease-specific survival. **B:** Effect of stage on survival. **C:** Effect of PNI on survival. **D:** Effect of angioinvasion on survival.

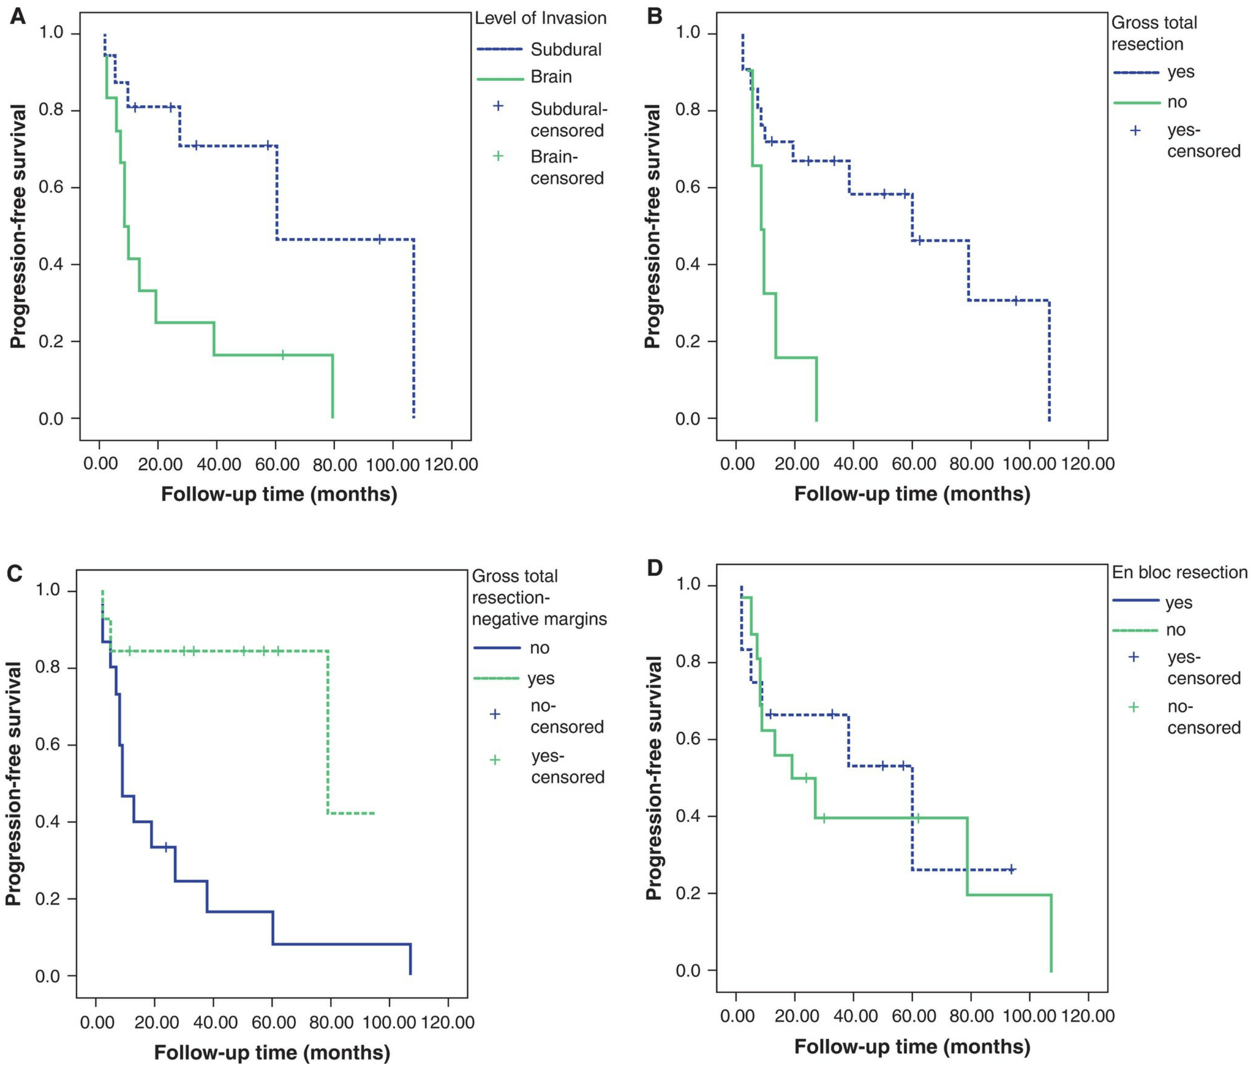

Figure 10.62. Prognostic significance of transdural invasion of cranial base malignancies in patients undergoing craniofacial resection. **A:** Brain invasion was a significant prognostic factor associated with PFS (p = 0.005). **B:** A significant association was found for PFS and gross total resection (GTR) (p = 0.003). **C:** In the cohort of patients with GTR, the ones with a microscopic negative surgical margin had a better PFS than those with positive margins (p = 0.02). **D:** No significant association was found for PFS between en bloc and piecemeal resection (p = 0.64). (Feiz-Erfan I, et al. Prognostic significance of transdural invasion of cranial base malignancies in patients undergoing craniofacial resection. Neurosurgery. 2007;61(6):1178–1185; discussion 1185, Ref. 53.)

SUMMARY

Progress in prognosis of patients with nasal and paranasal carcinoma has been made during the last 40 years (Fig. 10.1). This is probably due to advances in both the evaluation and treatment of these patients. Office endoscopy and high-resolution imaging allow better assessment of the extent of disease and hence better treatment planning. Advances in cranial base surgery and microvascular reconstruction have allowed more adequate resection of advanced sinonasal cancer, even if it involved the cranial base. Improvements in the delivery of radiation therapy using highly conformal radiation such as IMRT or proton therapy have allowed more targeted and homogenous dosimetry to the tumor while sparing nearby critical structures. The integration of more effective chemotherapeutic and targeted agents in the overall management of patients with sinonasal cancer has improved local control of the disease.

Despite these improvements, cancer of the paranasal sinuses remains a difficult and challenging problem. The vast majority of patients still present with advanced stage disease, as the paucity and nonspecific nature of their signs and symptoms from smaller tumors hamper early diagnosis of the disease. The propensity for early spread to surrounding critical structures, such as the cranial base, orbit, and brain, increases the complexity and morbidity of treatment while reducing its efficacy. These factors continue to impede further improvement of treatment outcome, and a significant number of patients still succumb to the disease. Therefore, the most effective strategy to further improve the treatment outcome of patients with cancer of the nasal cavity and paranasal sinuses is earlier detection of disease.

11 Nasopharyngeal Carcinoma

Brigette B. Y. Ma Michael K. M. Kam Anthony T. C. Chan

Background

Introduction

Nasopharyngeal carcinoma (NPC) has a unique epidemiology and pathogenesis, and the treatment of NPC has undergone several paradigm shifts over the last 30 years. Advances in the planning and delivery of radiotherapy (RT) and the adjunctive use of chemotherapy over the decades have all contributed to the improved prognosis of NPC. In Hong Kong where NPC is among the top 10 most common cancers with an age-adjusted mortality rate of 3.9 per 100,000 persons, the 5-year overall survival (OS) of patients with stage I and II NPC now approaches 90%.[1] However, worldwide, up to 65,000 people still died of NPC annually in recent times.[2,3] This is mainly due to the fact that 20% of patients with locoregionally advanced (i.e., stage III and nonmetastatic stage IV) NPC will invariably develop distant metastases despite modern treatment. In Hong Kong, the 5-year OS for nonmetastatic stage III and IV is ~60% in patients who were treated with 2-dimensional (2D) RT.[1,4] For patients with metastatic NPC, the median OS (12 to 18 months) is still well short of that of other cancers such as metastatic colorectal cancer (over 20 months) following modern drug therapy. Although concurrent chemoradiotherapy has significantly improved the treatment outcome for patients with stage III and nonmetastatic stage IV NPC, this approach also increases the incidence of certain acute and late toxicities. Thus, newer biomarkers and more accurate staging are needed to identify those patients who are most likely to benefit from multimodal therapy.

On a global scale, NPC is a rare cancer with ~80,000 new cases reported

per year and accounts for 0.7% of all cancers.[2] In nonendemic areas like North America and Europe, the incidence rate is <1 case per 100,000 populations. This is in marked contrast with the endemic or “high-risk” areas such as Hong Kong and Southern China, where the annual age-standardized incidence rates are as high as 20 to 30 cases per 100,000 population in men and 8 to 15 cases per 100,000 population in women.[5,6] Recent studies have suggested a fall in the incidence of NPC in the last 30 years in China. However, other reports have found a stable to rising incidence in certain parts of Southern China.[5,7] According to the Hong Kong Cancer Registry,[3] the age-standardized incidence rates of NPC in 2010 have decreased from 12.8 cases per 100,000 population in 2001 to 8.7 cases per 100,000 population for both sexes. Several studies have speculated on the reasons for this declining trend in Hong Kong. One report found that only the incidence rate of the keratinizing subtype of NPC has fallen, whereas the rate of the more common nonkeratinizing subtype has remained relatively stable.[8] Other studies have attributed the falling incidence to improvements in socioeconomic status and standard of living in the local population, as well as an improvement in the standards of medical care in Hong Kong.[1,9]

NPC is classified into different histologic subtypes: type 1 (I) squamous cell carcinoma, type 2a (II) keratinizing undifferentiated carcinoma, and type 2b (III) nonkeratinizing undifferentiated carcinoma. The World Health Organization (WHO) III subtype is the most common form of NPC in endemic areas and is ubiquitously associated with the Epstein-Barr virus (EBV). It also differs from WHO I NPC with regard to its sensitivity to chemotherapy and RT. The staging of NPC is based on the depth of invasion of the soft tissue, cranial nerves, and bony structures at and near the nasopharynx by the primary tumor, the involvement of local and regional lymph nodes of the head and neck, and the presence of distant metastases. In Hong Kong, the distribution of stage groups at presentation is as follows: stage II 7%, stage IIA to B 41%, stage III 25%, and stage IVA to B 28%. This means that nearly half of all patients with NPC in Hong Kong present at an advanced stage; hence, much of the clinical research in NPC has been focused on improving the treatment of advanced NPC.

Staging of Nasopharyngeal Carcinoma with Radiologic Imaging

The 7th edition of the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (AJCC) TNM classification for NPC is currently the most commonly used staging system internationally (Table 11.1). It is based purely on the anatomical spread of both the primary tumor and the metastatic nodes, without taking into account the size of the tumor or its histologic grade. Significant stage migration has been observed over time with the advances in imaging technology and treatment modalities. Magnetic resonance imaging (MRI) has generally replaced computerized tomography (CT) for local tumor staging because it provides better soft tissue resolution. MRI also plays an important role in RT treatment planning because it provides more accurate delineation of tumor target. For the staging of M stage, studies do not support the routine use of CT thorax, bone scan, or abdominal ultrasonography in average-risk patients because of the low positive detection rate for metastases, and such imaging is usually reserved for patients at high risk of distant metastasis.[10–13]

Table 11.1 The 7th Edition of the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (AJCC) TNM Classification for NPC

T Stage	N Stage
T1: Nasopharynx, oropharynx, or nasal fossa T2: Parapharyngeal extension T3: Bony structures, paranasal sinuses T4: Intracranial extension, cranial nerve, hypopharynx, orbit, infratemporal fossa(masticatory space)	N0: None N1: Unilateral cervical or retropharyngeal (irrespective of laterality), <6 cm, above supraclavicular fossa N2: Bilateral cervical node, <6 cm, above supraclavicular fossa N3a: >6 cm N3b: In supraclavicular fossa
M Stage	**Overall Stage**
M0: No distant metastasis M1: Distant metastasis is present.	I: T1 N0 M0 II: T1 N1 M0, T2 N0–1 M0 III: T1/2 N2 M0, T3 N0–2 M0 IVA: T4 N0–2 M0 IVB: Any T, N3, M0 IVC: Any T, any N, M1

^{18}F-fluoro-2-deoxy-D-glucose (^{18}F-FDG) positron emission tomography (PET)-CT has become increasingly popular in staging and as a tool to detect tumor persistence or recurrence. Several studies have compared the accuracy of PET-CT and MRI in detecting primary tumor, retropharyngeal nodes,

cervical nodes, and distant metastasis, but their results are inconsistent.[14]–[17] In the larger study by Ng et al.,[17] MRI appears to be superior for assessing the primary tumor and retropharyngeal nodes, whereas PET-CT is more accurate than MRI for detecting cervical nodal metastasis and more accurate than CT and bone scans for detecting distant metastasis. A recent meta-analysis of eight series has confirmed the reliable performance of PET or PET-CT in the evaluation of distant metastasis, with a pooled sensitivity of 83% and specificity of 97%.[18]

Early detection of local recurrence is crucial to successful salvage. However, it is notoriously difficult to diagnose submucosal or deep-seated recurrence by endoscopy alone, and MRI or CT is unable to distinguish post-RT scarring or inflammation from genuine recurrence.[19] Controversy remains as to the superiority of PET-CT over MRI on this aspect. In a systematic review of 21 articles, Liu et al.[20] suggested that PET was the best modality for diagnosis of local residual or recurrent NPC. In the foreseeable future, PET-CT is going to play a more important role in the staging of NPC at diagnosis and at recurrence and in the monitoring of treatment response.

Primary Treatment for Nonmetastatic Nasopharyngeal Carcinoma

Two-Dimensional Radiotherapy

External RT has been the mainstay treatment for nonmetastatic NPC since the introduction of megavoltage machines in the mid-1960s, when the OS was only 25% at 5 years. With improvement in simple two- to three-field arrangements delivering 60 to 70 Gy of two-dimensional RT (2DRT) to the nasopharynx and its regional lymphatics, the OS rate was typically in the order of 50% during the 1970s to 1980s, with the rate of locoregional failure over 25%.[21]–[23] The major drawback of 2DRT is the unnecessary irradiation of abundant normal tissues, and any attempt at vital organ sparing would inevitably compromise target coverage.[24] Further improvement of treatment

outcome was seen in the 1990s, and this occurred as a result of advances in diagnostic imaging and the use of more aggressive strategies such as RT dose escalation and chemotherapy. In a retrospective analysis on 2,687 patients treated during 1996 to 2000s, the OS rate was 75% and local failure-free rate was 85% at 5 years.[1]

Three-Dimensional Conformal Radiotherapy

The transition from 2DRT to three-dimensional conformal radiotherapy (3DCRT) marked a great advance in RT development in the late 1990s, and the development of computer planning system and multileaf collimator is a representative achievements during this period. The integration of CT or MRI images into the 3D treatment planning system provides more accurate spatial information on the tumor target and normal organs, which in turn enables a more flexible adjustment of the beam directions. The use of multileaf collimator allows better shaping of beam aperture that conforms to the shape of the target and avoids vital organs in the vicinity. The dosimetric advantage of 3DRT has been translated into significant improvement in patient survival as well as reduction in serious toxicities.[4]

Intensity-modulated Radiotherapy

The use of 3DCRT was rapidly overtaken by the introduction of intensity-modulated radiotherapy (IMRT), in the late 1990s. IMRT is an advanced form of 3DCRT with additional capacity to modulate beam intensity pixel by pixel across the treatment field. Working in conjunction with the inverse planning computer optimization algorithm, an optimized fluence can be obtained according to the dose–volume constraints set by the physician. It is particularly useful in generating a concave-shaped dose distribution with steep dose-gradient around the brainstem, spinal cord, and optic pathway. The principal benefit of IMRT in early-stage NPC is the sparing of the parotid glands. In locoregionally advanced NPC, IMRT offers better tumor coverage and protection of critical neurologic organs and allows room for dose escalation.[25–27] Moreover, IMRT permits the delivery of different dose intensities to different targets according to their clinical risks and enables biologic enhancement through the concept of simultaneous integrated boost (SIB) technique. A comparison of dose distribution between 2DRT and IMRT is demonstrated in Figure 11.1.

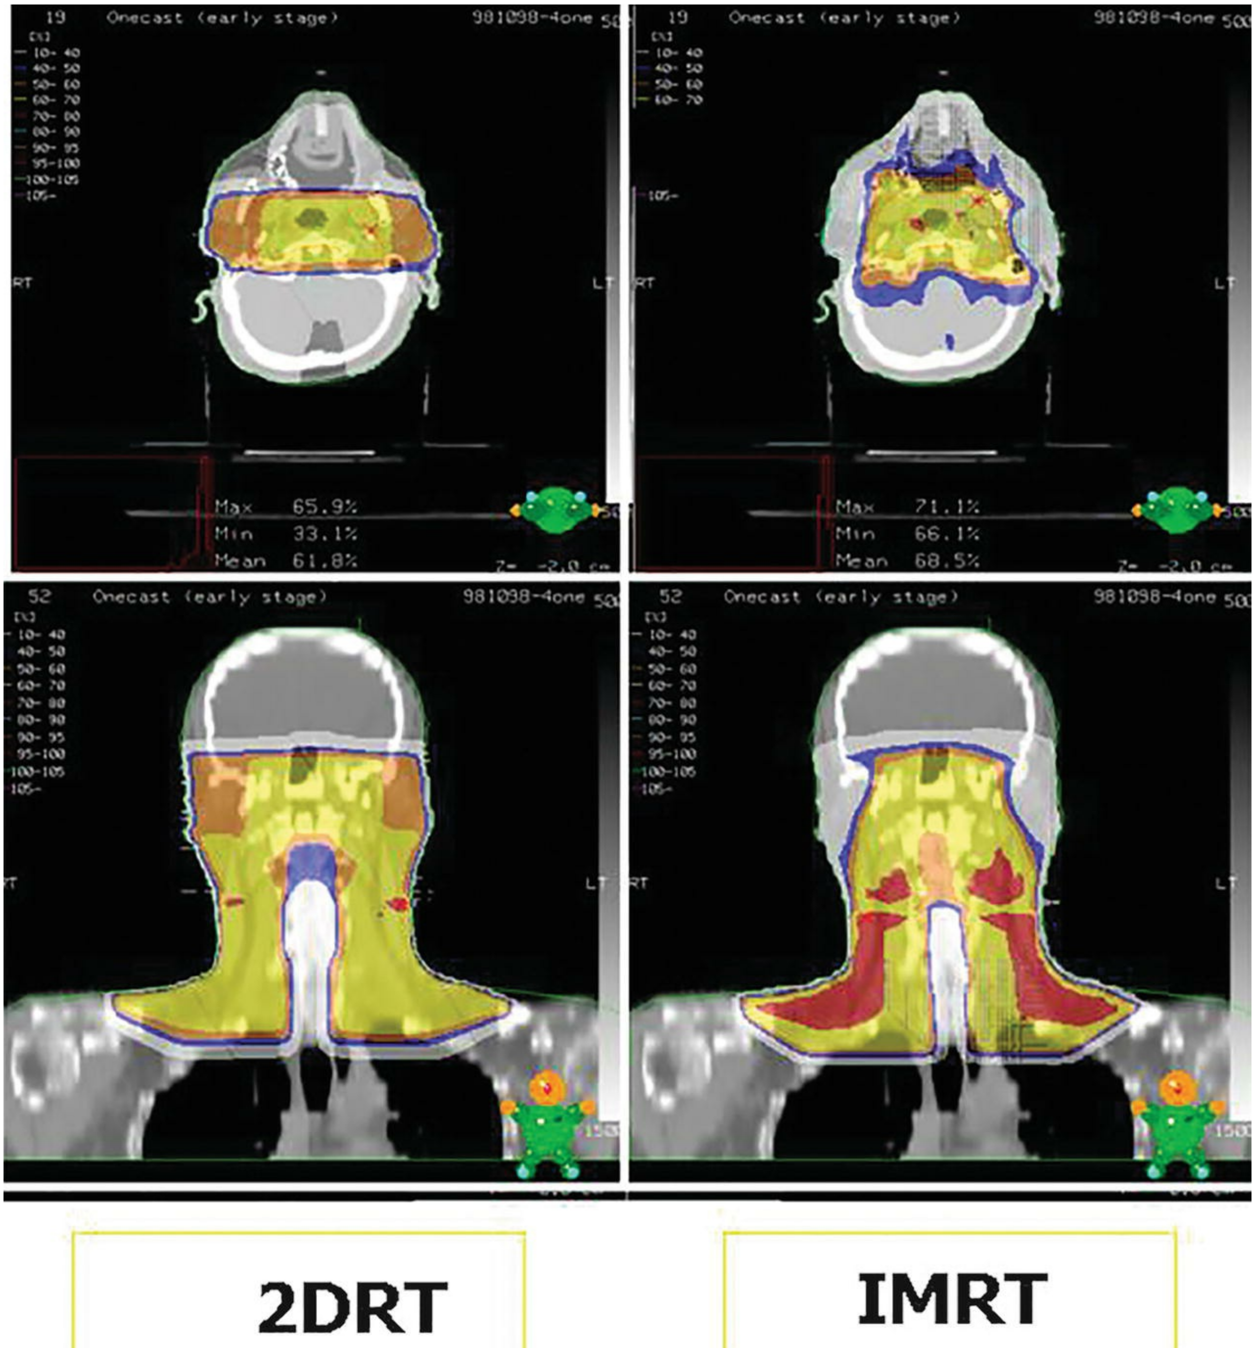

Figure 11.1. Comparison of isodose distribution between 2DRT and IMRT.

This dosimetric advantage has been translated into better local control rate as reported in many retrospective series[28]–[45] (Table 11.2). In addition, three randomized studies comparing IMRT versus 2DRT have been reported thus far. In early-stage NPC, Kam et al. and Pow et al. both confirmed that IMRT results in significantly better recovery of parotid salivary function than

2DRT.[49,50] Peng et al.[51] randomized patients to 2DRT or IMRT and found a significant improvement in 5-year local control rate (91% vs. 84%, $p = 0.046$) and OS (80% vs. 67%, $p = 0.001$) and significant reduction in late toxicities including cranial neuropathy, temporal lobe necrosis, xerostomia, trismus, and fibrosis of the neck. However, several controversies in IMRT remain unresolved. It is uncertain whether IMRT is superior to 3DCRT in terms of patient's outcome. Fang et al.[37] and Lee et al.[4] did not observe significant differences in locoregional control, OS, or toxicities between IMRT and 3DCRT. The suboptimal local control rate in locally advanced NPC patients, and the tangible figures on some severe RT complications are really too significant to be ignored.[29] The optimal total dose level and time–dose–fractionation schedule are still unclear, because several RT acceleration or dose escalation strategies (such as SIB technique, or sequential boost) have not been formally compared in randomized studies. Another outstanding issue is the need to validate and standardize the definition of clinical target volume (CTV). This is important because the therapeutic window of RT in NPC is narrow, and tailoring of treatment volume is essential to avoiding inadequate or futile treatment margins. Despite all these uncertainties as mentioned, IMRT is rapidly becoming a contemporary standard of care for the treatment of NPC worldwide.

Dose Escalation

The dose–response effect in NPC has been well established. Lee et al.[52] showed that risk of local failure was found to be decreased by a factor of 9% per additional Gy. The value of dose escalation after a basic course of 66 to 70 Gy large-field 2DRT has also been demonstrated by a retrospective review from the Hong Kong NPC Study Group on 2,462 patients, of whom 65% received brachytherapy, 2DRT, 3DRT, or stereotactic RT (SRT) boost.[53] The use of RT boost in patients with T1 to T2a and T3 to T4 disease was a significant determinant of local control. The commonly agreed standard total dose should be more than or equal to 70 Gy at 2 Gy fraction per day. The achievable total dose is limited by the tolerance of the surrounding normal critical organs, in particular, the temporal lobe.[54] Several techniques have been studied to achieve a total dose beyond 66 to 70 Gy, which include brachytherapy boost or 3DRT/IMRT/SRT boost after the conventional fractionation RT and the SIB technique in the IMRT era.

Brachytherapy Boost

Studies from Hong Kong have shown that the use of two to three fractions of brachytherapy could significantly enhance local control in early T-stage disease.[55,56] The indication of the brachytherapy boost is currently confined to the treatment of early T-stage disease due to its limited dose penetration. Because distant failure is the dominant mode of failure in more advanced disease, the role of brachytherapy boost is questionable. Levendag et al.[57] reviewed 411 patients with advanced NPC (T1 or T2 with nodal metastases, or T3 or T4 and node-negative disease), of whom 50% of patients received brachytherapy boost of 11Gy. A significant reduction in local failure was observed in the early T-stage subgroup (0% vs. 14%, $p = 0.023$), but not in the advanced T-stage group.[57] Rosenblatt et al.[58] randomized 274 patients with stage III and nonmetastatic stage IV NPC to chemoradiotherapy with or without brachytherapy boost thereafter. The 3-year local recurrence-free survival was not significantly improved in either the whole T-stage or the early T-stage group.[58]

Sequential Conformal/IMRT/Stereotactic Boost

SRT boost has been investigated by the Stanford University (USA) and Taiwan groups, who used CyberKnife or linear accelerator-based technologies to treat NPC patients following radical 2DRT or IMRT.[59,60] A high control rate in T4 disease was also observed, but the Stanford series reported a temporal lobe necrosis rate of 12% in the entire group and 11% among IMRT-treated patients.[60] In response, the investigators have now decreased their SRT dose to 8 Gy in single fraction or 12 Gy in 3 fractions, whereas the total dose to the temporal lobes is kept below a maximum total dose of 55 to 60 Gy. The long-term safety of this approach and its impact on the therapeutic ratio are yet to be established. In the report by Kam et al.[46], 63 patients were treated with 66 Gy to the gross tumor volume (GTV) using IMRT, and dose escalation was performed in 36% of patients with T2b to T4 disease via IMRT or stereotactic plan (8 Gy in 4 fractions). In this study, dose escalation was found to be a favorable prognostic factor for progression-free and distant metastases-free survival, and the incidence of temporal lobe necrosis was 3%. In a retrospective analysis by Lee et al.[61] on patients who were irradiated with a 3D conformal technique (2 Gy/fraction/day to 70 Gy), 8.3% temporal lobe necrosis rate was detected at 5 years among patients who received fractionated SRT boost. In summary, although there is strong evidence of a dose–response relationship above 66 to 70 Gy, the impact on local control is more obvious after 2DRT and less compelling with IMRT. Caution must be taken to optimize the target conformity, dose heterogeneity, and dose spillage to the neurovascular structures. As IMRT is capable of pushing the therapeutic ratio further owing to its steep dose gradient, the demand for a meticulous design of margin requirement and thus the higher dependence on the setup accuracy cannot be overemphasized.

Simultaneous Integrated Boost in IMRT

SIB, also called simultaneous modulated and accelerated RT (SMART), exploited the “dose-painting” capacity of IMRT by delivering different dose levels to different regions according to the level of risk. This allows a “once-a-day” fractionation schedule with selective dose acceleration to different tumor targets without undue damage to normal organs. Consequently, a higher biologically equivalent dose can be delivered to the gross tumor than

the microscopic disease. A number of studies have evaluated SIB in NPC with a nominal total dose of 64.8 to 76 Gy to the GTV in 2.12 to 2.4 Gy/fraction over 27 to 35 fractions.[30,34,36–39,42,44,45,47,48] Despite the variation in SIB dose fractionation across these studies, the local or locoregional control rate was 88% to 96% after 2 to 5 years of follow-up. However, the incidence of severe late toxicities remains a concern. Bakst et al.[34] reported 12% temporal lobe necrosis rate, whereas Kwong et al.[42] reported moderate to severe hearing impairment in 42% and carotid pseudoaneurysm in 4% of patients.

Other centers used a “mini-SIB” schedule with a lower fraction size. The Radiation Therapy Oncology Group (RTOG) 0225 multicenter phase II study examined a schedule of 70 Gy per 33 fractions in 2.12 Gy/fraction and reported a 2-year local progression-free survival (PFS) of 92.6% and regional PFS of 90.8%.[48] The “mini-SIB” schedule has been tested in a phase III randomized study by Peng et al.[51] who compared IMRT (70 Gy at 33 fractions) with 2DRT in 616 NPC patients. The IMRT arm was associated with a significant improvement in locoregional control and OS and reduction in the incidence of hearing impairment, late xerostomia, temporal lobe neuropathy, trismus, and neck fibrosis. For T4 disease in particular, the use of “mini-SIB” (<2.12 Gy/fraction) or conventional 2 Gy per fraction in combination with chemotherapy may be safer without significantly compromising tumor control if the temporal lobes are kept below 65 Gy.[31]

Incorporation of Chemotherapy in the Treatment of Locoregionally Advanced Nasopharyngeal Carcinoma

Background

Because distant metastasis is the main cause of treatment failure following RT, over a decade of research has been devoted to the intensification of

treatment for locoregionally advanced NPC by incorporating adjunctive chemotherapy. To date, at least seven meta-analyses have concluded that the addition of chemotherapy during RT (at any time point) confers a survival advantage over conventional RT alone in patients with locoregionally advanced (i.e., stage III to IVB) NPC.[62–66] Of these studies, only the one by Baujat et al.[64] was based on patient-derived data, whereas the rest were based on published data. Several observations can be made from these analyses as outlined in Table 11.3.[62–68] The use of concurrent chemotherapy will lead to a 26% to 52% reduction in the risk of death, which amounts to an absolute OS benefit of around 20% after 5 years.[63,64] This benefit has been associated with improvement in locoregional and distant recurrence rates.[63,64] Of the three sequences of chemotherapy that were evaluated—induction, concurrent, and adjuvant chemotherapy, concurrent chemotherapy is by far most consistently associated with the largest magnitude of improvement in OS and PFS than other sequences.[63,64]

Concurrent Chemoradiotherapy

The US Intergroup study was the first to demonstrate a survival advantage of adding concurrent cisplatin-based chemotherapy to RT over RT alone in a multicenter randomized study of patients most of whom had locoregionally advanced NPC.[69] In this study, 147 patients with nonmetastatic stage III to IV NPC were randomized to either RT alone or RT with three cycles of concurrent cisplatin followed by three cycles of adjuvant cisplatin and 5-flurouracil (5FU). Unlike NPC from endemic regions where nearly all of the

cases were of the WHO type II and III histologic subtypes, around 20% of patients enrolled in this study had WHO type I (squamous) form of NPC. At a median follow-up of 2.7 years, the RT alone arm was associated with a hazard ratio (HR) of 4.34 (95% confidence interval, CI, 2.47 to 7.69) for progression and/or death and an HR of 2.50 (95% CI, 1.29 to 4.84) for death compared with the combined arm (Table 11.4).[81–85] This landmark study did not immediately change clinical practice in Asia, as Asian investigators were eager to validate their result in local population where nearly all NPC were of the WHO type II to III histologic subtypes. Several multicenter randomized studies have been published since 2002 (Table 11.4).[69–80] Six of the eight selected studies showed an OS advantage at 5 years,[69,71,75,79,86] with HRs of 0.51 at 3 years[75] and 0.54 to 0.71 at 5 years.[71,79,80] Of the six positive studies outlined in Table 11.4, a variety of concurrent chemotherapy regimens were used, which included a weekly schedule of low-dose cisplatin,[71,79,80] 3-weekly high-dose cisplatin,[69,75] and a two-drug regimen such as cisplatin–FU.[86] The total doses of RT delivered in these studies were between 66 and 74 Gy (Table 11.4).[71,79,86] In the phase III study by Chan et al.,[71,72] which used weekly concurrent cisplatin during RT, the HR was 0.71 (p = 0.049) favoring the concurrent arm for the entire group of patients with stage II to IVB NPC, whereas the magnitude of benefit for the T3 to T4 subgroup was higher with an HR of 0.51 (95% CI = 0.3 to 0.87, p = 0.013). Some of the studies found an association between OS benefit with improvement in distant metastasis or with failure-free survival, thus further adding weight to the hypothesis that chemotherapy may improve survival by controlling micrometastases.[75,79,86]

adjuv, adjuvant; chemo, chemotherapy; HR, hazard ratio for death for concurrent chemoradiotherapy over RT alone; CRT, concurrent chemoradiotherapy; RT, radiotherapy; OS, overall survival; DFS, disease-free survival; FFS, failure-free survival; RFS, relapse-free survival; CI, confidence interval; MFS, metastasis-free survival; wkly, weekly.

Toxicities and Treatment Compliance

Table 11.5 outlines the acute toxicities and compliance to concurrent and/or adjuvant chemotherapy in the phase III clinical trials. Although different criteria were used to report toxicities and different RT planning techniques were used by these studies, the types of moderate to severe (grade 3 to 4) toxicities that are more commonly encountered with concurrent chemotherapy were oropharyngeal mucositis and neutropenia, followed by emesis and RT-related skin reaction. Neutropenic fever and treatment-related deaths were not commonly encountered (where reported).[77] Taking into

account that these studies were published before IMRT was commonly used, the rate of grade 3 to 4 mucositis would generally be increased by 10% to 20% with the addition of concurrent chemotherapy (Table 11.5).

Table 11.5 Toxicities of Selected Phase III Studies of Concurrent Chemoradiotherapy Versus Conventional RT (Non-IMRT)

Compliance to concurrent chemotherapy in the phase III studies as outlined

in Table 11.5 was mixed, with the rates of completion of planned chemotherapy reported to be around 45% to 90% (Table 11.5). The number of cycles of cisplatin delivered during RT has been shown to be a prognostic factor in some retrospective analyses.[87–89] Lee et al.[89] showed that patients who received three or more cycles of high-dose cisplatin during RT were more likely to derive OS benefit than were those who did not.

Some studies have compared the incidence of late toxicities (beyond 3 years) associated with concurrent chemoradiotherapy. In a phase III study that compared conventional fractionated RT with or without high-dose cisplatin, the 3-year actuarial rate of late toxicities was higher in the concurrent arm than the RT alone arm (28% vs. 13%, $p = 0.024$; HR = 1.87; 95% CI, 1.08 to 3.26). The most common grade 3 to 4 late toxicities in the concurrent arm were hearing loss (21%), endocrine dysfunction (8%), and peripheral neuropathy (2%).[76] In another study, which compared conventional versus hyperfractionated RT with or without concurrent chemotherapy, the 3-year actuarial rates in the RT and concurrent arm were, respectively, 14% versus 31% for all late toxicities, 9.5% versus 15.7% for grade 3 to 4 hearing loss, and 0% versus 2% for grade 3 to 4 RT-related skin fibrosis.[90] Chen et al.[80,91] found that patients treated with concurrent chemoradiotherapy experienced a greater incidence of grade 3 to 4 hearing loss (28% vs. 18%, $p = 0.048$), cranial neuropathy (10% vs. 4%, $p = 0.042$), and peripheral neuropathy (2% vs. 0, $p = 0.041$) than RT alone. The incidence of serious brainstem damage, myelitis, and RT-related secondary malignancies was uncommon (1% to 3%).[76,80]

Several studies have reported the incidence of acute and late toxicities of adding concurrent chemotherapy to IMRT.[33,40,46–48,92] In a study by Wolden et al. in which 65% of patients received concurrent chemotherapy during IMRT, 41.2% of patients experienced grade 3 to 4 acute mucositis, 7% had grade 3 hearing loss, and 4% had grade 3 dysphagia 4%.[47] In a study by Wang et al.,[92] which included 300 patients with stage III to IVB NPC who received concurrent cisplatin–RT, grade 3 acute mucositis, dermatitis, and xerostomia were observed in 33.3%, 4.0%, and 4.7% of patients, respectively. At 24 months, grade 2 xerostomia (no grade 3) occurred in 12.3% and grade 3 hearing loss in 0.4% of patients. In a study from Hong Kong, in which over 80% of 1,593 patients with stage III to IV NPC received concurrent cisplatin during IMRT, the risk of hearing impairment was higher

(HR = 1.56) with the addition of cisplatin. The risk of temporal lobe necrosis and cranial neuropathy were not increased.[4] Overall, these studies suggest that the addition of cisplatin to IMRT is safe with acceptable rates of grade 3 to 4 acute and late toxicities.

Induction Chemotherapy

Successive generations of phase II single-arm studies on induction chemotherapy have reported high tumor response rates with platinum-based doublets or triplets and promising early survival rates.[93–95] Despite the initial promise, subsequent randomized studies have failed to demonstrate an OS benefit of induction chemotherapy versus conventional RT alone (Table 11.6).[81–85] Using concurrent chemoradiotherapy as a strategic framework in the treatment of locoregionally advanced NPC, numerous phase II studies have reported their experience with adding induction chemotherapy to chemoradiotherapy throughout the 2000s.[94–103] Despite the heterogeneous nature of these studies in terms of the number of cycles and types of chemotherapy used, studies that employed platinum-based drug triplets reported impressive tumor response rates of 86% to 100% and 3-year OS rates between 88% and 94.8%.[94,95,99,103] For the studies using drug doublets, the overall response rates (79% to 100%) and 3-year OS rates (80% to 91.8%) were reported.[96–98,100–102] At the Prince of Wales Hospital (Hong Kong), concurrent chemoradiotherapy alone was compared with induction chemotherapy followed by chemoradiotherapy in a randomized phase II trial of 65 patients with stage III to IV NPC.[104] Although the study was not powered to detect a difference in survival between the two arms, a significant reduction in the risk of death (HR = 0.17; 95% CI = 0.037 to 0.82; $p = 0.013$) and a 17% absolute improvement in 2-year OS was found.[104] A subsequently published meta-analysis by Ouyang et al.[66] found that the addition of induction chemotherapy was associated with a modest absolute OS benefit of 5.13% at 3 years. To address the question of whether induction chemotherapy adds benefit to concurrent chemoradiotherapy, several phase III studies are now being conducted across Asia, Europe, and North Africa (National Cancer Institute trial numbers: NCT00997906, NCT00201396, NCT00828386, NCT01245959, NCT00379262). A Singaporean group has recently presented their result in abstract form. Tan et al.[105] randomized 180 patients with stage III to IVB NPC to concurrent weekly cisplatin–RT with or

without three cycles of induction chemotherapy with a triplet regimen consisting of cisplatin, paclitaxel, and gemcitabine. This study was powered to detect a 15% difference in OS, and at a median follow-up of around 3 years, no significant difference in OS between the two arms was found. In another recently published study of 803 patients with stage III to IVB from Hong Kong, which consisted of six different treatment arms, preliminary analyses have failed to show that the addition of induction cisplatin–capecitabine could improve the primary endpoint of PFS.[106] The results of other studies are eagerly awaited.

Table 11.6 Phase III Studies Comparing Induction Chemotherapy with RT Alone or Chemoradiotherapy

First Author	Year	*N*	Patients	Arms	Result (All Stage)			
						RT%	CRT%	*p-value*

All are intention-to-treated data.

BEP, bleomycin, epirubicin, cisplatin; EC, cisplatin, epirubicin; CBF, cisplatin, bleomycin, 5-fluorouracil; OS, overall survival; DFS, disease-free survival; RFS, relapse-free survival; FFS, failure-free survival; CRT, concurrent chemoradiotherapy.

Adjuvant Chemotherapy

Phase III studies comparing RT alone versus RT and adjuvant chemotherapy have failed to find a survival benefit with the addition of adjuvant chemotherapy in patients with locoregionally advanced NPC (Table 11.7).[74,107–109] In the largest multicenter study published to date, over 500 patients with stage III to IVB NPC from China were randomized to concurrent chemoradiotherapy with or without adjuvant chemotherapy with failure-free survival being the primary endpoint.[109] Compliance to chemotherapy was comparable with historic rates from other phase III studies

(see Table 11.4), with 63% of patients completing all planned chemotherapy.[109] This study did not identify a statistically significant difference in failure-free survival in the intention-to-treat population or in any patient subgroups. However, the 2-year follow-up period is relatively short and only 63% of patients could complete the planned chemotherapy. For patients who have been identified to be at higher risk of disease recurrence using prognostic biomarker such as plasma EBV DNA, the significance of adjuvant chemotherapy is being investigated as will be discussed below.

Table 11.7 Selected Phase III Studies that Compared RT Alone Versus Adjuvant Chemotherapy

First Author	Year	*N*	Patients	Arms	Result (All Stage)			
						RT%	RT-C%	*p-value*
Rossi[107]	1988	229	II–IV	RT RT → VAC × 6	*2 y* *OS* *RFS*	 55.8 67.3	 57.7 58.3	 *NS* *NS*
Chi[108]	2002	157	IV	RT RT → PFL × 9	*5 y* OS RFS	 60.5 49.5	 54.5 54.4	 *NS* *NS*
Chen[109]	2011	508	III–IV (exclude N0 pts)	Cisplatin–RT Cisplatin–RT → cisplatin–5FU × 3	*2 y* OS DFS	 94 88	 92 86	 *NS* *NS*

VAC, vincristine, cyclophosphamide, and adriamycin; PFL, weekly cisplatin, 5-fluorouracil-leucovorin; RFS, relapse-free survival; OS, overall survival; RT, radiotherapy; C, chemotherapy; 5FU, 5-fluorouracil; DFS, disease-free survival.

Stage II Nasopharyngeal Carcinoma—Concurrent Chemoradiotherapy or Not?

In the largest retrospective study of over 2,600 patients in Hong Kong, ~41% of patients had stage II NPC at diagnosis with a 5-year OS of 84% and PFS of 73% following treatment with mainly RT alone.[1] Approximately 13% of patients with stage II NPC develop distant metastasis within 5 years from RT.[1] Some investigators have proposed the use of adjunctive chemotherapy during RT for patients with stage II disease. Subgroup analysis of stage II cohorts in several phase III clinical trials have yielded mixed results.[71,110] In the largest phase III study reported to date from China,[87] 236 patients with stage II NPC were randomized to either RT alone or RT plus weekly

cisplatin. The Chinese 1992 staging system was used in this study where stage II NPC was defined via MRI and clinical examination. Translating these into the AJCC criteria, this meant that around 10% to 16% of subjects actually had stage III NPC in this study. At a median follow-up of 60 months, the addition of concurrent cisplatin to RT significantly improved the 5-year OS rate with an HR of 0.30 (95% CI = 0.12 to 0.76; $p = 0.007$) and the 5-year PFS with an HR of 0.45 (95% CI = 0.23 to 0.88; $p = 0.017$).[87] The magnitude of benefit reported seemed larger than what has been reported for patients with stage III to IV NPC (Table 11.4), despite the fact that the dose of cisplatin (30 mg/m^2/week) was lower than the dose used in a previously published phase III study in Hong Kong (40 mg/m^2/week).[71] This could be partly due to the better rate of compliance to chemotherapy where 78% of patients had six cycles of chemotherapy, compared to 44% in the Hong Kong study.[71,87] The 5-year OS rate of 85.8% is within the range reported by the Hong Kong NPC study group for stage II to III NPC.[1] However, because 2DRT was used in this study, the applicability of this study's data on current practice should be interpreted with caution in light of the now broader application of IMRT. Further studies on how patients with stage II NPC should be selected for concurrent chemoradiotherapy using plasma EBV DNA level are warranted.[111]

Prognostication with Plasma Epstein-Barr Virus in Patients Undergoing Cytotoxic Therapy

The almost universal presence of EBV genome in nonkeratinizing NPC tumors has opened up the opportunity of developing a new tumor marker, based on the detection of EBV DNA fragments in patient's blood. There is now ample evidence to show that plasma level of EBV DNA reflects tumor burden and disease stage in patients with EBV-positive NPC, and this level can be quantified accurately and reliably using a quantitative real-time PCR (qRT-PCR) technique that targets two regions of the EBV genome—the BamHI-W and EBNA-1 regions.[112–117] The reproducibility and relative affordability of this biomarker has enabled its validation in large-scale multicenter prospective studies and broadened its utility in the therapeutic monitoring of patients undergoing cytotoxic therapies. Kinetic studies in NPC patients undergoing radical RT have shown that the median half-life of

plasma EBV DNA is around 3.8 days,[115] and the prognostic role of plasma EBV DNA has been investigated in patients with locoregionally advanced NPC undergoing radical RT. In a study at the Prince of Wales Hospital (Hong Kong), patients with plasma EBV DNA levels of over 500 copies per mL at 6 to 8 weeks following RT were found to have a relative risk of cancer recurrence of 11.9 (95% CI 5.53 to 25.43).[118] This plasma cutoff has a positive and negative predictive value for NPC recurrence of 87% and 83%, respectively. A subsequent study also found that detection of an elevated plasma EBV DNA level at an earlier time-point during RT has been similarly associated with a higher risk of recurrence, with an HR for distant failure of 12.02 (95% CI 2.78 to 51.93).[119] This suggests that plasma EBV DNA monitoring during and after RT may be useful in identifying those patients who may benefit from more intensive systemic therapy. For patients undergoing palliative chemotherapy for metastatic NPC, plasma EBV DNA half-life analyzed during the first 4 to 5 weeks of therapy may predict radiologic tumor response and survival.[120]

To test the hypothesis that patients with elevated plasma EBV DNA at 6 to 8 weeks after RT may benefit from having adjuvant chemotherapy compared with observation alone, the Hong Kong NPC Study Group is conducting a multicenter phase III study (NPC0502) where patients with detectable plasma EBV DNA level will be randomized to adjuvant cisplatin and gemcitabine for six cycles or observation alone. To date, over 500 patients have been recruited with 95 patients having detectable EBV DNA who were subsequently randomized (NCT00370890). In an effort to standardize plasma EBV DNA assay across different centers as a prelude to conducting multicenter, multinational clinical trials where plasma EBV DNA will be used as an integral biomarker, four major centers from the United States, China, Hong Kong, and Taiwan have reported the first international collaborative exercise in the harmonization of quantitative RT–PCR analysis of plasma EBV DNA.[121] An international study led by the NRG has been initiated in which patients with persistently positive plasma EBV DNA following chemoradiotherapy will be randomized to either adjuvant cisplatin–5FU or gemcitabine–paclitaxel, whereas patients with negative plasma EBV DNA following chemoradiotherapy will be randomized to either cisplatin–5FU or observation. The NPC0502 and NRG HN001 studies are critical in addressing the question of how patients can be optimally selected for

therapeutic intensification soon after completion of definitive RT.

Treatment of Recurrent Nasopharyngeal Carcinoma

Treatment of Locoregional Recurrence

Locoregional control in NPC has improved in the last two decades[4]; however, 10% of all patients (20% to 25% in the T4 subgroup) still suffer from local failure despite modern treatment.[4,28,122] Latency for local recurrence varies widely, but the peak incidence is usually observed between the 2nd and 3rd year after primary RT, whereas late recurrence occurring beyond the 5th year is relatively uncommon.[123,124] Because the majority of patients with local recurrence do not have synchronous distant relapse,[124,125] aggressive salvage approach has been advocated because long-term survival is possible. Treatment options include surgery or reirradiation with curative intent, whereas palliative chemotherapy may be considered for those patients who are unfit for aggressive treatment. Unfortunately, therapeutic margin is narrow especially for those patients with advanced local recurrence. Careful patient selection is important in maximizing the therapeutic ratio, and therapeutic decisions should generally be based upon important factors such as the stage at recurrence, tumor volume, latency from primary treatment, pre-existing late complications, and general well-being of the patients. In a retrospective review of 275 NPC patients with local recurrence from Hong Kong, the 3-year OS rate for the entire cohort was 74%.[125] Patients who received salvage treatment had a significantly better OS than those who did not, but a subgroup analysis failed to find any survival advantage in patients with stages rT3 to rT4 disease. There was also no significant difference in survival between patients treated with radical RT or surgery.[125] There is a lack of randomized study comparing surgery versus reirradiation in patients with very early rT stage disease or comparing more aggressive treatment versus conservative approach in more advanced local recurrence. The current treatment recommendation is merely based on retrospective data and may change with time as therapeutic technologies evolve.

The efficacies of brachytherapy, high-dose external reirradiation or surgery are comparable in terms of treatment outcome in patients with early local recurrence, but their toxicity profiles are quite different. Brachytherapy is only suitable for small recurrences confined to the central nasopharynx (rT1) because the anchorage of radioactive source at the lateral wall or outside the nasopharynx would be technically difficult. External beam reirradiation is an alternative to surgery for rT2 disease, and it is often the only option for more advanced disease (advanced rT2, rT3-4) in which surgical resection is not feasible. Nasopharyngectomy is mainly reserved for tumors that do not involve the skull base or internal carotid artery (ICA) (rT1 and limited rT2). Depending on the location and extent of tumor involvement, different surgical approaches have been employed.[126–140] From these studies, the 5-year local failure-free rate for rT1 lesions after surgery has been reported to be ~65% to 77% and the corresponding disease-free survival rate ~54% to 73%. For regional recurrence, radical neck dissection is the standard treatment because the outcome of surgery is significantly better than reirradiation.[141–144] Interestingly, more aggressive surgical approaches that involved vascular bypass and cranial–facial resection have been tried in more advanced tumors, and their long-term results are eagerly awaited.

Reirradiation

Understanding the radiobiology of reirradiation is important to achieving the best clinical result. Whereas high reirradiation dose (60 Gy) is essential for tumor control, it will also increase the risk of mortality if the normal tissue tolerance is exceeded. Lee et al.[121] showed that the hazard of local failure was decreased by 1.7% per Gy of reirradiation given, whereas the hazard of toxicity was increased by 4.2% per Gy of primary RT. Partial recovery of normal tissues, including the brain and spinal cord, was observed as early as 6 to 12 months after the primary course.[121] Historically in patients who were reirradiated for local recurrence, long-term survival can be expected if a sufficient amount of radiation dose in excess of 60 Gy could be given.[121,145–149] Tolerance of normal tissue to cumulative radiation is the main dose-limiting factor, particularly in the brain and spinal cord. Thus, the fundamental principle of reirradiation should be aimed at concentrating high radiation dose to the tumor target with a rapid dose gradient to maximize the protection of adjacent normal organs. Brachytherapy, stereotactic

radiosurgery (SRS), or external beam reirradiation have been evaluated in several studies (Table 11.8).[121,146–148,150–165] As a general working rule for reirradiation, brachytherapy is applicable only for rT1 tumors, whereas SRS or fractionated stereotactic radiotherapy (FSRT) (with or without intensity modulation) is applicable for rT1 or T2 tumors. For more extensive T3 and T4 recurrences, IMRT and fractionated stereotactic IMRT (FS-IMRT) with or without chemotherapy and with or without dose escalation using brachytherapy or SRT are all regarded as reasonable options in contemporary practice.

Table 11.8 Results from Series Using Radiotherapy for NPC Local Recurrence

Author	Patient *N* (rT1%)	Radiation Method and Median Dose	FU Year (Median)	Local Control (%)	Overall Survival (%)
Lee et al.[121]	654 (35% rT1)	2DRT (40–46 Gy) + brachytherapy	5	23	16

Brachytherapy

Brachytherapy can deliver a high dose to a small tumor volume and is applicable to tumors confined to the nasopharyngeal cavity and away from the skull base. Intracavitary brachytherapy is a more common approach nowadays. It has been used most often as a boost after nasopharyngectomy or external beam reirradiation. Combined external and intracavitary approach was shown to be less toxic than external reirradiation alone in some retrospective series, most of which employed 2DRT.[121,147,151,152,160] The advantage of brachytherapy boost exists even when more conformal external RT technique is used at the outset. Koutcher et al.[160] showed that combined conformal RT/IMRT (45 Gy) and brachytherapy (20 Gy) incurred significantly less severe late toxicity than conformal RT/IMRT alone (59 Gy) (8% vs. 75%) for the same degree of tumor control and OS.

Stereotactic Radiosurgery/Fractionated Stereotactic Radiotherapy

SRS was initially applied to the treatment of small volume T1/2 recurrence because of its high degree of precision and steep dose gradient.[155,156,166–168] For tumor that is large, irregular, or close to the brain or major vessels, hypofractionated SRT is radiobiologically less damaging to the normal tissue. A joint analysis on 56 patients with early local recurrence showed 75% local control rate at 3 years using 48 Gy in 6 fractions.[157] Chua et al.[167] compared SRS (median 12.5 Gy single dose) with hypofractionated SRT (median 35 Gy in 4 to 6 fractions) in a matched cohort analysis consisting of 86 rT1-4 patients. FSRT was associated with a significantly higher 3-year local control rate than SRS (83% vs. 51%) especially in the rT2 to T4 subgroup, but the OS was similar and the incidence of severe late complications was higher in the SRS group.[167] Seo et al.[158] used CyberKnife SRT to deliver a median dose of 33 Gy in 3 to 5 fractions to 35 patients (43% rT1) and achieved 5-year local control of 79% and OS of 60% without serious neurologic complication. In a retrospective comparison of CyberKnife FSRT (30 Gy in 5 fractions) versus 3DCRT (median dose of 57 Gy), Ozyigit et al.[159] observed similar 2-year local control between the two groups (82% vs. 80%), but FSRT had significantly lower incidence of grade 3 or more overall rate of late toxicities (21% vs. 48%). However, the incidence of massive hemorrhage was substantially higher in the FSRT group (17% vs. 4%), whereas the treatment mortality rate remained high in both groups (13% vs. 15%).[159]

These studies suggest that a high dose is needed for a successful tumor control, which comes at a price of increased severe morbidities or even mortality particularly in patients with more advanced recurrence. Along with the restriction of dose and volume of neurovascular tissue irradiation, other factors such as dose homogeneity, dose falloff, and the use of lower dose per fraction are all important dosimetric factors that can affect the outcome of treatment. Advances in frameless SRT in conjunction with image-guidance technologies enhance the feasibility for more protracted fractionation, which may hopefully help to reduce the risk of neurovascular damage associated with SRS and hypofractionated SRT.

Intensity-modulated Radiotherapy

IMRT can potentially improve the therapeutic ratio by achieving a more optimal dose distribution between tumor target and critical normal organs, and IMRT has therefore been evaluated in the treatment of NPC local recurrence. Han[162] and Lu et al.[161] reviewed 239 patients (46% rT4) who received IMRT for local recurrence. The 5-year OS was 44.9% and local recurrence-free survival was 85.8%, but as much as 34.7% of patients died of radiation injury. Qiu et al.[165] reported the outcome of 70 patients retreated with IMRT at a median dose of 70 Gy and reported a 2-year locoregional recurrence-free survival and OS of 65.8% and 67.4%, respectively. Moderate to severe late toxicities were noted in 35.7% of patients (17% deafness and 24% cranial neuropathy).[165] In a recent report by Chen et al.[164] using 68.5 Gy IMRT to treat 54 patients with rT1 to rT4 recurrences, the 2-year local PFS was 64% and OS of 44%. Severe late toxicity was seen in 48% of patients (including 11% massive bleeding, 18.5% temporal lobe necrosis, 20% dysphagia, and 31.5% mucosal ulceration), and the treatment-related death occurred in 25% of patients.[164] The high incidence of radiation damage is still the major limitation for the successful delivery of high-dose radiation to the recurrent tumor, despite the use of IMRT and stereotactic setup. The treatment outcome for rT4 disease is particularly disappointing. Careful selection of patients with favorable prognostic factors will help to avoid futile treatment and undesirable complications. Using prognostic factors such as tumor volume, rT stage, rN stage, preexisting toxicity, age, and performance status to calculate a prognostic score, patients within the “high-risk” category have a 5-year survival of 8% only despite the use of IMRT. This group of high-risk patients should better be managed conservatively.[169]

Salvage Surgery

For local recurrence, different surgical approaches have resulted in different outcome and complication depending on the location and extent of tumor involvement. Overall, the 5-year local failure-free rate for rT1 lesions after surgery was 65% to 77%, and the corresponding disease-free survival rate was 54% to 73%.[126–140] The surgical outcome is worse with more advanced lesions because it is difficult to achieve adequate surgical margin without damaging critical neurovascular structures such as the carotid artery or cranial nerves.

Advances in minimally invasive surgery have enabled small tumors located in the posterior wall of the nasopharynx to be resected via endoscopic approach through the nasal or oral cavity.[140,170–172] En bloc resection is performed with an electric knife or a laser. Microwave coagulation therapy has also been used successfully through transnasal route.[173] Resection of larger tumor with more lateral extension can now be performed with the versatile “endowrist” of the robotic instruments (transoral robotic surgery, TORS).[174] TORS is currently only limited to the resection of tumors not close to the ICA because the robotic arm lacks tactile surveillance for the carotid pulsation. For more bulky recurrent tumors, an open surgical approach is required for more adequate visual exposure. The nasopharynx can be accessed through the infratemporal fossa from the lateral approach,[175,176] with possible complications of conductive hearing loss and trigeminal nerve dysfunction. When the tumor is located in the central nasopharynx without lateral extension, resection can be performed from the inferior aspect via the transpalatal, the transmaxillary, or the transcervical approach.[177,178] Maxillary swing nasopharyngectomy is another widely practiced anterolateral approach that provides adequate exposure of the tumor in the nasopharynx and the parapharyngeal region. Resection of tumor in conjunction with any parapharyngeal or even retropharyngeal disease is feasible with this approach.[179] In an update on 312 patients using the maxillary swing approach, Chan et al.[180] reported a 5-year actuarial local control rate of 74% and OS of 62%. A number of prognostic factors such as tumor size, resection margin status, and the presence of gross tumor in the sphenoid sinus were found to influence local tumor control. The resection margin status, synchronous cervical nodal recurrence, and cavernous sinus

invasion were found to negatively affect OS after this surgical approach.[128] The same group also evaluated staged operations (intracranial–extracranial vascular bypass, craniofacial resection, and microvascular free flaps) on advanced recurrences that were initially deemed to be inoperable due to ICA encasement or skull base invasion. With this extended approach, 81.8% of curative resection rate was achieved on 22 patients, and the OS was 100% at a mean follow-up of 38.8 months.[181] Common surgical complications include facial numbness, ectropion, epiphora, trismus, palatal fistula, and middle ear effusion.

For patients with regional nodal recurrence, radical neck dissection is the standard treatment because the outcome of surgery is significantly better than reirradiation.[143,144] Chua et al.[144] analyzed 43 patients with synchronous locoregional relapse and found that the 3-year nodal control rate after radical neck dissection was 65%, compared with 24% by reirradiation alone. Previous irradiation also limits the amount of radiation that can be given at recurrence without significant toxicities to vital structures like the brachial plexus, carotid artery, and spinal cord. In contrast, the outcome of patients after radical neck dissection has made steady progress as a result of better imaging support and surgical technique, achieving a 5-year regional control rate and OS rate of 68% and 58% to 66%, respectively.[141,142] Modified radical neck dissection has been advocated in some institutions with the aim of preserving the patient's quality of life by sparing the internal jugular vein or spinal accessory nerve. However, this should be regarded as investigational at present because the tendency of isolated tumor cell clustering, muscle invasion, and extranodal extension from these recurrent nodal diseases may jeopardize the rate of complete resection.

Treatment of Metastatic Disease

The majority of cases of metastatic NPC diagnosed in endemic regions are due to distant failures following definitive RT, although very few patients present with distant metastases from the outset.[21,182] In the study by Hong Kong NPC Study Group, distant metastasis was the most common cause of treatment failure with a 5-year actuarial rate of 14.9% for all disease stages.[183] Of the 476 patients who developed distant metastasis, 79.6% presented with distant metastasis alone, 12.3% with locoregional recurrence initially followed by distant metastasis, and 8.1% presented with distant and

locoregional recurrence synchronously.[183] Patients who develop locoregional recurrence were also at higher risk of developing subsequent distant metastases at a rate of 20% to 34%.[183] The most common site of distant metastasis was the bony skeleton followed by the liver and lung.[184–186] The prognosis of patients with metastatic NPC is quite variable with a marked heterogeneity of OS observed among different metastatic sites, and patients with metastases limited to the lung have the longest survival with a median OS of 3.9 years.[183–185,187] Over 80% of distant recurrences tend to present within 3 years after definitive RT, but recurrences beyond 5 years are not uncommon.[182,188]

Long-term survival (beyond 5 years) has been well described in metastatic NPC,[23,182,189] and most long-term survivors tend to have younger age, male gender, and prior treatment with platinum-based chemotherapy.[23,182,187,189] Retrospective series suggest that patients with distant metastases that were amenable to multimodal treatment seemed to live longer than did those who received chemotherapy or local therapy alone.[23,187] This underscores the important role of multidisciplinary approach in the management of metastatic NPC.

Although chemotherapy has never been compared with supportive care alone in metastatic NPC, platinum-based chemotherapy is regarded as the therapeutic cornerstone because of their well-proven activity in the literature. Most of the data are derived from single-armed phase II studies conducted in a single center; thus, there is a paucity of randomized trials comparing different regimens. The results of these nonrandomized studies need to be interpreted with caution for several reasons. Some of these studies were underpowered and the enrolled subjects could be quite heterogeneous in terms of histology, disease burden, sites of metastases, and extent of prior exposure to adjunctive chemotherapy during RT. The inclusion of a higher proportion of patients with only locoregional recurrences may potentially underestimate the tumor shrinkage rate, as some irregularly shaped recurrent tumors such as those at the skull base or the nasal cavity may be hard to assess using the Response Evaluation Criteria in Solid Tumors (RECIST).[190,191]

First-line Clinical Trials

In the late 1970s, nonplatinum agents such as cyclophosphamide, doxorubicin, bleomycin, and methotrexate were reported to yield single-agent response rates of 38%, 39%, 28%, and 17%, respectively, in patients with recurrent NPC.[192] Since the introduction of cisplatin in the treatment of squamous head and neck cancers in the early 1980s, the earliest reports on the use of platinum-based chemotherapy in NPC described response rates of over 50% in patients with recurrent NPCs who were treated with cisplatin and 5-fluorouracil (5FU) or with cisplatin–bleomycin–vincristine as a triplet or other combinations with more than three drugs including bleomycin, vincristine, methotrexate, and/or doxorubicin.[193,194] Several prospective phase II studies conducted in predominantly chemotherapy-naïve patients with recurrent or metastatic NPC have been published (Table 11.9).[193–208] The majority of these studies reported impressive and durable response rates with multiple drug combinations of three or more drugs (maximum of five drugs). However, the incidence rates of grade 3 to 4 marrow toxicities were high with occasional reports of treatment-related deaths.[199,201,209]

[c]Only 44 patients treated with chemotherapy without radiotherapy were outlined here.

NR, not reached; 5FU, 5-fluorouracil; GEMOX, gemcitabine and oxaliplatin; TTP, time to progression; PFS, progression-free survival; OS, overall survival.

With the introduction of more modern regimens in the late 1990s, platinum-based doublets using taxanes, gemcitabine, and capecitabine have gained increasing popularity in contemporary practice because of their efficacy, safety, and convenience. As shown in Table 11.9, regimens such as cisplatin–gemcitabine, carboplatin–paclitaxel, and cisplatin–capecitabine could yield response rates that are comparable to the older regimens with fewer grade 3 to 4 hematologic toxicities.[200,202,206,207,210] Ngan et al.[202] showed that patients with distant metastasis alone had a higher response rate (80%) than those with locoregional disease (55%) to cisplatin–gemcitabine. This finding highlights the importance of taking into account of the proportion of enrolled subjects with distant versus locoregional disease when interpreting response rates from single-armed phase II studies in NPC.[202] The clinical experience with docetaxel in NPC has been marred by two reports of excessive myelotoxicities,[203,211] but recently published Korean study found that an alternative schedule of cisplatin and weekly docetaxel was very well tolerated in patients with NPC.[208] This result is promising and may re-establish the role of docetaxel in the palliative treatment of NPC.

Various platinum derivatives such as the second-generation agents carboplatin and nedaplatin and the third-generation agent oxaliplatin have been evaluated in NPC. Nedaplatin is a cisplatin analogue that has been evaluated as a substitute for concurrent cisplatin during RT and in patients who had failed prior cisplatin in the palliative setting.[212,213] Oxaliplatin has been investigated in combination with gemcitabine in the "GEMOX" regimen, with a median OS (19.6 months) and time to progression (9 months) that were comparable to the report on cisplatin–gemcitabine.[202,205] These data suggest that oxaliplatin could be an effective substitute for cisplatin in patients who are intolerant to cisplatin. Although there is no randomized data to suggest which platinum is the drug of choice in the palliative setting, cisplatin and carboplatin are often regarded as the prevailing backbone for

first-line chemotherapeutic regimens for recurrent or metastatic NPC. Overall, for patients with good performance status and predominantly distant metastases, the use of platinum-doublets should be expected to yield at least a response rate between 56% and 70% and a median TTP between 6 and 10 months. The OS rates of patients enrolled in phase II studies have improved over the last decade, and this may be partly due to improvement in supportive care, less toxic chemotherapeutic agents, and the increasing awareness that certain patients subgroups with only pulmonary metastases may benefit from a more aggressive and multimodal therapeutic approach.

Clinical Trials of Chemotherapy in Subsequent Lines

For patients who fail prior platinum-based chemotherapy for recurrent NPC, there is no universally accepted standard of care in terms of drug regimen Table 11.10.[213]–[223] outlines some of the published phase II studies on patients who have failed one or more lines of prior chemotherapy. In the studies of single agents, the reported response rates varied between 14% and 48% and the median OS rates between 7 and 16 months. The durability of treatment response varies considerably across these studies, with median time to progression ranging from 1.5 to 7.5 months. Most of the studies described in Table 11.10 involved nonplatinum agents, and the sample sizes of these studies are too small to draw any conclusions about the merits of using multiagent regimens over single agents in patients who progressed after first-line platinum-based therapy. It is also difficult to estimate the magnitude of benefit of chemotherapy in this setting, as chemotherapy has not been compared with supportive care alone. These views are reflected in some guidelines from the National Comprehensive Cancer Network (NCCN) and European Society of Medical Oncology (ESMO), although significant differences in institutional preferences exist.[224,225]

Table 11.10 Selected Phase II Trials of Chemotherapy in Subsequent Lines of Treatment in Metastatic or Recurrent Nasopharyngeal Carcinoma

Novel Therapy

Targeted Therapy

To date, the clinical evaluation of molecularly targeted therapies in NPC has mainly involved inhibitors against the epidermal growth factor receptor (EGFR) and its related signaling kinases, and antiangiogenic agents against vascular endothelial growth factor receptor (VEGFR)-mediated signaling. Most of the published reports have mainly been single-arm phase II studies enrolling unselected populations of patients with recurrent or metastatic NPC who have been heavily pretreated with chemotherapy. A few studies have investigated the feasibility of combining antibodies with concurrent chemoradiotherapy in locoregionally advanced NPC.

Epidermal Growth Factor Receptor Inhibitors

One of the earliest categories of targeted agents that have been evaluated in NPC was the EGFR inhibitors. The *EGFR* gene is among one of several important oncogenes such as *RAS*, *C-MYC*, *C-MET*, and *BCL-2* that are frequently up-regulated in NPC.[226] *EGFR* gene amplification and overexpression can be found in 40% and 80% of NPC tissues, respectively.[227,228] In phase II trials of patients with recurrent or metastatic NPC, the lack of activity of gefitinib as monotherapy may be attributed to the lack of activating EGFR mutations in NPC.[229–231] The combination of

cetuximab and carboplatin have shown modest activity in this patient population in a multicenter phase II study, with a partial response rate of 11.7% and stable disease rate of 48.3%.[232] However, the response was short-lived as the time to progression was just 2.7 months for the whole group.

Antiangiogenesis Inhibitors

The class of agents that has currently reached the most mature stage of clinical development in NPC is the inhibitors of angiogenesis. Sunitinib and pazopanib are the predominantly anti-VEGFR, multitargeted kinase inhibitors that have been evaluated in phase II studies in heavily pretreated patients with recurrent or metastatic NPC.[233–236] In the studies on sunitinib and pazopanib, the majority of patients experienced prolonged SD, and objective responses were uncommon (<6%). However, the pazopanib study failed to reach its predefined level of drug response, whereas the study of sunitinib was prematurely terminated because of excessive bleeding–related toxicities.[233,236] The risk of serious bleeding from sunitinib seemed to occur in patients with previously irradiated locally recurrent tumor involving the ICA.[233] The authors recommended that such patients should be excluded from future studies of antiangiogenic agents. The activity of the anti-VEGF antibody bevacizumab is currently being evaluated in a phase III study comparing chemotherapy alone versus chemotherapy and bevacizumab in the first-line treatment of recurrent and metastatic NPC in China.

Incorporation of Targeted Therapy with Radiotherapy

For patients with nonmetastatic stage III to IV NPC, ~20% of patients with T3 to T4 NPC still develop locoregional recurrence despite the use of modern RT techniques.[183] One novel strategies that may enhance local control is the incorporation of novel radiosensitizers such as antibodies against EGFR or VEGF. At the Prince of Wales Hospital in Hong Kong, the safety of adding weekly cetuximab to concurrent cisplatin at a weekly schedule and IMRT was investigated in patients with nonmetastatic stage III to IV NPC.[237] Although the 2-year PFS rate of 86.5% (95% CI, 74.3% to 98.8%) compared favorably with historic data (2-year PFS of 76%),[71] the rate of acute mucosal toxicities encountered in this study (grade 3 to 4 oropharyngeal mucositis of 87%) were much higher than the rates reported with 2DRT and IMRT—

where the grade 3 to 4 mucositis was around 40% to 48%.[46,71] In the RTOG 0615 study, bevacizumab was evaluated in combination with concurrent cisplatin at a 3-weekly schedule and IMRT in patients with stage IIb to IVb NPC.[238] The primary endpoint was the incidence of grade 3 to 4 bleeding or any grade 5 events. The result showed that bleeding episodes were mostly grade 1 to 2 in severity and there were no treatment-related deaths. Although cross-trial comparison is fraught with bias, the 2-year PFS rate of 74.7% (95% CI 61.8% to 87.6%) appears to be similar to historic data with chemoradiotherapy alone in a phase III study as mentioned above.[71]

Immunotherapy

EBV is ubiquitous in nonkeratinizing NPC, and EBV antigens have been exploited as potential targets for immunotherapy. However, NPC only expresses a set of poorly immunogenic latency type II viral antigens, namely, EB nuclear antigen (EBNA)-1 and latent membrane protein (LMP) 1 and LMP2. EBNA-1 is expressed frequently in NPC and is a dominant target for CD4 T cells. LMP1 and LMP2 are expressed in around 50% of NPC tumors and are both targets for CD8 cytotoxic T lymphocytes (CTL). Although LMP1 is the key EBV oncogenic protein, it is poorly immunogenic, and thus, LMP2 is a more likely target antigen for a CD8 CTL-based therapy.[239,240] Studies in healthy subjects revealed that these latent proteins are not the dominant targets of T-cell response associated with natural EBV infections. However, some of the latent proteins such as EBNA-3, LMP2, and, less commonly, EBNA-2, EBNA-LP, and LMP1 can provide immunodominant epitopes that are restricted through the HLA-1 and HLA-A2 family of alleles.[241] The objective of boosting anti-EBV responses in circulating CD8 T cells in NPC patients, such as boosting CD8 immunity to LMP2 epitopes, has formed the basis for the clinical development of vaccine and adoptive T-cell therapies in NPC.

The use of autologous EBV-specific CTL in the treatment of patients with advanced NPC has been shown to be safe and effective in inducing LMP2-specific immune responses, and sustained clinical responses have been reported in several clinical trials.[242–245] Adoptive T-cell transfer is an ideal form of personalized therapy that has the potential to enhance long-lasting antitumor immunity, but the process of T-cell expansion is costly, labor intensive, and restricted to specialist centers. An alternative way of T-cell

expansion that could circumvent some of these limitations is a vaccine-based approach as reported by Smith et al.,[246] on an adenovirus vector–based polysaccharide vaccine, which contained the combined antigenic epitopes of EBNA-1, LMP1, and LMP2. The feasibility of a sequential approach of upfront carboplatin–gemcitabine followed by LMP1- and LMP2-specific CTLs in the first-line treatment of recurrent and metastatic NPC has also been recently reported.[247] The median OS almost reached 30 months (95% CI: 20.8 to 39.3 months), which compared favorably with historic data on survival for patients who received first-line chemotherapy alone (Table 11.9). Interestingly, atypical responses were observed in some patients, where there was an initial radiologic tumor progression, followed by late responses.[247]

Two main vaccine-based approaches have been reported to date, namely, autologous dendritic cell-based vaccines and a non–cell-based approach of using a modified vaccinia Ankara (MVA) recombinant vector that expresses tumor-associated viral antigens. Lin et al.[248] demonstrated the feasibility of a vaccine containing dendritic cells that were pulsed with LMP2-derived peptides, in boosting peptide-specific T-cell responses and durable tumor response in a small group of patients with advanced NPC. Another dendritic cell-based method was an adenovirus–DeltaLMP1–LMP2 transduced dendritic cell vaccine, but the investigators did not observe any LMP1- or LMP2-specific T-cell response in patients with metastatic NPC.[249] Using a total different approach, Hui et al.[250] investigated an MVA-based vaccine, which was constructed using sequences cloned from a typical Chinese EBV strain and encodes a functionally inactive fusion protein containing the CD4 epitope–rich C-terminal half of EBNA-1 and the CD8 epitope–rich LMP2A. The combination of both EBV antigens has the potential advantage of boosting host response to both CD4- and CD8-mediated immunity. A phase I study has demonstrated the safety and immunogenicity of this vaccine in patients with NPC following definitive RT. T-cell responses to one or both vaccine antigens were increased in most patients in a dose–response manner. This vaccine is currently being evaluated in a phase II trial in patients who have either residual plasma EBV DNA following RT or residual disease following response to palliative chemotherapy for metastatic NPC (NCT01094405).

Conclusion

Advances in the prognostication and treatment of NPC have significantly contributed to an improvement in patient survival in endemic regions such as Hong Kong. RT remains the cornerstone in the treatment of early disease, and a multidisciplinary approach to the multimodal treatment of advanced and recurrent disease has largely become the standard of care in many expert centers. As more long-term data on safety and efficacy are now available, IMRT has been widely adopted in routine practice. Controversy remains in the role of concurrent chemotherapy in stage II NPC and the optimal application of plasma EBV DNA in selecting patients for adjuvant chemotherapy following definitive chemoradiotherapy. The systemic treatment of recurrent and metastatic NPC is challenging, and immunotherapy using vaccine-based approaches is an area of active research at present.

12 Cancer of the Lip

Jessica J. Peck Daniel Petrisor, Mark K. Wax

Approximately 25% of all carcinomas of the oral cavity involve the lips, making the lips the most commonly affected subsite in the oral cavity. The prominent location of cancers of the lip allows for early detection of pathology. The lips play such a prominent role in how we present ourselves to the outside world that any abnormality is immediately noticed and reacted to. The fact that lesions of the lips are detected so early makes treatment relatively easy and successful, making cancer of the lip one of the most curable cancers of the head and neck. Unfortunately, even with the prominent location and ease of detection, as many as 15% of the cases, the disease will demonstrate aggressive behavior manifested by recurrence, metastasis, and death from disease. Late presentation due to neglect or poor access to health care accounts for a portion of these cases. The vast majority of cancers of the lip are treated with local resection followed by repair through local tissue rearrangement. Reconstruction of larger defects after resection of larger tumors may require complex composite flaps to optimize both function and cosmesis.

ANATOMY OF THE LIP

The upper and lower lips are the most dominant feature of the lower third of the face. The area of the lips extends vertically from the subnasale to the mental crease and horizontally to each oral commissure. Embryologically, the lips are formed by the union of five facial processes. The upper lip is formed from the two lateral maxillary processes that fuse centrally with the frontomedian process, whereas two mandibular processes meet in the midline to form the lower lip.

The lip is a complex anatomical structure, which includes a muscular

layer that is a part of the oral sphincter, lying between a mucosal layer and the overlying skin. This muscular layer is composed of the orbicularis oris muscle, which is derived from the second branchial arch. The muscle fills most of the body of the lip and completely encircles the mouth creating the oral sphincter. This skeletal muscle helps in the regulation of food entrance and maintenance within the oral cavity. The orbicularis muscle of the lip is not a simple sphincter because, in its periphery, it receives fibers from the many different surrounding facial muscles. These act together with the orbicularis to produce the various shapes and functions that are possible with the lips, such as smiling, frowning, kissing, blowing, whistling, articulating speech, and closing the lips.

The most characteristic feature of the lip is the vermilion—a transitional mucosal surface that covers the free margin of the lip and bridges the external skin with the internal mucosa. The mucocutaneous junction forms the anterior vermilion border, whereas the posterior point of contact of the lips, when they are held closed, marks the posterior vermilion border.

Sensory innervation of the lip is supplied by the second and third division of the trigeminal nerve. The upper lip is supplied by the infraorbital branch of the maxillary nerve (V2), exiting from the infraorbital foramen. The oral commissure is supplied by the buccal branch of the mandibular nerve (V3). Lower lip sensation is supplied by the mental branch of the mandibular nerve, which enters the mandible as the inferior alveolar nerve at the inferior alveolar foramen. The nerve traverses the mandible and exits through the mental foramen as the mental nerve. The nerve transitions from posterior to the mandible to anterior as it passes through the mandible. As the nerve of the second branchial arch, the facial nerve provides lip motor innervation via the buccal and marginal mandibular branches. The buccal branch of the facial nerve supplies the upper lip, whereas the lower lip motor functions are supplied through the marginal mandibular branch.

The arterial supply to the lips is provided principally by the left and right facial arteries, from which arise first the inferior and then the superior labial arteries. These vessels encircle the left and right side of the mouth passing between the respective orbicularis and submucosa. Venous drainage is supplied by the left and right anterior facial veins. These run posterior to the facial arteries with their corresponding branches. Interconnections are abundant, and the total lip complex can survive on the contralateral supply.

Lymphatic drainage of the upper lip and oral commissure is accomplished by an interconnecting network of delicate vascular structures found in both the submucosal and subcutaneous tissue planes. This network goes on to drain into five collecting trunks on either side, which in turn drain laterally to the preauricular, infraparotid, submandibular, and submental lymph nodes. Embryonically, the central frontonasal process separates the lateral maxillary processes. As such, there is no contralateral drainage from the upper lip. By contrast, the mandibular processes of the lower lip fuse at midline, allowing numerous crossing anastomoses to occur. Lymphatic drainage to the lower lip therefore occurs to the submental and submandibular nodes bilaterally.

EPIDEMIOLOGY OF CANCER OF THE LIP

The incidence of cancer of the lip varies significantly throughout the world. It is presumed that the variations are due to such factors as race, environment, and personal habits. Overall, cancer of the lip is most commonly observed in the white, male, smoker, over the age of 50, with fair complexion and blue eyes. Thus, it should not be surprising that the highest incidence of lip cancer is reported among the white populations of Canada and Australia. More than 50% of oral cancers in Australians are located on the lip. Lip cancer is rare in the nonwhite populations, as darkly pigmented populations have greater amounts of protective pigment within their vermilion.[1]

Although a number of identified factors are felt to be associated with the development of cancer of the lip, ultraviolet light exposure is by far the greatest contributing factor and is associated with 90% of cases of cancer of the lip. Because the lips are located on the face, they are subjected to greater exposure to ultraviolet light than most of the other areas of the body. Eighty-eight percent to ninety-eight percent of cancers of the lip are found in the vermillion of the lower lip.[2] It is believed that this is caused by outward projection of the lower lip together with a downward angulation that favors direct exposure of the vermilion to overhead sunlight.

On the lower lip, cancer is most frequently found on the exposed vermilion border, arising at the point midway between the oral commissure

and midline. Cancer arises in the commissure of the lip in fewer than 1% of all cases. This rate is roughly proportionate to the actual exposed surface area. Although the upper lip is also outwardly projected, its vermilion surface faces downward, away from direct sunlight. Malignancy arising in the upper lip vermilion constitutes only 2% to 7% of reported cases.[3] When they occur, they most frequently arise near the midline where exposure to direct sunlight may be greatest.

Much of the evidence that has implicated ultraviolet light exposure as etiologic in cancer of the lip is derived from associations that have been made in case series studies and epidemiologic surveys. These studies and surveys show that at least one-third of patients who develop cancer of the lip have outdoor occupations, presumably subjecting them to substantial ultraviolet light exposure. UV radiation is known to produce mutations in DNA. When the body fails to repair these mutations, cancer may form. Regardless of the patient's age, the damaging effects of excessive solar exposure can be expected to be found in patients who develop cancer of the lip. Typical findings include generalized atrophy of the vermilion, loss of elastic fibers, atrophy of adipose tissue, and glandular elements, as well as cellular changes such as hyperkeratosis and atypia. Advanced chronic solar injury to the lip often produces fading of the sharp color contrast normally seen at the mucocutaneous line. Areas of the vermilion that have sustained particularly severe solar injury may display areas of chronic scaling or crusting (actinic cheilitis) that are analogous to actinic keratoses found in sun-damaged skin. In general, patients with cancer of the lip will often be found to have other sun-induced malignancies or premalignant changes in the surrounding vermilion and facial skin.

Exposure to tobacco products has clearly been shown to increase the risk for malignancy particularly within the oral cavity. The relationship between tobacco use and the development of cancer of the lip is less clear. The data so far have been based primarily on information obtained from various case series that have identified a large proportion of patients with cancer of the lip that has regularly used tobacco products. Some case controlled studies, however, have failed to support a distinct relationship of tobacco use with cancer of the vermilion of the lip.[4]

Immunosuppressed populations show a markedly increased risk for development of malignancies. This is particularly true for the development of

squamous cell carcinoma (SCC) of exposed cutaneous surfaces. The increased risk of lip cancer among renal allograft patients on immunosuppressive therapies may be as great as 30-fold.[5] People receiving higher doses of immunosuppressant’s tend to develop more nonmelanoma skin cancers than those on lower doses. These patients are also at an increased risk for development of second primary cancers of the lip.

A variety of other factors have been reported to have some association with the development of cancer of the lip. These include thermal injury, mechanical irritants, trauma, use of alcohol, poor oral hygiene, chemical exposure, influence of various infectious diseases, and prolonged exposure to harsh weather conditions (e.g., wind, cold, dryness). Currently, most of these can be considered only associations, because well-designed and controlled studies to establish a firm causative relationship are lacking.

HISTOLOGY OF THE LIP

Histologically, the lips are covered by three distinct epithelial surfaces. The external skin is keratinizing stratified squamous epithelium with a rich complex of hair follicles, sweat, and sebaceous glands located in the dermis, whereas the lip vermilion is composed of nonkeratinizing stratified squamous epithelium, adapted for external exposure. It remains smooth and dry, due to the paucity of glandular structures in the submucosal layer. Finally, the labial mucosa contains many serous, mucous, and mixed salivary glands in its submucosal layer, keeping the epithelial surface moist. Both the vermilion and labial layers are pink due to the presence of many elongated, vascular connective tissue papillae that project into the epithelial layer.

HISTOPATHOLOGY OF CANCER OF THE LIP

Squamous Cell Carcinoma

More than 90% of cancers of the oral cavity are of squamous cell origin. This cancer first appears as a nonhealing blister, recurrent crusting, lip induration, or an exophytic growth. Clinically, it may be impossible to distinguish

between actinic cheilitis and early squamous cancer, creating a low index of suspicion for biopsy. Three primary subtypes of SCC are identified in SCC of the lip: exophytic, ulcerative, and verrucous.

The exophytic form develops as an area of thickened epithelium that rises up from the surrounding tissue as it develops. With continued growth, there is a tendency for the base of the tumor to take on a saucer shape (**Fig. 12.1**). This base extends only a few millimeters under the epithelium, but externally, the lesion becomes heaped up upon itself extending outwardly a centimeter or more. Laterally, lesions may extend several centimeters with relative little invasion or metastasis.

Figure 12.1. SCC of the lower lip demonstrating exophytic growth.

The ulcerative type of SCC of the lip begins like the exophytic type, that is, as an epithelial thickening or blister. Ulceration usually occurs earlier and, in fact, may be present as a first symptom. As the lesion enlarges, it tends to take on a round or oval shape. Ulcerative carcinomas tend to bleed more easily than other subtypes. Further growth of the lesion tends to be more endophytic, displaying a relatively greater degree of invasion when compared

with a similar-sized exophytic tumor.

Verrucous carcinoma occurs rarely on the lips. It is a unique form of SCC in both its clinical behavior and morphology. Clinically, the lesion develops with a warty surface. Verrucous types are usually broad based and locally invasive. Histologically, they are well differentiated with few malignant features, save for invasion. The margins tend to push, and the integrity of the basement membrane is generally preserved. Biopsy of suspected verrucous carcinoma should include the full thickness of the lesion and a segment of adjacent uninvolved tissue. It is otherwise possible for the diagnosis to be confused with other forms of hyperplasia or hyperkeratosis as well as other SCC forms.

Basal Cell Carcinoma

Basal cell carcinoma is the second most common malignancy of the perioral region, accounting for 1% of cancers occurring in this region. These cancers occur with approximately equal frequency in both the upper and lower lips, but because of the infrequency of other cancers affecting the upper lip, basal cell carcinoma vastly dominate the total percentage of lesions of the upper lip.[6]

There has been considerable debate in the medical literature as to the actual existence of basal cell carcinoma arising from the vermillion portion of the lip. It is argued that the vermillion is involved only by direct extension of a lesion, which began periorally. Indeed, nearly all basal cell carcinomas found involving the vermilion are reported as arising from the cutaneous portion of the lip, at or near the mucocutaneous borer.

Melanoma

Melanoma may arise at the cutaneous, vermilion, or mucosal portions of the lip from melanocytes normally found in those sites. When arising from the lip vermilion, it is considered a mucosal melanoma subtype. Mucosal melanoma is most frequently found in the palatal or gingival mucosa and is found with less frequency in the buccal mucosa and vermilion. It presents as a smooth, black, or blue submucosal nodule that is covered by a thin, intact mucosa. However, before the diagnosis of a mucosal melanoma is accepted, careful screening of other body sites is required to confirm that it does not actually

represent a metastasis from a distant primary melanoma.[2]

PROGNOSTIC FEATURES ASSOCIATED WITH SQUAMOUS CELL CARCINOMA

Overall, carcinoma of the lip carries an excellent prognosis with 5-year survival rates reported at 79%.[2] The fact that most patients present with relatively small and early tumors is obviously an important factor in achieving this outcome. Even so, most of these cancers will have been present in some form for many months after home treatment with antibiotic ointment or skin creams has failed. But this delay is often offset by the fact that these cancers tend to be slow growing, tending toward more superficial lateral growth while remaining confined to the vermilion or immediate submucosal tissues until later in their course. A small percentage of patients will postpone evaluation until later in the course of the disease, by which time the cancer has grown to involve the musculature of the lip.

The size of the primary cancer is one of the most significant factors in predicting prognosis. That when tumors grow to a size larger than 4 cm (T3), the 5-year survival rates drop to 60%. Studies also consistently indicate that the rate of metastases increases with the size of the cancer; regional nodal metastasis has been found to be 5% for T1 lesions, 50% for T2 lesions, and 70% for T3 lesions.[7] When nodal metastasis occurs, 5-year survival is decreased to a reported rate of 40% to 80%.

Eighty percent of patients with perineural spread will have concomitant nodal metastasis. This further decreases 5-year survivor rates to 35%.[8] Although only occurring in 2% of patients, perineural spread requires special consideration for treatment and prognosis. SCC and other malignancies of the lip may invade the mandible by perineural spread along the mental nerve. Invasion of the maxilla can also occur via the infraorbital nerve. Classical clinical symptoms of perineural spread such as tingling, numbness, and pain cannot be relied upon as early indicators. Several cases have been reported with early spread along the inferior alveolar nerve extending to the cranial cavity, despite the lack of symptoms and a relatively small cancer.

MANAGEMENT OF CANCER OF THE LIP

A lesion of the lip that is nonhealing or in any other way suspicious for malignancy should be biopsied to obtain diagnosis. Once histopathologic verification is made, a treatment plan can be formulated. This must include curative management of the primary cancer and for any regional metastasis that may be present. Choice of treatment is made based on the preferences of both physician and patient, taking into account size, location, age, concomitant medical conditions, the likelihood that function of the lip and/or cosmesis can be preserved or restored, the relative ease of treatment delivery, and considerations of time and cost. A variety of therapeutic methods have been successfully employed in the treatment cancers of the lip, to include surgical excision alone, radiation therapy alone (external beam, or brachytherapy), or combined surgical excision and radiation therapy. Most studies have shown that surgery or radiation therapy produce similar cure and cosmetic results for small tumors.[9] These types of therapy are discussed below.

Radiation Therapy

Radiation therapy may consist of brachytherapy, external beam, or a combination of the two. Brachytherapy is a method of radiation therapy that employs the use of interstitial placement of radioactive implants. These are placed directly into the cancer and are carefully positioned to give a planned therapeutic dose to all parts of the cancer. Current practice favors the use of lower-energy radioisotopes such as iridium-192. First, hollow, nonradioactive needles are placed and checked radiographically for proper placement. The radioactive source is then placed. Placement of multiple needles during several treatment sessions may be required. It is important that accurate spacing of the needles be performed at each session, as overlapping of the radiation points creates problems of uneven distribution of the radiation. Brachytherapy has a reported local recurrence-free survival of 93% following treatment.[9] However, due to the complexities associated with brachytherapy, it has largely given way to external radiation, which is more versatile and controllable.

External beam radiation has become the preferred form of radiation therapy when treating lip cancers, particularly for tumors smaller than 1.5 cm. Treatment dosages typically vary from 5,000 to 7,000 cGy depending on the extent of the tumor and are generally fractionated over the course of 6 weeks.[7] Smaller daily fraction doses that are spread over a longer period generally result in fewer adverse long-term tissue changes, such as atrophy, fibrosis, and telangiectasia.

Treatment with either external beam or brachytherapy can be a very effective tool in the management of small (T1–T2) cancers of the lip. Radiation should also be considered to treat cancers of the lip that are relatively superficial but involve an area encompassing more than one-third of the lip. Cancers that involve the commissure and significant portions of either lip and cancers that are recurrent are also candidates for radiation therapy. The use of radiation requires that consideration be given when patients will return to high levels of sun exposure as the treated areas are more susceptible to further UV damage. Radiation may be an option for those patients who either refuse or otherwise cannot undergo surgery. Use of radiation requires that consideration be given when patients will return to high levels of sun exposure as the treated areas are more susceptible to further UV damage. Radiation therapy is frankly not appropriate for primary treatment of cancers with deep infiltration, perineural spread, or erosion of the mandible. Radiation is also not appropriate for use in large cancers where extensive tissue destruction has occurred, resulting in an anatomic deficit of the lip that will require surgical reconstruction.

The use of adjuvant radiation therapy has been shown to decrease recurrence rates following cases of close or positive margins following surgical excision. Cancers of the lip that are deeply invasive, especially those that involve the mandible or mental nerve or that have metastasized to regional lymph nodes, must be considered as a serious situation that require aggressive treatment. Surgical resection is usually necessary for curative treatment, but adjuvant treatment with radiation therapy may be considered for the treatment of locally advanced lip cancers (T4 and many T3).[7] Radiation therapy should be given serious consideration when cancer is recurrent, when there have been positive surgical margins, when there is perineural spread or extracapsular spread (ECS) of nodal metastases, or when tumors are poorly differentiated.

Surgery

Surgical excision, with histologic confirmation of tumor-free margins, is the primary preferred modality treatment of cancer of the lip. It allows for rapid treatment with immediate reconstruction of the lip. Surgery also allows for the taking of multiple tissue specimens from which the full scope of favorable or unfavorable histopathologic features can be assessed. Unlike radiation therapy, where negative effects of ionizing radiation are imposed on healthy tissues, the adjacent uninvolved tissues of the lip are affected only as mandated by acceptable surgical practice.

Any surgical procedure chosen for the management of cancer of the lip must focus on complete en bloc removal of the tumor with additional normal tissue at all margins of the resection. Anything less than this is oncologically insufficient and would likely result in treatment failure. Most surgical resections for primary cancer of the vermilion require some form of full-thickness excision of the involved portion of the lip. The most frequently selected configurations of excision are V shaped, W shaped, or rectangular. The converging lines of a V or a W excision must not be allowed to come too close to the lateral margins of the tumor. Cosmetically, it is ideal if the unit of lip resection can be confined to the borders of the anatomic lip unit, that is, mental crease or melolabial crease. Skin incisions should be planned to minimize the secondary deformity and facilitate reconstruction, but not at the expense of achieving margins negative for disease.

Effective surgical treatment involves not only eradication of the tumor itself but all of its microscopic extensions as well. Careful attention to the microscopic extensions leads to better local control of malignancy and, therefore, should be a primary goal of surgical treatment of lip cancer. Unfortunately, what constitutes an adequate margin to insure the removal of microscopic extension remains controversial. Detailed studies comparing the adequacy of various margin sizes during excision of cancer of the lip have not been performed. It is generally accepted, however, that a margin of 5 to 10 mm is adequate. Even when such margins are maintained, studies show that up to a 13% risk remains and that the final surgical specimen will display positive margins.[10] Thus, it is recommended that intraoperative frozen sectioning be performed with re-excision until clear margins are obtained.

Intraoperative frozen sections of the mental or infraorbital nerve may also

be necessary. If cancer cells are present at the infraorbital foramen, segmental resection of the maxillary bone may be indicated. The revised distal nerve stump is then biopsied to determine if further resection and/or other treatments are needed. Treatment of cancer, which encroaches on the alveolar process or the outer cortex of the mandible, should include a marginal mandibulectomy. However, actual invasion of the mandible requires generous segmental resection.

Management of the Neck

The management of regional lymph nodes in patients with cancer of the lip currently remains controversial. At initial presentation, SCC of the lip is associated with 15% rate of cervical metastasis,[11] the lowest among the subsites of the oral cavity. However, an additional 13% of patients will later develop cervical metastasis. The management of regional lymph nodes in patients with lip carcinoma, therefore, requires a thorough understanding of the patterns of lymphatic drainage system for comprehensive tumor assessment and effective treatment planning.

Metastasis of SCC and most other malignant tumors of the lip are almost always initially to the adjacent or regional lymph nodes, which reflects the known patterns of lymphatic drainage from the perioral region. Cervical metastasis from both the upper and lower lips occurs in a predictive orderly fashion. Cancers occurring in the upper lip metastasize first to the preauricular or infraparotid lymph nodes, followed by the submandibular nodes. Cancers of the lower lip tend to spread to the submental and submandibular nodes first, followed by the upper deep cervical nodes. Due to embryologic fusion planes, contralateral or bilateral metastases may develop in patients with lower lip cancers.

In patients with clinically palpable metastatic lymph nodes, cervical lymphadenectomy is appropriate. When metastasis is present in the parotid lymph nodes, a parotidectomy, with preservation of the facial nerve, should be done in conjunction with neck dissection. If metastases are confined to level I, the risk of level IV or V involvement is extremely low, and a supraomohyoid neck dissection is adequate. Ipsilateral neck dissection is sufficient if postoperative radiation is planned, to include the contralateral N0 neck. Such a strategy preserves the contralateral facial artery, which in turn will improve blood supply to local reconstructive flaps. Postoperative

radiation therapy is recommended for stage III or IV disease, recurrence, and ECS.

Generally accepted medical practice at this time dictates that neck dissection should be undertaken in oral cancers carrying a significant risk for occult cervical metastasis. T2 cancer of the lip, for example, carry an approximate 50% metastasis rate. On the other hand, T1 lesions carry a metastases rate of only 5%,[11] and therefore, neck dissection might not be mandated in the absence of other features. The presence of such aggressive features such as recurrence, perineural invasion, and poorly differentiated histology requires evaluation and consideration before a decision not to perform a neck decision is made. Bilateral supraomohyoid dissection should be considered when high-risk tumors involve the central portion of the lower lip. The functional and cosmetic consequences of supraomohyoid dissection can be kept to a minimum. If bilateral metastases are found, full bilateral neck dissection is indicated, normally with an attempt to preserve the internal jugular vein on at least one side. With cancer of the upper lip, an ipsilateral dissection of the superficial or lateral lobe of the parotid gland may also be indicated.

Adjuvant radiotherapy has been used for elective treatment of the neck in selected high-risk patients. It is often advisable following neck dissection with high-risk features, such as in the identification of multiple nodes or nodes with ECS. It should not, however, be considered a replacement for neck dissection because 54% of patients treated prophylactically with neck radiotherapy will go on to develop neck metastases within 2 years of treatment.[8]

The use of sentinel lymph node biopsy in the treatment of lip cancer has been reported, with promising results in a few small pilot studies.[12] As in other oral cavity sites, the lip readily lends itself to the identification of lymph node metastasis with this technique. Patients with large or poorly differentiated lip cancers are most likely the ones to benefit from this technique.

RECURRENCE

Recurrent cancer is most likely to present in the primary field, as regional lymphatic metastasis, or both. Recurrence at distant sites is extremely rare

once the primary has been locally and regionally controlled. Local recurrence of cancer of the lip following initial treatment with surgery or radiation ranges from ~5% to 25% overall and is the most common form of treatment failure. As would be expected, the rate of local recurrence tends to increase proportionately with the size of the original cancer. The specific involved subsite has been associated with varied chances for local recurrence. The highest incidence has been noted with cancer of the commissure, and the lowest with cancer of the lower lip.

Recurrence of cancer of the lip is best managed with aggressive surgical resection, incorporating the use of intraoperative margin assessment to assure complete clearance of the tumor. Because up to one-fourth of patients presenting with cancer of the lip will present with subsequent cervical lymph node metastases, strong consideration to elective neck dissection should be considered. Except in cases of bone involvement, local recurrences of cancer of the lip should not be expected in 60% to 85% of cases where appropriate surgical management techniques have been employed.[12] The salvage rate is considerably lower if the local recurrence is associated with cervical lymph node metastases.

RECONSTRUCTION OF THE LIP

The treatment of cancer of the lip can result in a variety of defects, ranging from small superficial deformities treatable with primary closure to larger deformities requiring free tissue transfer. Regardless, the goals of reconstruction remain to restore oral competence, maintain oral opening, and achieve an aesthetic result that approaches normal appearance. For adequate function of the lip, it is best if continuity of the orbicularis muscle sphincter can be restored in some fashion, particularly in the lower lip. Aesthetically, it is best if all incisions can be placed along the peripheral borders of the lip unit (mental and melolabial creases) or parallel with the lines of relaxed skin tension of the lips.

When approaching reconstruction of the lip, one should first assess the lesion and attempt to determine the amount of mucosa, muscle, and skin that will be required. Accurate assessment of three-dimensional tissue loss and required volume for reconstruction is paramount to the success of reconstruction of the lip. The effect of lip defects upon facial appearance will

be exaggerated as a result of the displacement of wound edges by the lateral pull of the facial muscles. These defects can be divided into vermilion-only defects, defects that involve less than one-third of the total lip length, defects that involve between one- and two-thirds of the total length of the lip, and finally total lip defects.13

Vermilionectomy or “lip shave” is an indicated treatment of carcinoma in situ and actinic cheilitis. Defects isolated to the vermilion may be approached with healing by secondary intention, direct primary wound closure, and mucosal advancement flaps. Healing by secondary intention is appropriate for small superficial defects confined to the vermilion. Small defects, which do not distort the remaining vermilion or lip contour, are amenable to primary closure, although this technique may lead to unsightly bunching of the remaining vermilion. More commonly, the resulting defect is large enough to require an advancement flap of the labial mucosa. Dissection for this flap is done in the submucosal plane toward the gingival buccal sulcus. Two back cuts at each commissure toward the gingival buccal may be required to facilitate advancement. Neural and vascular connections can be preserved and stretched forward with the advancing flap, optimizing sensory function for the restored vermilion. Occasionally, the mucosal flap is of insufficient bulk to accomplish a desired result. In such cases, a pedicled orbicularis oris can be rotated into the base of the defect to improve cosmesis.

Generally, defects involving less than one-third of the horizontal length of the lip can be closed primarily. The length of the lower lip horizontally measures 7 to 7.5 cm allowing primary closure of a defect of up to 2.5 cm. The lip lends itself well to primary closure due to its remarkable tolerance for stretching. Small cutaneous defects can usually be closed in routine fashion with fusiform closure, whereas full-thickness defects benefit from wedge-shaped closure (**Fig. 12.2**). The long axis of either closure should be oriented parallel with relaxed skin tension lines leading to a more obliquely oriented flap in the lateral portions of the lip. M-plasty is often helpful to allow avoidance of crossing subunit borders and prevent alar or vermilion distortion. For full-thickness defects, the mucosa is reapproximated first, followed by the muscle layer, and finally the skin, with an emphasis on precise reapproximation of the vermillion. Re-establishment of the vermilion border is essential because even minute misalignment is easily recognizable.

can be closed primarily. **A:** Lesion involving 25% of the lower lip. **B:** Converted to a wedge shape to aid in closure. **C:** Appearance following wound closure. **D:** Result 4 months following wedge excision and primary closure.

The cheeks and, less commonly, the chin are the natural sites to obtain additional tissue for lip reconstruction. A large variety of techniques have been described that transfer tissue from these areas into the lip. The most commonly chosen method involves transposition of skin and subcutaneous tissue from the melolabial fold, using a pedicle that is either superiorly or inferiorly based. The melolabial flap is designed so that the donor site, as it is closed, is well hidden within the melolabial crease. The use of a superiorly based pedicle tends to cause greater cosmetic detraction because it disrupts the medial portion of the melolabial crease—a situation that can be improved later by placing an incision across the pedicle in a fashion that restores the full line of the crease. Melolabial transposition may be used for cutaneous resurfacing of the lip and in some situations for full-thickness lip deficits (**Fig. 12.3**). It is not capable of truly restoring the orbicularis muscle but rather relies on a certain degree of tightness. It is therefore less ideal in full-thickness reconstruction of the lower lip. Surfacing for the underside of these flaps may be done either with a second flap, including the skin or oral mucosa, or with application of a graft of skin or mucosa. A skin graft can be buried beneath the cheek flap in a "delayed" fashion for 2 to 3 weeks, allowing the combined tissues to be later transferred as a composite. Defects greater than one-third, but less than two-thirds of the horizontal lip, are ideally reconstructed with pedicled or tissue flap rotated from the opposing lip. In general, this corresponds to defects between 2.5 and 4.5 cm in length. The majority of the reconstructions of this size are achieved with the aid of an Abbe cross-lip flap, an Estlander cross-lip flap, or a Karapandzic flap.

Figure 12.3. Melolabial transposition may be used for cutaneous resurfacing of the lip. **A:** Intraoperative design of melolabial transposition flap. **B:** Partial-thickness island of tissue rotated to fill the defect. **C:** Appearance following flap inset and closure.

Both Abbe and Estlander flaps use full-thickness tissue transferred from opposing lips pedicled on the labial artery. They differ in that the Abbe flap is used for defects medial to the oral commissure. An Abbe flap is usually designed in a wedge shape and is kept viable through a small pedicle containing the labial artery, which extends across the oral commission (**Fig. 12.4**). The pedicle is released during a second procedure 2 to 3 weeks later (**Fig. 12.5**). In a single-stage procedure, donor tissue is rotated around the oral commissure to the opposing lip (**Fig. 12.6**). This technique typically results in blunting of the commissure angle and may require a commissuroplasty at a later date.

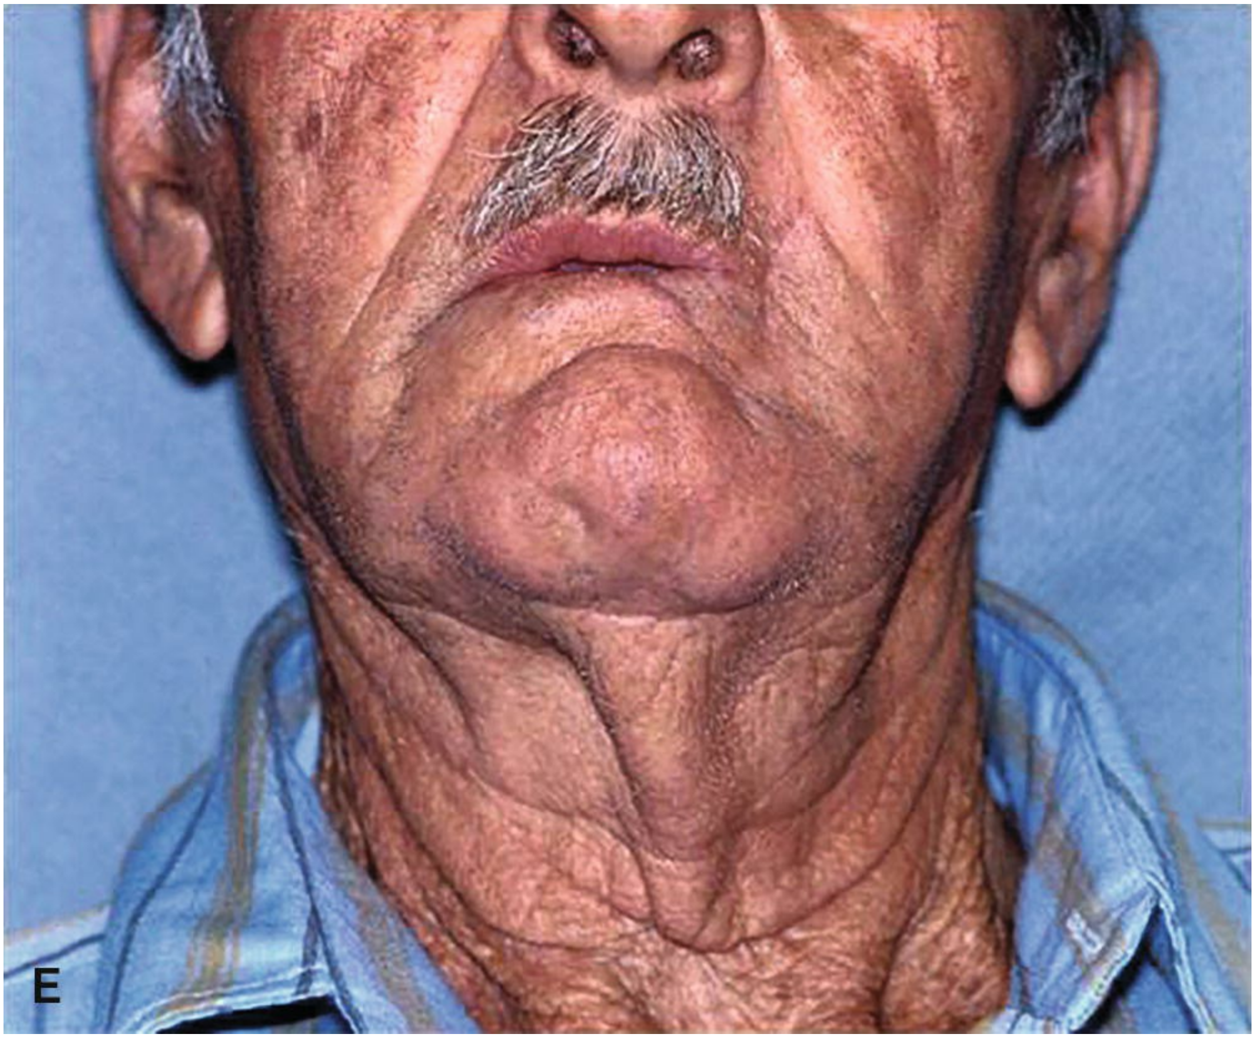

Figure 12.6. Estlander cross-lip flap utilized for closure of lateral lip defects. **A:** The anticipated resection is marked out. **B:** Defect involving the lateral third of the lip is shown with designed Estlander flap. **C:** Tissue from the upper lip rotated inferiorly while maintaining small pedicle containing the labial artery. **D:** Estlander flap following onset. **E:** Long-term results following reconstruction win an Estlander flap.

Traditionally, both flaps are designed with the same height as the defect and half the width. This results in a decrease in length of the donating lip, proportional to the increase of the received lip. It is particularly important to ensure that the full vertical height of the defect is replaced with the transposed tissue. Asymmetry of the horizontal length is easily overlooked, but even minor elevations in vertical height draws attention.

Although originally described with a wedge shape, cross-lip flaps may be

also designed in a rectangular or M shape when desired. Both Abbe and Estlander flaps also lend well to combinations with other forms of reconstruction, and multiple cross-lip flaps may be used simultaneously. The biggest drawback to the use of cross-lip flaps is the total denervation that occurs as they are transferred; however, some motor and sensory function will generally redevelop over the course of several months to a year.

The Karapandzic flap is a circumoral advancement technique that preserves the vascularity, sensation, and the function of the remaining orbicularis oris muscle. It is designed by making circumoral skin incisions around the peripheral margins of the lip, starting, when possible, within the mental or melolabial creases (**Fig. 12.7**). As the incisions approach the vicinity of the oral commissure, however, the Karapandzic flap should be extended out to the surrounding cheek because the melolabial crease closely approximates the commissure. The muscle is then released as necessary to allow for advancement by spreading parallel to the muscle fibers (**Fig. 12.8**). The integrity of the neurovascular supply and muscle fibers of the orbicularis oris muscle is thereby preserved, which results in good functional and aesthetic outcomes. Blunting of the oral commissure does occur. Because it occurs bilaterally, however, it is usually of little significance. However, the degree of resulting microstomia created can be limiting, especially in patients who wear dentures.

Figure 12.8. Preservation of muscle fibers and neurovascular supply while performing Karapandzic flap.

In the mid-19th century, Bernard and von Burow separately described a method for reconstruction of full-thickness defects, which are larger than two-third of the lip. It involves direct medial advancement of tissue from the cheeks, which is facilitated by removal of strategically placed triangles of skin that allow for a more even redistribution of the facial tissues. This concept of reconstruction is often referred to as “Bernard cheiloplasty,” and von Burow’s eponymous credit comes with the term “Burow triangle.” The procedure was originally done with full-thickness incisions but was later modified to minimize disruption of the facial musculature. Overall functional and cosmetic results with this reconstruction are typically only fair because satisfactory restoration of the orbicularis sphincter is often difficult to achieve.

Several modifications of the Bernard cheiloplasty have been described in attempt to produce more favorable scars and better muscle function. Most notably, Webster's modification (**Fig. 12.9**) moved the Burow triangles laterally, resulting in a scar that lies entirely within the melolabial fold. The excised triangles are partial thickness only, thereby preserving the neurovascular supply to the orbicularis oris and buccinators muscles. This technique can be used to restore near-total loss of the lip and may be adapted for reconstruction of either the upper or the lower lip. Webster made a further refinement for upper lip reconstruction, with the perialar crescent advancement flap (**Fig. 12.10**). This flap uses incisions placed within the alar crease and includes the removal of crescent-shaped areas of cheek tissue adjacent to the alae. This prevents deformity of the alar base, lip, and oral commissure by preserving the alar crease. The perialar crescentic advancement flap works well for defects of the upper cutaneous lip, especially those located immediately inferior to the nasal sill.

Reconstruction of total defects of the lip is a challenging problem. Not only do the internal and external lining have to be replaced, but oral competence needs to be restored. In such cases, the rotation of large amounts of local tissues may lead to further facial disfigurement, and microstomia. These issues, however, can be overcome with microvascular reconstruction, which allows for single-stage reconstruction of such defects that include surrounding affected areas such as the cheek or chin. Additionally, if there is bone involvement, the mandibular arch can be reconstructed with the use of an osseofasciocutaneous flap.

The most commonly used microvascular free tissue transfer is the radial forearm flap. The radial forearm flap was initially described by Sakai et al. in

1989.[14] For reconstruction of the lip, it carries the advantages of being relatively easy to harvest, has a long pedicle length, and provides a good color match and pliable skin paddle (**Fig. 12.11**). The radial forearm free flap is based on the radial artery with its venae comitantes. The proximity of the facial vessels to the resection makes them ideal for use in revascularization. They are of adequate caliber and readily accessible at the angle of the mandible. For an anastomosis at this level, a pedicle length of approximately 8 cm should be sought.[15] It can also be harvested with the lateral antebrachial cutaneous nerve, providing sensation to the reconstructed site. This addition can play an especially important role in patient rehabilitation as the sensation of drooling aids in the rehabilitation of a competent oral stoma.

Figure 12.11. Free flap reconstruction aids in reconstruction of total lip defects. **A:** SCC involving the entire lip. **B:** Anticipated area of resection. **C:** Skin markings for radial forearm free flap. **D:** Radial forearm free flap pedicled to radial artery, venae comitantes, and cephalic vein. **E:** Radial forearm free flap following inset for reconstruction of total lip defect. **F:** Patient 5 weeks following radial forearm free flap reconstruction of total lower lip defect. **G:** Postoperative demonstration of mouth opening following radial forearm free flap.

Restoration of oral competence must be especially addressed when considering reconstruction of the lower lip. When resection has disrupted the

central mimetic musculature or distal branches of the facial nerve, the reconstructed lip should be supported with a static or dynamic sling.[15] This is achieved with the use of the composite radial forearm–palmaris longus muscle flap. The function of the palmaris longus is to flex the wrist, which is duplicated by the flexi carpi muscle group, allowing for harvest of this tendon with little added morbidity. The folded radial forearm skin provides both external and mucosal resurfacing, whereas the tendon may be suspended to the modiolus providing support to the lip. Such a technique supplies static suspension of the lower lip improving cosmesis, but does not provide adequate oral competence during motion when used for lower lip reconstruction. To overcome these deficits, various alterations have been described. In an attempt to achieve dynamic function, Jeng et al.[16] modified the radial forearm–palmaris longus flap to include the passing of both ends of the palmaris longus tendon intramuscularly through the modiolus bilaterally. The palmaris longus is then anchored to the ends to the remaining orbicularis muscle of the upper lip near the philtral columns. This addition mimics the function of the horizontal fibers of the orbicularis oris and hence restores some integrity of an intact oral sphincter. Dynamic slings can also be incorporated into free flap reconstructions to improve the degree of voluntary control of commissure position and lip tone. Techniques incorporating both a free flap for lip resurfacing and a simultaneous temporalis sling for elevation have been described for this purpose.[17]

Further dynamic restoration is achievable with the incorporation of reinnervated muscle to replace the resected orbicularis oris, which is most commonly performed with the gracilis muscle flap.[18] This flap has been used extensively in the dynamic reconstruction of facial paralysis, and its ability to regain dynamic function after transfer is well documented. The gracilis flap is based on the adductor vessels, branches of the profunda femoris, with motor nerve input from the anterior branch of the obturator nerve. The pedicle of the caliber and length are sufficient, but often less than that of the radial forearm free flap. The lack of a skin paddle will often require free flap reconstruction for mucosal lining.

SUMMARY

Cancer of the lip is often encountered in practice. In most cases, it is easily

treated with surgical resection and reconstruction. When the cancer advanced locally, thought must be given to the reconstruction so that the rehabilitation of the patient is optimal. With all the tools available in the armamentarium of the reconstructive surgeon, good functional outcomes should be possible in the majority of cases.

In some patients with poor prognostic indicators, ancillary treatment with radiation therapy should be considered.

13 Squamous Cell Cancer of the Oral Cavity

Laureano A. Giraldez-Rodriguez Brett Miles Eric M. Genden

EPIDEMIOLOGY

Cancer of the oral cavity represents ~30% of all cancers of the head and neck. Squamous cell carcinoma (SCC) constitutes 90% of all oral malignancies whereas the remaining 10% include cancer arising in minor salivary glands, and odontogenic cancers, and sarcomas.[1] The incidence of oral carcinoma is ~6 cancers per 100,000 in Americans with a male-to-female ratio of 2.2:1. In North America, this represents ~1.4% of all new malignancies and 0.6% of all cancer-related mortality. Based on the most recent Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute data, the overall 5-year survival for cancer of the oral cavity is 62.2% (2003 to 2009) compared to 53% two decades earlier (1975 to 1979). The average age of diagnosis is 60 years and the vast majority of patients (>95%) are older than 40 years (http://seer.cancer.gov). Although these data are important, they can be misleading because the cancer of the oral cavity encompasses diverse anatomy from the lips to the tonsillar pillars. Although the lips and the oral tongue are anatomically close, cancer in these regions of the oral cavity may behave differently. For example, carcinoma of the lip behaves very differently from carcinoma of the lateral tongue; and carcinoma of the lateral tongue behaves differently from cancers of the hard palate. The lip, the tongue, and the hard palate are anatomically included within the *oral cavity* site, yet malignancy in each of these subsites behaves very differently. This must be considered as one interprets the data because the majority of data are the results of studies inclusive of patients across the various oral cavity subsites.

ETIOLOGY

The risk factors for developing SCC of the oral cavity in North America and Europe are tobacco and alcohol consumption. Independently, they are associated with a dose-dependent risk of developing oral SCC. Cigarettes contain over 60 carcinogens.[2] Despite a decline in the rate of cigarette smoking since the release of the first US Surgeon General’s Report on Smoking and Health in 1964, 21.6% of men and 16.5% of women continue to use tobacco; ~80% of tobacco users are daily smokers.

Alcohol is another common carcinogen contributing to mucosal irritation and increased cell permeability. Excessive alcohol consumption is associated with vitamin and nutritional deficiencies, which independently contribute to oral carcinogenesis. Combined, these toxins have synergistic effects and translate to a relative risk of developing oral SCC of between 7.2 and 35.[3–5] Smokeless tobacco is associated with a twofold increased risk of oral SCC, is estimated to be used by 6% of the US adult male population, and is significantly more common in the southern United States where the rate raises to 30%.[6] In areas where chewing betel or areca nut is more commonplace, such as South Asia, this behavior is associated with a sevenfold increased risk of developing oral SCC.[7] The practice of reverse smoking, commonly practiced in India, further contributes to an increased rate of oral cavity SCC, which constitutes an impressive 25% of all cancers in that region.[8] Less well-studied risk factors include poor oral hygiene and ill-fitting dentures; however, these conditions have both been recognized as independent risk factors. The proposed etiology is that mechanical irritation produces a cascade of inflammatory mediators that contribute to the development of dysplasia and carcinoma.[9]

Over the past three decades, there has been a rise in human papillomavirus (HPV)-associated cancer of the oropharynx, oropharyngeal squamous cell carcinoma (OPSCC).[10] It is suggested that this trend may correspond with changing sexual behaviors and is consistent with the mode of transmission of HPV and the relative increased rate in males versus females.[11] The correlation between HPV and cancer of the oral cavity is less clear. Some reports demonstrate that up to 24% of oral cavity carcinomas are associated with HPV; however, most literature suggests a significantly lower association.[12,13] There remains a significant proportion of oral squamous cell

carcinoma (OSCC) that cannot be attributed to the traditional risk factors of tobacco or alcohol use, particularly among women and young patients.[5] Recent epidemiologic studies have identified an increasing incidence of SCC of the oral tongue in younger patients and found that gene-specific mutation and copy number alteration frequencies were similar between young and old patients. This observation supports the recent developments illucidating the significant role that genetic instability and genetic susceptibility play in the etiology of oral SCC and the poorly understood functional impact of smoking on carcinogenesis.[14–16]

ANATOMY

The anterior border of the oral cavity is at the junction of the skin and vermilion border of the lip.[16,17] Posteriorly, the oral cavity is limited by the junction of the hard and soft palates superiorly and the circumvallate papilla inferiorly. The anterior tonsillar pillars define the posterior lateral aspects of the oral cavity. The oral cavity is composed of the oral cavity gingiva, lip, hard palate, oral tongue, floor of the mouth, retromolar trigone, and buccal mucosa (Fig. 13.1). In addition, the underlying mandible and maxilla are often included in the anatomy of the oral cavity. The oral cavity is lined by squamous cell epithelium populated by minor salivary glands. Although minor salivary glands can be demonstrated throughout the mucosa of the oral cavity, they are most concentrated within the hard and soft palate. For this reason, minor salivary gland tumors exist most commonly within these sites in the oral cavity.

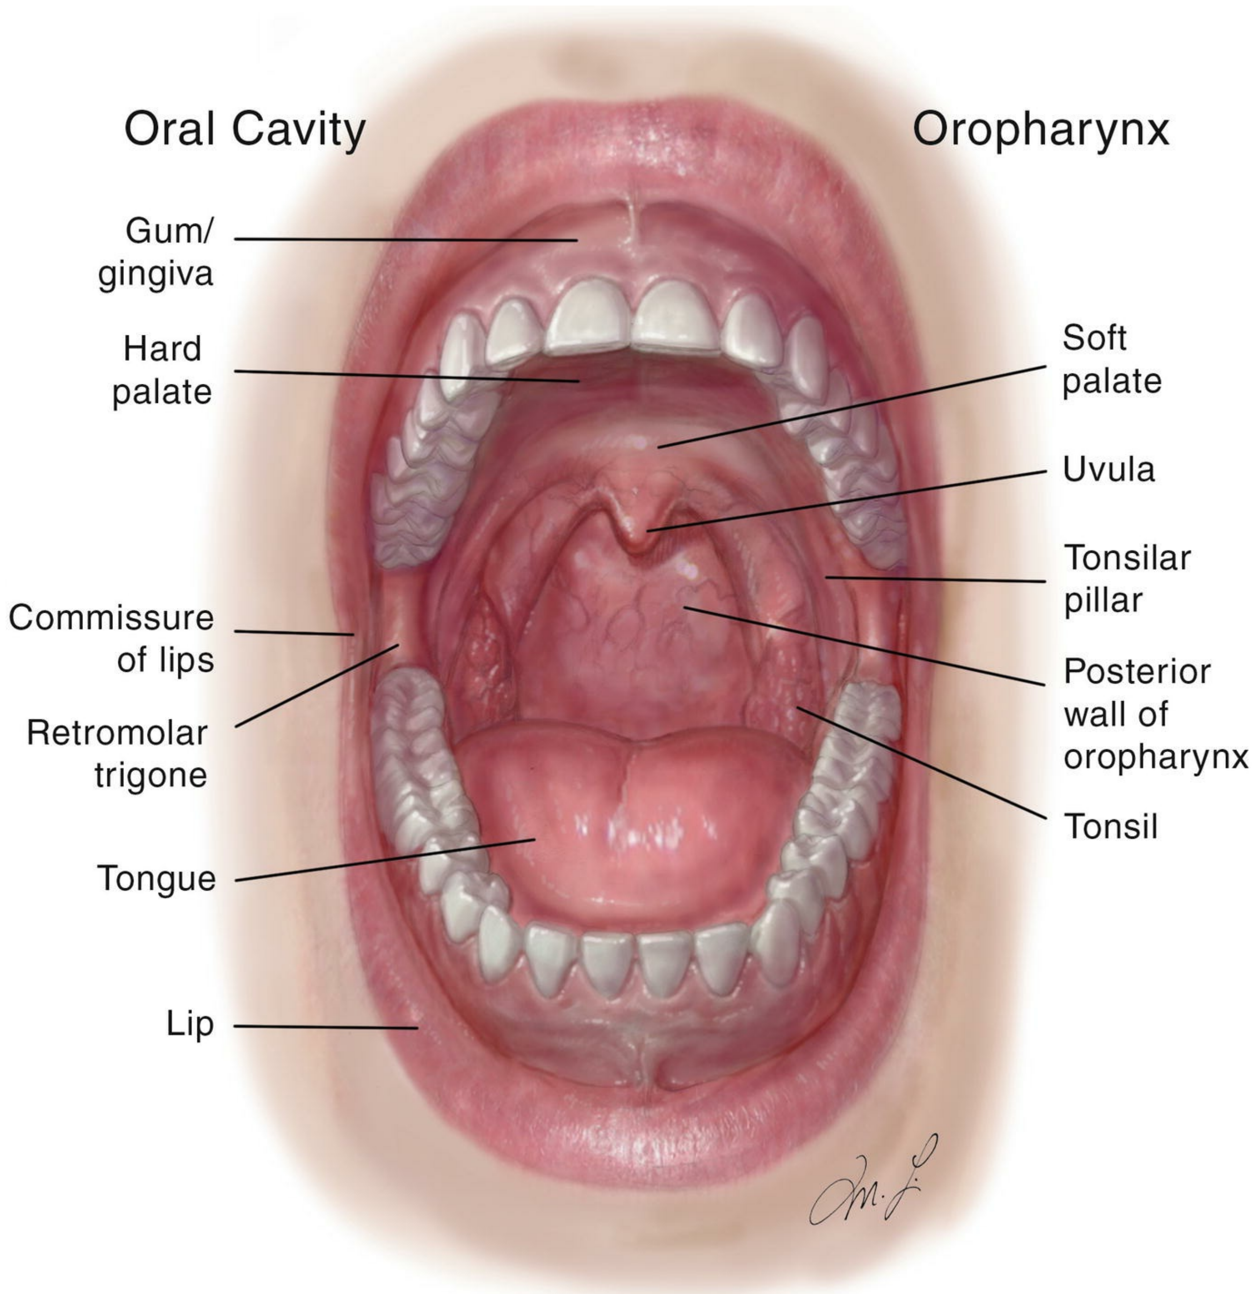

Figure 13.1. Anatomy of the oral cavity. The anterior border of the oral cavity is at the junction of the skin and vermilion border of the lip. Posteriorly, the oral cavity is limited by the junction of the hard and soft palates superiorly and the circumvallate papilla inferiorly. The anterior tonsillar pillars define the posterior lateral aspects of the oral cavity. The oral cavity is composed of the oral cavity gingiva, the lip, the hard palate, the oral tongue, the floor of the mouth, the retromolar trigone, and the buccal mucosa.

In addition, the mandibular and maxillary alveoli are included in the oral cavity. The retromolar trigone, which is an area located in the posterior oral cavity posterior to the last mandible tooth, is a common site for cancer of the oral cavity. The overlying periosteum is particularly thin in the area of the retromolar trigone, making invasion of the cortex a common occurrence. The floor of the mouth extends from the inner margin of the inferior alveolus to the ventral surface of the oral tongue. The structures of the floor of the mouth are supported by mylohyoid, geniohyoid, and genioglossus musculature. These muscles insert along the mylohyoid line found on the medial aspect of the mandible. The sublingual structures lie cranial to the mylohyoid line, whereas the submandibular structures lie below the mylohyoid line. The oral tongue located within the floor of the mouth is lined with squamous epithelium and fungiform, filiform, and circumvallate papilla. The intrinsic muscles responsible for swallowing and the articulation of speech generate the complex movement of the tongue. Several branches of the external carotid artery, including the facial and lingual arteries, provide the blood supply of the oral cavity structures.

The pattern of lymphatic drainage of the oral cavity has been well established in the literature.[18–20] The presence of cervical lymph node metastasis has been repeatedly correlated with the size, depth of invasion, location, and the degree of differentiation of the primary tumor. In general, the frequency of lymph node metastasis increases with the size and depth of penetration of the lesion. Additionally, the more posteriorly a primary is located, the higher the risk of lymphatic spread to lower echelon nodal basins (level III to IV). The lymphatic spread of oral SCC generally occurs in an orderly manner, involving first levels I to II, followed by levels II to III, and finally the inferior cervical lymph nodes, level IV. However, "skip" metastases have been reported, wherein metastatic spread from oral cavity structures to lymph nodes in level IV of the neck can occur in the absence of nodal involvement in levels I, II, and III.

The pattern of lymphatic spread often follows the vascular territory of the region in which the primary cancer is located. The lip, cheek, and anterior gingiva drain to submandibular and submental lymph node basins (level I to II) and occasionally the inferior parotid nodal basin (Fig. 13.2A–C). The posterior gingiva and palate drain to the internal jugular chain and lateral retropharyngeal nodes (level II to IV). Lymphatic drainage for the tongue and

floor of the mouth includes the internal jugular, subdigastric, omohyoid, submandibular, and submental nodal basins (level I to III). The deep lymphatic network for the oral tongue consists of anterior, lateral, and central lymphatic pathways. The anterior pathway drains the tip of the oral tongue and primarily drains to level III (or less commonly level I to II). The lateral group drains the lateral one-third of the dorsum of the tongue from the tip to the circumvallate papillae to submandibular, and internal jugular nodal basins and occasionally the submental node basin (level I to III). The central pathway drains the central two-thirds of the tongue. These vessels drain to the submental region (level I) or the upper cervical chain nodal basin via the sublingual nodes (level III).[21] Primary cancers, which approach midline, often drain to bilateral nodal basins. This is especially true for cancers of the tongue and floor of the mouth as there exists significant lymphatic crossover in this region.[22,23]

C

Figure 13.2. A–C: The lymphatic spread of oral SCC generally occurs in an

orderly manner, involving first levels I to II, followed by levels II to III, and finally the lower cervical lymph nodes, level IV. The pattern of lymphatic spread often follows the vascular territory of the region in which the primary tumor is located. The anterior pathway drains the tip of the oral tongue and primarily drains to level III (or less commonly levels I to II). The lateral group drains the lateral one-third of the dorsum of the tongue from the tip to the circumvallate papillae to submandibular, and internal jugular nodal basins and occasionally the submental node basin (level I to III).

Premalignant Lesions of the Oral Cavity

Unlike other head and neck sites, the oral cavity can be easily examined and is therefore amenable to screening protocols to identify early cancers. Awareness of the common signs and symptoms of premalignant and malignant oral lesions is paramount to the early detection and recognition of these lesions. Pain is the presenting symptom in 50% to 60% of malignant lesions and should therefore prompt further evaluation with a biopsy, excision, or close follow-up, especially in the setting of pain that persists.[24] Patients with symptomatic lesions often present to primary care physician or dental health professional. In contrast, asymptomatic lesions can grow undetected. This underscores the importance of screening. The American Dental Association has enacted a screening program that has proven successful in identifying oral premalignancies and early cancers.

It is often difficult to differentiate premalignant lesions from early invasive cancers. Invasive SCC often develops as a result of an evolution of molecular transformations in suppressor and/or promoter genes.[24] The evolution, however, does not always follow a prescribed pathway resulting in an invasive carcinoma. Premalignant lesions of the oral cavity may be detected at any point in this progression. Some may be actively progressing toward malignancy, whereas others may remain in a state of abeyance, neither progressing nor regressing. Suspicious findings on examination include a nonhealing or indurated ulcer or a mucosal lesion with a palpable firm mass.

Leukoplakia

Leukoplakia is a descriptive term, not a pathologic diagnosis. This

descriptive terminology refers to white patches on the mucosal surface that histologically correlate with hyperkeratosis, acanthosis, and inflammatory cell changes. These changes may be premalignant or associated with atypia. Tobacco is the most commonly associated risk factor for developing leukoplakia. In a large case series of clinically diagnosed leukoplakia reviewed microscopically, only 7.6% had severe dysplasia or invasive carcinoma.[25] Over a 10-year period, leukoplakia has been reported to progress to carcinoma in 0.9% to 17% of cases.[26] Leukoplakia may also occur without a preexisting environmental exposure. In either case, the presence of leukoplakia often warrants a biopsy, with smaller lesions undergoing an excisional biopsy. Some suggest observation of a small confluent leukoplakia lesion if there is no evidence of progression, ulceration, or change in character. Some tobacco-related keratosis present as a very thin confluent white patch over the mucosal surface in direct contact with the tobacco. These lesions are less suspicious for transformation with cessation of tobacco use. They should be followed up closely with biopsy reserved for transforming lesions.

Erythroplakia

Erythroplakia, defined as a flat red patch, is a more concerning lesion than leukoplakia and is more likely associated with atypia or progression to carcinoma. The homogeneous type of oral erythroplakia has been correlated with a 51% rate of invasive carcinoma and a 40% rate of carcinoma in situ.[27] Therefore, these lesions should be promptly biopsied and appropriately managed. Erythroplakia may present as an isolated lesion or in the presence of leukoplakia. In some cases, leukoplakia may progress to erythroplakia as the lesion develops into an invasive carcinoma.

Submucosal Fibrosis

Oral submucosal fibrosis is a chronic condition with premalignant potential that predominately affects patients from Southeast Asia with a significant history of betel quid chewing. Histologically, submucosal collagen deposition and fibrotic bands characterize submucosal fibrosis. This translates clinically to thickened and keratotic bands that restrict the pliability and flexibility of the buccal mucosa. For these reasons, the buccal mucosa becomes thickened and tight and the patients develop trismus. These lesions should be closely

monitored for the development of oral cavity SCC.[28]

CLINICAL PRESENTATION OF CANCER OF THE ORAL CAVITY MALIGNANCY

The presentation of cancers of the oral cavity may vary depending upon the histology and the location. Cancers may present as an ulcerative lesion, as a raised exophytic lesion, or as an irregular mucosal mass. Not uncommonly, ulcerative lesions may present as a subtle lesion on the surface; however, on further inspection and palpation, the lesion may extend deep into the soft tissue. For this reason, palpation is a key part of the examination. Similarly, cancers of the alveolus may present as an irregular patch of mucosa adjacent to a tooth socket. Peridental cancers may present as a limited lesion on the surface of the mucosa, yet they may extend deep into the tooth socket and mandibular canal. In contrast, exophytic lesions may present as a papillomatous mass often described as “cauliflower-like” growth. Although benign lesions may present in a similar fashion, bleeding or ulceration suggests malignancy.

Cancer of the oral cavity may present as a painful lesion; however, the presentation may be variable. Because cancers in this region are exposed to saliva, contamination with commensal and pathogenic organisms commonly leads to infection and pain. In contrast, if a malignant lesion erodes into sensory nerves, that is, the lingual or alveolar nerves, the patient may present with anesthesia or hypesthesia of the lip or oral cavity. Finally, when a patient presents with complaints of trismus, invasion of the pterygoid space must be assumed until proven otherwise. Although infection and inflammation may also result in trismus, invasion of the pterygoid muscular by carcinoma defines advanced local involvement.

Prognostic Indicators

The prognosis of oral cavity cancer is predicated on a variety of factors including stage, depth of invasion, and the presence of neural and vascular invasion. Other prognosticators include the histologic findings including an infiltrating pattern, minimal lymphocytic response, and the presence of tumor

emboli. The American Joint Committee on Cancer (AJCC) tumor, node, and metastases (TNM) staging system for oral cavity (Table 13.1) accounts for some of these factors but not all of them. All patients evaluated for cancer of the head and neck should be staged according to the AJCC system because the staging system is designed to predict the patient's prognostic based on their TNM status and also to provide a uniform platform to develop treatment strategies and compare results. It does not, however, account for all of the important histologic characteristics that may portend the biologic behavior of a cancer. The location of a cancer is another predictor of behavior, and this is often overlooked. Locoregional recurrence rates are highest in the buccal mucosa (75%), followed by the sinopalatal region (50%) and the mobile tongue (27%).[29] Although all of these subsites are a part of the oral cavity, cancers in each subsite behaves differently. To account for many of the factors not included in the AJCC system, other staging systems have been proposed in order to improve accuracy, but they have failed to gain general acceptance.[30]

Table 13.1 AJCC TNM Classification: Oral Cavity SCCA

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor 2 cm or less in greatest dimension		
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension		
T3	Tumor more than 4 cm in greatest dimension		
T4	(Lip) Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face, that is, chin or nose		
T4a	(Oral cavity) Tumor invades through cortical bone, into deep (extrinsic) muscle of tongue (genioglossus, hyoglossus, palatoglossus, and styloglossus), maxillary sinus, or skin of face		
T4b	Tumor involves masticator space, pterygoid plates, or skull base and/or encases internal carotid artery		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension		
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension		
N2a	Metastasis in single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension		
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension		
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension		
N3	Metastasis in a lymph node more than 6 cm in greatest dimension		
Distant Metastasis (M)			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
Anatomic Stage/Prognostic Groups

Histopathology

There are a series of histopathologic features that may have significant impact on the prognosis of oral cavity carcinoma. The depth of invasion, presence of perineural invasion (PNI), and lymphocytic response are examples of histopathologic parameters that are not included in the AJCC staging system. Extracapsular spread, which is associated with a 50% reduction in survival, has a significant impact on the prognosis of a patient with cancer of the oral cavity and regional metastases.

Depth of Invasion

The depth of invasion has been shown to accurately predict the likelihood of nodal metastasis and therefore prognosis.[31,32] The depth of invasion that warrants elective lymph node dissection in the neck is controversial and has been reported to be between 3 and 5 mm.[22] The deeper the cancer invades, the more likely the presence of occult nodal metastases and local recurrence. Yuen et al.[31] reported a retrospective review of 85 glossectomy specimens and revealed that a depth of <3 mm, 3 to 9 mm, and >9 mm is associated with a 10%, 50%, and 65% rate of regional metastases, respectively. In patients with stage I or II tongue SCC with a clinically negative neck, a depth of invasion of >4 mm has been associated with a risk ratio of 9.4 in developing cervical metastases within a 5-year period.[32] Ganly et al. retrospectively reviewed a cohort of 164 early-stage oral tongue SCC in which multivariate analysis indicated that cancer thickness <4 mm versus ≥ 4 mm independently and significantly predicted regional recurrence-free survival of 94% versus 72%, respectively.[33] As a result of this study and others, 4 mm has emerged as the more commonly accepted depth of invasion mandating management of the neck. However, most of these studies are retrospective. The ability to detect occult micrometastases in cervical lymph nodes is dependent on the number of histologic sections prepared from each lymph node and may be missed during routine histopathologic evaluation.[34] Therefore, the data related to this topic are only as reliable as the methods used to assess the lymph nodes.

Perineural Invasion and Lymphovascular Invasion

PNI and lymphovascular invasion (LVI) are poor prognostic features also not

included in the TNM staging.[29,35] As a result, these features influence the need for adjuvant therapy. The presence of PNI or LVI has independently been associated with a compromise in disease-free survival; however, the addition of postoperative radiation therapy has been shown to improve survival.[36]

Extracapsular Spaced and Positive Margins

The presence of extracapsular space (ECS) of pathologic lymph nodes is the most significant prognostic feature and has been associated with a 50% reduction in overall survival. Despite adjuvant therapy, up to one-third of patients with ECS will experience either locoregional or distant recurrence.[37,38] Similarly, positive margins after surgical excision that cannot be re-resected in a timely manner are associated with a poor prognosis. A comparative analysis of the selection criteria, clinical and pathologic risk factors, and treatment outcomes of two randomized control trials (the EORTC[39,40] and RTOG trials[40]) was performed to determine the indications for postoperative concurrent chemoradiation therapy that would offer a survival advantage. This study determined that microscopically involved resection margins and extracapsular spread of cancer from neck nodes are the most significant prognostic factors for poor outcome. Furthermore, this study demonstrated that concurrent chemoradiotherapy offered a significant survival advantage for advanced cancer of the head and neck in the setting of ECS or microscopically positive involved surgical margins.[41] Although ECS is a nonmodifiable risk factor, the presence of positive margins can potentially be avoided, and therefore, when possible, it is critical to achieve a negative surgical margin.

Mandibular Invasion

Plain radiography has been used extensively in the past for the diagnosis of extensive cancer invasion of the mandible; however, subtle changes associated with the cortex have been more difficult to identify. The introduction of the panoramic x-ray, computed tomography (CT), and magnetic resonance imaging (MRI) scans has increased the accuracy of preoperative imaging and staging. Significant debate still exists regarding the optimal modality or combination of modalities recommended for preoperative assessment. Although CT is a very accurate method for

identifying gross bone invasion,[42] prior work has suggested that bone invasion may be missed in as many as 27% of patients with preoperative CT scans (Fig. 13.3). The sensitivity of CT scan for bone involvement of the retromolar trigone is ~50% with a negative predictive value of 60%; however, the positive predictive value is ~90%. It has been concluded that although the CT scan is accurate when bone erosion is clearly identified, its negative predictive value is unacceptably low and therefore an inaccurate indicator of bone invasion at the retromolar trigone. The CT scan renders an excellent view of both the soft tissue and bone of the mandible; however, it has several limitations, the most significant being artifacts caused by dental amalgams. Dental amalgams commonly create a shadow leading to artifact that can obscure invasion of the mandibular cortex. Additionally, the CT scan may misleadingly detect defects in the cortex secondary to irregular tooth sockets or periapical disease.

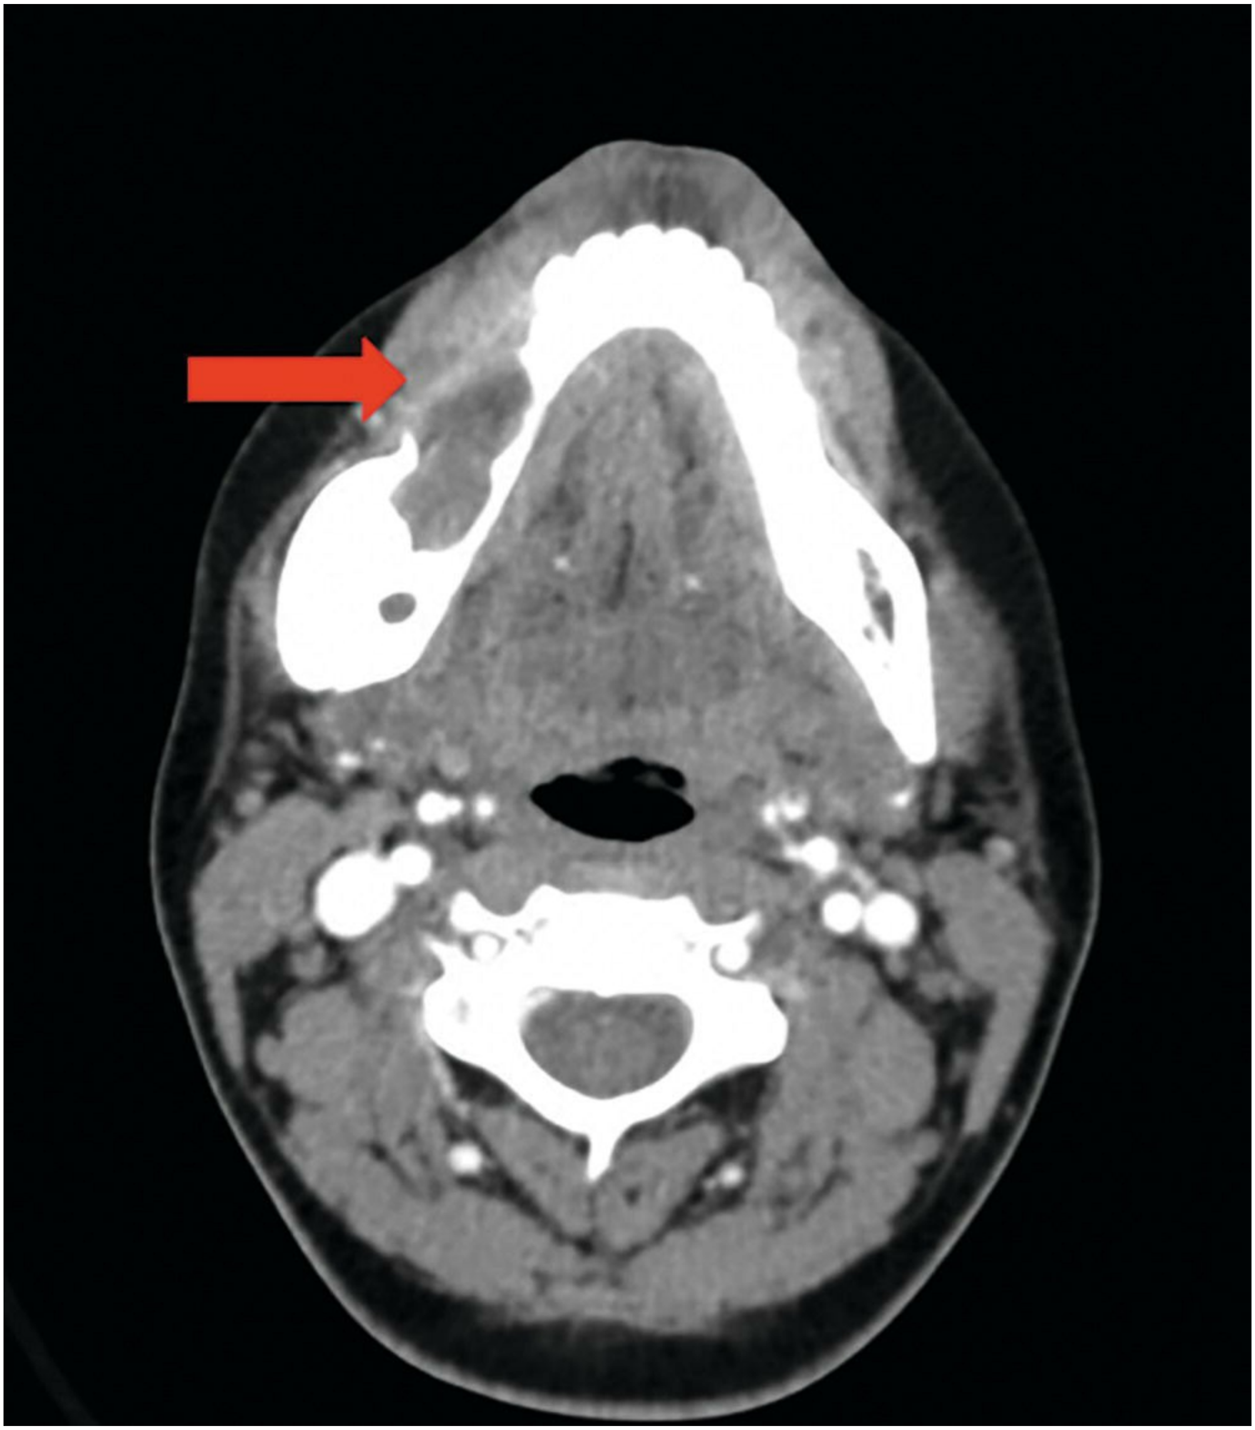

Figure 13.3. The tumor may involve the mandible by adherence or direct extension into the cortex or more deeply involve the mandible by infiltration into the medullary space. In general, osseous invasion is evaluated with CT imaging. (*Arrow* marks mandibular invasion.)

In light of these shortcomings, several investigators have reported on the

use of a DentaScan. The DentaScan was introduced in the early 1980s to assist oral maxillofacial surgeons in planning for osseointegrated implants. The DentaScan images are derived by reformatting standard axial CT scans in two views, panelliptical and parasagittal. This reformatting permits assessment of the buccal and lingual cortices. The diagnostic value of the DentaScan is accurate yielding a sensitivity of 95% and a specificity of 79% with a positive predictive value of 87% and a negative predictive value of 92%. The DentaScan is an accurate method for preoperative evaluation of invasion of the mandible in patients with SCC of the oral cavity.

Whereas the CT scan and DentaScan may offer excellent methods for assessing bone, the MRI scan offers the advantage of imaging soft tissue and potentially the medullary cavity space. Several studies have examined the use of MRI in assessing invasion of the mandible and it has been concluded that the MRI scan is superior for evaluating the medullary space of the mandible[43] but inadequate for assessing mandibular invasion. Shaha[44] examined the value of various studies including panoramic x-rays, dental films, routine mandible films, bone scans, CT scans, and MRI and found that CT scanning was not very helpful mainly because of the presence of irregular dental sockets and artifacts. Many suggest that clinical evaluation is the most accurate in determining the presence of bone invasion and the optimal method of resection, marginal versus segmental.

Most centers consider the combination of a CT scan and a panoramic x-ray acceptable for preoperative imaging of the mandible and maxilla; however, the most accurate measure of bone invasion is determined clinically. Unless there is frank invasion of the cortex, periosteal stripping followed by frozen section examination at the time of surgery is often the most reliable way of detecting bone invasion.

Traditionally, invasion of the mandible by oral SCC has been considered a poor prognostic indicator and has remained one of the criteria defining a T4 stage. However, there are conflicting reports as to the prognostic significance of bone invasion. Recently, a multivariate analysis of nearly 500 patients with oral SCC revealed that there was no association between cortical invasion and overall or disease-specific survival. However, medullary invasion independently predicted a reduced overall and disease-specific survival.[45]

DIAGNOSIS AND EVALUATION

The initial evaluation of a patient with an oral cavity lesion consists of a detailed history including the patient's oral hygiene practices as well as use of alcohol and tobacco. The oral cavity is easily amenable to examination, and this should be performed thoroughly by inspection and palpation of all the oral cavity subsites. Although brush biopsies can be easily performed and are noninvasive, their sensitivity and specificity are low.[46] Suspicious changes in the mucosa should be evaluated with a full-thickness surgical biopsy to include the pathologic architecture required to diagnose invasive carcinoma. Following an oral cavity examination, one should perform a detailed examination of the neck. Either direct or indirect examination of the upper aerodigestive tract should be part of the clinical examination especially in a patient at high risk for cancer of the head and neck. The presence of second primaries of the upper aerodigestive tract is common and should be evaluated by physical examination and with dedicated radiography.[47] Distant metastases should be ruled out, especially with advanced oral malignancies, using dedicated imaging. PET-CT, discussed below, has emerged as an optimal choice in investigating metastatic cancer.[48] However, chest radiographs and CT scanning of the chest are also useful screening modalities, especially in those patients with a lower locoregional disease burden.

Local Cancer

Following a diagnosis of SCC, a thorough assessment of the extent of the cancer and the potentially premalignant surrounding mucosa is required. Fluorescence imaging has proven a useful tool in increasing the sensitivity of identifying pathologic mucosa and is a promising technology.[49] Although extensive lesions may present with neuropathies, trismus, and decreased tongue mobility, the absence of these symptoms does not rule out invasion. CT with intravenous contrast evaluates the extent of mucosal, soft tissue, and bone involvement. MRI offers superior accuracy in predicting the degree of soft tissue or neural involvement and can be helpful in determining bone marrow invasion especially when CT is compromised by dental artifact. Enhancement of named nerves such as the lingual, hypoglossal, or alveolar nerve on MRI may predict PNI and is especially helpful in nonepidermoid

carcinomas such as adenoid cystic carcinoma. However, CT and MRI have equivalent accuracy for staging the oral cavity primaries and both are limited in characterizing superficial lesions.[50]

Invasion of the Mandible

The presence and extent of invasion of the mandible portend a worse prognosis and determine the extent of surgical resection.[45] The cancer may involve the mandible by adherence or direct extension into the cortex or more deeply involve the mandible by infiltration into the medullary space. In general, osseous invasion is evaluated with CT imaging (Fig. 13.3). Alternative techniques may be useful including dental radiographs, panoramic radiographs, cone-beam CT scanning, MRI, and bone scintigraphy with single photon emission computed tomography (SPECT). CT provides adequate assessment of the soft tissue and bony architecture; it is however limited by dental artifact and irregularly shaped alveoli or periapical disease that may incorrectly be attributed to mandibular invasion. MRI offers superior assessment of the soft tissue and medullary space but is inferior in determining cortical involvement and is limited by motion artifact. Compared to MRI and SPECT imaging, which overestimate bone invasion, CT tends to underestimate cortical invasion.[51,52] For example, the negative and positive predictive values of CT in predicting bony involvement of the retromolar trigone are 60% and 90%, respectively.[42] The DentaScan protocol, derived by reformatting standard axial CT scan in two views, affords assessment of the buccal and lingual cortices with a negative and positive predictive value of 87% and 92%, respectively, in predicting mandibular invasion.[53] MRI is superior for evaluating the medullary space of the mandible but not in determining cortical involvement alone.[43] Other modalities with a high diagnostic accuracy of cortical involvement include the technetium 99 m bone scintigraphy.[54]

Although clinical evaluation and imaging are critical in predicting the presence of bony invasion and the extent of surgical resection in the absence of gross invasion, intraoperative periosteal stripping followed by frozen section analysis is likely the most reliable indicator of bone invasion.[37]

Cervical Lymphadenopathy

To evaluate the presence and extent of lymphadenopathy in the neck, both CT and MRI are routinely used and have been shown to be equivalent.[55,56] Generally speaking, in the occult neck, between 40% and 60% are identified on CT or MRI[37] (Fig. 13.4). Several advances in MRI technology, diffusion-weighted imaging and dynamic contrast enhancement, have been applied with improved diagnostic accuracy.[57,58] In addition, the introduction of ultrasmall superparamagnetic contrast agents that preferentially accumulate in benign compared to malignant lymph nodes may further improve accuracy.[59] However, this is limited by requiring delayed images 24 to 48 hours after contrast administration.

Figure 13.4. To evaluate the presence and extent of lymphadenopathy in the neck, cross-sectional imaging tests including CT are routinely used with excellent accuracy. (*Arrow* marks regional lymph node metastasis.)

Ultrasound is also commonly used to evaluate the neck, and although the accuracy of this technique depends on the experience of the sonographer, it has the unique advantage of being combined with a fine needle aspiration (FNA) with a 100% specificity. In the clinically negative neck, ultrasound-

guided FNA detects occult disease with a sensitivity of up to 48% to 73% that is comparable to CT and MRI.[55,60]

Positron emission tomography (PET) is a functional imaging technique utilizing a radiolabeled tracer, namely, 18-fluoro-2-deoxyglucose (FDG), which allows for the in vivo localization of increased tissue metabolism. FDG is a glucose analog and has preferential uptake in tissues with increased metabolism as is often the case in malignancies. As the radiolabeled FDG is transported intracellularly, it is phosphorylated by hexokinase, preventing any further metabolism, and in turn collides with gamma rays in an annihilation reaction that produce positrons that are measured by the PET scanner. PET has been fused with a noncontrast low-dose CT (PET-CT) and MRI (PET-MRI), which have significantly improve on the lack of anatomical detail with PET alone.[61] However, this has not translated to an improved diagnostic accuracy compared to PET alone.[48] It is important to note that the specificity of PET is limited by variable physiologic uptake and its sensitivity is significantly decreased with lesions <5 mm in size.[62] Therefore, the reported sensitivity of PET-CT for detecting lymph node metastases is similar to that of CT or MRI alone.[63] The primary role of PET in oral SCC is in detecting subclinical metastatic disease and in posttreatment follow-up.

Molecular Markers

There are several tumor markers that have been associated with a poor prognosis in oral SCC. Although there is potential that in the future, these markers will identify patients with aggressive disease and dictate the choice of adjuvant therapy, the prognostic relevance of most tumor markers is still not quite clear.[64–66]

MANAGEMENT OF CANCER OF THE ORAL CAVITY

The overwhelming majority of cancers involving the oral cavity are SCC; however, minor salivary gland cancers may also occur. Epidermoid cancer of the oral cavity may be treated with radiation, surgery, or combined therapy. Although the goal is to achieve a cure, it is optimal to manage patients with the fewest modalities possible, as each modality is associated with less

treatment-related morbidity and thus contributes to a decrement in quality of life.

Early Stage

Stage I and II oral SCC can be treated with equivalent oncologic outcomes with either radiation therapy or surgical resection. Therefore, the optimal choice is dictated by a combination of the expected quality of life, patient preference, and comorbidities. However, as compared to cancer arising in other sites in the upper aerodigestive tract, the oral cavity is more often treated with surgery as the primary modality. Most early-stage oral SCC can be effectively managed surgically through a transoral approach with minimal morbidity during a single intervention. Although radiotherapy has equivalent oncologic outcomes, the potential for long-term radiation sequelae, such as xerostomia, taste disturbance, fibrosis, and osteoradionecrosis, contributes to surgical management being the mainstay of therapy. Furthermore, radiation therapy requires daily treatments for 6 to 7 weeks.

Advanced Stage

Stage III and IV cancers require a multimodality approach that most often consists of surgery followed by postoperative radiation or chemoradiation therapy. Preoperative radiation or chemoradiation therapy has been applied in the treatment of advanced oral SCC with success.[67] However, this technique may be associated with an increased risk of postoperative complications. Furthermore, although the original cancer may decrease in size and improve the ability to surgically ablate the remaining cancer, it is common to surgically address the original border of the cancer to remove potentially viable islands of cancer cells.[37] Traditionally, T4 lesions with bone invasion have had superior outcomes with primary surgery followed by postoperative therapy; however, more recently, there is evidence that primary chemoradiotherapy for selected T4 lesions may have comparable oncologic and functional outcomes.[68]

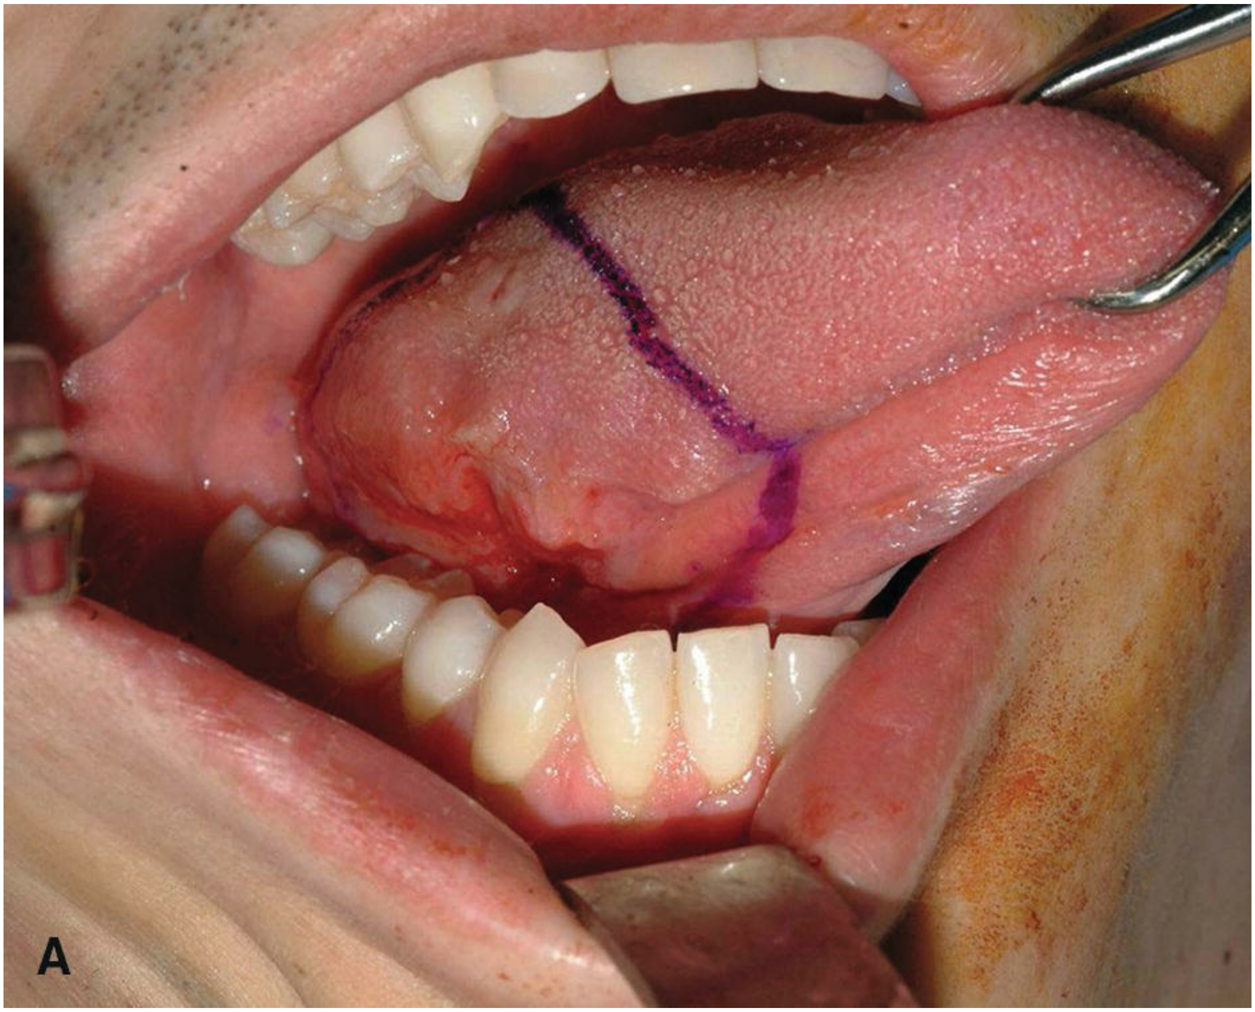
The primary oncologic goal of surgical resection of the primary cancer is to achieve a negative margin. Close margins are generally considered <5 mm. In the setting of a positive margin, surgical re-resection is recommended provided the original margin can be identified and that re-resection will not

significantly compromise functional outcomes. Radiation therapy to the primary is indicated in cases with close margins, lymphovascular or PN invasion, T3 or T4 cancer, or high-grade lesions. The indications for postoperative radiation therapy to the neck include N2 or N3 disease.[69] The indications for the addition of chemotherapy to postoperative radiation in oral SCC are positive margins or extracapsular extension, with many also including multiple pathologic lymph node involvements as an indicator.[40,41]

Cancer of the Oral Tongue

The oral tongue is the most common location for oral SCC. Early-stage cancer can be routinely excised via a transoral approach. Care should be taken to provide a 1-cm circumferential mucosal and deep margin. Frozen section analysis can aid in determining negative margins. It is important to recognize that achieving negative deep margins within the musculature of the tongue can be challenging to achieve when the initial deep margins are positive. This is due to the elastic recoil of transected muscle fibers, which can transport cancer cells deeper within the tongue musculature. Therefore, it is recommended to consider initially taking wide margins around cancers infiltrating into the tongue musculature.

The partial glossectomy defect may be closed primarily or left to granulate secondarily, or a split-thickness skin graft or acellular dermal graft can be applied to prevent tethering, particularly when the floor of the mouth is involved. For more advanced OSCC that results in an ablative defect greater than one-third of the tongue (Fig. 13.5A), one should consider a vascularized free tissue transfer to improve speech and swallow and help prevent an orocutaneous fistula (Fig. 13.5C). Adjacent submandibular or sublingual ducts should be recognized and rerouting or marsupialization should be considered if appropriate. Cancers that extend to involve a significant portion of the base of the tongue, floor of the mouth, or lingual surface of the mandible should prompt the surgeon to consider alternate approaches including a transcervical approach or a paramedian or posterior mandibular osteotomy, which facilitates obtaining free margins in all three dimensions. The factors influencing the need for, and extent of, an elective neck dissection are controversial and are discussed below. Lymphadenopathy that is clinically or radiographically suspicious for pathologic involvement should be addressed with a neck dissection.



A

B

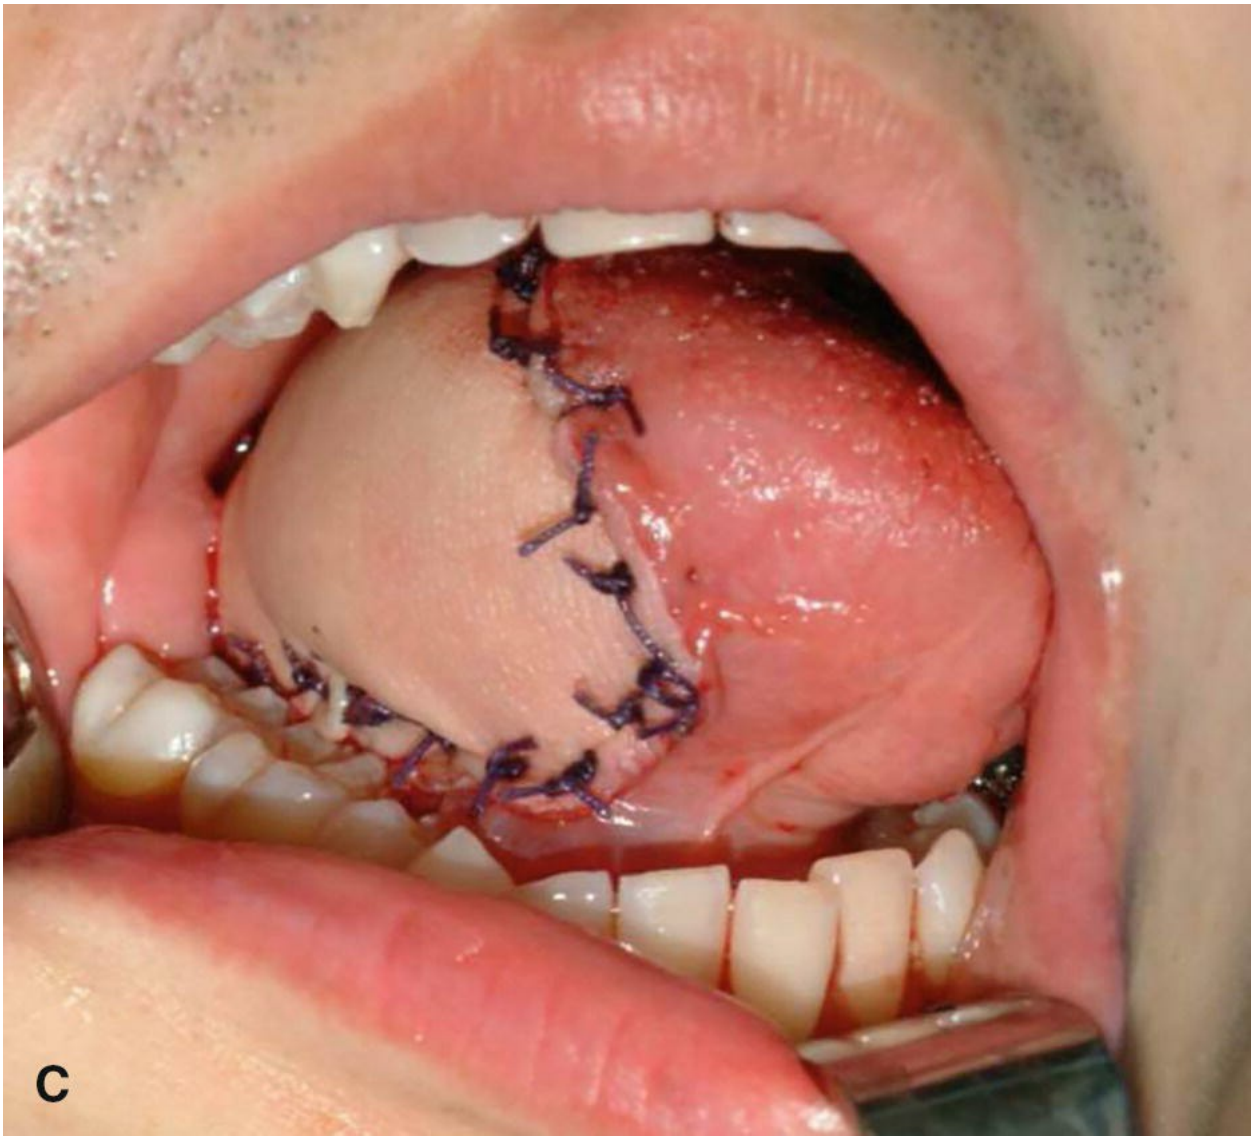


Figure 13.5. A–C: For more advanced oral cavity squamous cell cancer that results in an ablative defect greater than a third of the native tongue, one should consider a vascularized free tissue transfer to improve speech and swallow and help prevent an orocutaneous fistula. This group of photos demonstrates the radial forearm donor site used to reconstruct the oral tongue defect.

Floor of the Mouth

The floor of the mouth is rich in neurovascular structures including the lingual artery and nerve, the hypoglossal nerve, as well as the submandibular duct and sublingual gland. This area lacks a fascial boundary, and therefore, cancers in this region have the ability to invade deeper structures and lymph

node metastases are common. Clinical signs and symptoms provide valuable information as to the involvement of the lingual or hypoglossal nerve or submandibular duct. MRI is a valuable tool in determining the extent of soft tissue and PN invasion and is less affected by dental artifact compared to CT. The role of elective neck dissection is controversial with some suggesting that clinically negative neck can be observed for regional metastases because subsequent pathologic adenopathy can be effectively addressed with surgery and radiotherapy without impacting on survival.[70] Others have recommended elective neck dissection for early removal of occult disease with minimal morbidity.[71,72]

Most cancers of the floor of the mouth can be adequately excised through via a transoral approach or combined with a transcervical approach. For advanced cancers, a mandibulectomy may be required to provide for an adequate surgical margin and can readily be performed without a lip-splitting procedure. As always, a wide excision of the primary cancer, including at least a 1-cm margin of normal tissue, should be performed. Care should be taken to address the ipsilateral lingual artery, with careful attention to the location of the hypoglossal nerve. Although branches of the hypoglossal nerve are inevitably sacrificed during the ablation, the remaining trunk should be preserved to provide motor innervation to the remaining tongue. Unless dictated by the oncologic resection, excision of the sublingual gland is associated with increased complication rates and should not be performed routinely.[73] Should an osteotomy be expected, the preoperative assessment should include reviewing the available images (CT or panorex) to examine the location of the proposed osteotomy with careful attention to the adjacent teeth and mental foramina.[74]

Mandibular Invasion

The degree of invasion of the mandible will dictate the extent of surgical resection and may include either a marginal mandibulectomy or a segmental mandibulectomy. Cancers that are confined to the periosteum or outer cortex without medullary bone involvement may be managed with a marginal mandibulectomy provided that there remains at least 1 cm of native mandible (Fig. 13.6). Cancers extending to involve the medullary bone can travel within the neurovascular bundle both proximally and distally and should be managed with a segmental mandibulectomy. The extent of the

mandibulectomy is complicated by the inability to obtain bony frozen sections. While the use of preoperative imaging may predict bone erosion, intraoperative clinical evaluation with periosteal stripping increases the sensitivity of bone erosion and helps determine the extent of surgery.[29]

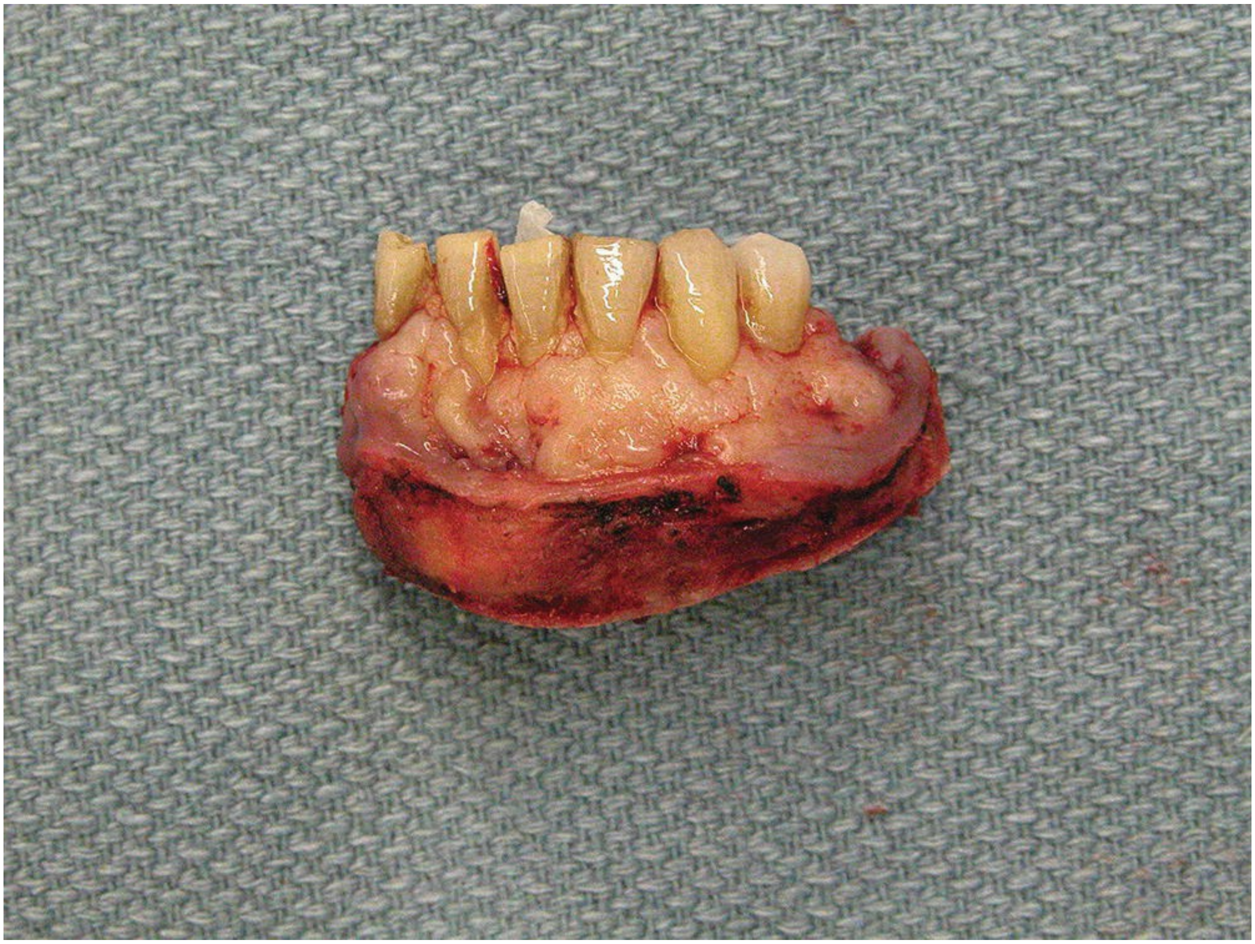

Figure 13.6. Cancers that are confined to the periosteum or outer cortex without medullary bone involvement may be managed with a marginal mandibulectomy provided that there remains at least 1 cm of native mandible. This photo demonstrates the marginal mandibulectomy specimen.

The periosteum presents a barrier to cancer spread. However, long-standing or histologically aggressive cancers can erode the periosteum and invade the adjacent mandible. Specifically, this process can be *infiltrative* or *erosive* in nature. The *infiltrative* process invades the cancellous bone through finger-like projections without the intervening connective tissue layer and has minimal osteoclastic activity. The *erosive* process is

represented by a broad front that includes the connective tissue layer and has an aggressive osteoclastic behavior. These distinct behaviors have an impact on disease-free survival, with the infiltrative pattern portending worse outcomes.[75] Although in most centers invasion of the mandible is an absolute indicator for postoperative radiation therapy, others have suggested that superficial invasion without other poor pathologic indicators can be managed conservatively. Nonetheless, the infiltrative pattern is a poor prognostic indicator and we feel that such cases should be managed with postoperative radiation therapy.[37]

Oral cavity cancer can extend along the mucosa to involve the attached gingiva where it comes in close contact with periosteum. At this point, the cancer cells will continue along the path of least resistance. In dentate patients, this will often occur as the cells migrate down the alveolus in the medullary bone. In edentulous patients, this path may proceed through defects with cortical bone at the site of prior dentition and can lead to unimpeded access to the medullary bone of the mandible. Less commonly, cancers will gain access to the mandible via the mental or mandibular canals.

Retromolar Trigone

Cancer involving the retromolar trigone has been associated with a relatively lower 5-year survival and an increase in locoregional recurrence relative to other oral cavity subsites. This may be related to an underappreciated rate of bone involvement based on imaging criteria. Therefore, a higher suspicion of bone involvement should be considered in primaries along the retromolar trigone, and at least a marginal mandibulectomy should be considered to obtain clear margins.[42,76]

Buccal Mucosa

Cancer of the buccal mucosa constitutes fewer than 10% of oral cavity SCCs. The disease can occur in one of two forms: verrucous carcinoma an indolent form of the disease and invasive SCC, the more aggressive form of the disease. Verrucous carcinoma is a progressive lesion with high recurrence and excellent 5-year survival rates. It has a low incidence of bone invasion and cervical node metastasis is unusual. The disease often derives from the benign precursor, proliferative verrucous hyperplasia. Surgery is the preferred

treatment. In contrast, invasive SCC is associated with a relatively poor 5-year survival and an increase in locoregional recurrence.[77] The primary therapy consists of a wide surgical excision and it is essential to achieve negative margins. More than one-half of buccal mucosa present as deeply invasive tumors, and MRI is an ideal imaging modality to characterize the extent of the cancers and involvement of soft tissue within the masticator space.[58] The proximity of the cancer to the parotid duct and potential tracking along the duct should be considered. When the duct is in close proximity, a frozen section margin from the duct can be very useful, and often repositioning of the parotid duct is required. Invasive cancers that involve the buccal adipose tissue should be treated by resecting the entire adipose tissue pad. Involvement of the masseter muscle and hard palate should also be ruled out.

The buccal mucosa is associated with a rich lymphatic network, and therefore, the presence of pathologic adenopathy should be carefully evaluated. Ipsilateral neck dissection is indicated for > T1 lesion and is often considered for T1 lesions suspicious for deeper invasion or with >5 mm thickness.[78,79] Careful attention to the perifacial lymph nodes is paramount to clearing pathologic adenopathy as these are often the first echelon nodes from a buccal mucosa primary. The addition of postoperative radiation therapy is reserved for cancers involving the buccinator muscles or associated with pathologic adenopathy or with poor prognostic indicators mentioned previously.

Hard Palate

In contrast to other subsites where SCC is the most common malignancy, the hard palate consists of abundant minor salivary glands and therefore is the site of both benign and malignant salivary gland cancers. Superficial or benign salivary gland cancers can be managed with simple excision using the periosteum of the hard palate as the deep margin. However, salivary gland cancers, similar to SCC, require wide local excision, often requiring removal of the hard palate, alveolus, or even dentition to achieve negative margins. Preoperative imaging is critical to determine the extent of cancer involvement and particularly bone invasion. High-resolution CT is a superior tool for characterizing the palatal and nasal bones. Cancers in or near the greater palatine foramen or the trigeminal nerve should be investigated for neural

involvement. Clinically, this may present as pain or anesthesia in the nerve distribution. MRI with gadolinium can be used to determine nerve invasion as evidenced by nerve edema or enhancement. Neurotropic salivary cancers of the palate, including adenoid cystic carcinoma, may have quite extensive proximal perineural spread to the pterygomaxillary space, foramen rotundum, and even the cavernous sinus, requiring appropriate preoperative imaging for staging and treatment planning.

Cervical metastases from minor salivary gland cancers of the hard palate are uncommon, and therefore, neck dissections should be reserved for clinically or radiologically suspicious lymphadenopathy.

NECK

The neck may be treated electively with surgery or irradiation. The clinical indicator for an elective neck dissection in OSCC is a topic of ongoing debate. The reported incidence of occult cervical metastases varies from 6% to 46% and is a reflection of the dependency of identifying occult metastases on the choice of imaging modality for preoperative assessment of nodal metastases and the technique and thoroughness in identifying involved lymph nodes on pathology. The classical works of lymph node metastases performed by Lindberg et al.,[80] were carried out prior to the widespread application of CT. Since then, there is still no single preoperative imaging modality that can reliably detect nodal micrometastases. The diagnostic accuracy of CT and MRI is limited among N0 oral cavity SCC patients.[81–83] Despite the reasonably high overall accuracy of PET-CT in the N0 neck, there is limited sensitivity for small metastatic deposits and this is further confounded by a relatively high number of false-positive findings.[82] Furthermore, immunohistochemistry and molecular analysis of pathologic neck specimens can identify occult metastases that can be missed on traditional light microscopy.[84,85] Therefore, for T1 stage cancer with a clinically N0 neck, a combination of the cancer's location, grade, and tumor depth can help guide the decision to perform an elective neck dissection. The use of a selective supraomohyoid neck dissection of levels I to III as the elective treatment of the neck is well established, with some authors extending the dissection to involve level IV to address "skip metastases".[86,87] Several recent prospective trials have demonstrated that level IIB rarely is

involved with isolated cervical metastases, and therefore, the added morbidity to the accessory nerve can be reliably spared in most elective neck dissections of oral cavity cancers.[88,89]

Traditionally, patients with clinically palpable metastatic lymph nodes were treated with a radical neck dissection of levels I to V lymph nodes of the neck including sacrifice of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve. Ward et al. modified this technique to spare the spinal accessory nerve,[90] and subsequent modifications included sparing of the internal jugular vein and the sternocleidomastoid muscle commonly known as the modified radical neck dissection. The risk of level V cervical lymph node metastasis in oral cavity SCC is low, and therefore, the utility of a level V dissection, unless clinically or radiographically apparent, is low for most of these lesions.[91,92] Recently, several investigators have reported employing a selective neck dissection, including levels I, II, and III with similar locoregional controls and overall survival compared to the modified radical neck dissection.[93,94] Selective neck dissection can be used to effectively treat clinically positive metastases to the neck in selected patients, particularly when adjuvant radiotherapy or chemoradiotherapy is also included in the overall treatment scheme.[14,94] However, others recommend a more aggressive cervical neck dissection with advanced-stage disease.[95,96] Bilateral neck dissection should be performed in the elective setting for cancers involving or approaching midline structures and should be considered in patients with ipsilateral metastases.[97] As discussed earlier, the use of postoperative irradiation often with chemotherapy to the neck is reserved for large or multiple metastatic lymph nodes, metastatic nodes in level IV or V, or extracapsular extension.[39,40]

SENTINEL NODE BIOPSY

Sentinel lymph node biopsy (SLNB) has been successfully applied as a minimally invasive technique to determine the presence of metastatic cancer in cutaneous melanoma and breast cancers. It has also recently been applied in the management of oral and oropharyngeal SCCs. Although it has become part of standard practice in many regions of the world, it is considered to be still under extensive investigation in North America. The variable lymphatic drainage and the presence of deep lymphatics in the oral cavity and neck as

well as the proximity of the primary site to draining nodal basins make routine application of this method difficult. Nonetheless, SNLB has potential in decreasing the number of elective neck dissections and the inherent morbidity associated with it. The early validation trials of this technique have been promising,[98,99] with more recent reports of the rate of neck recurrence following SLNB of <5% with no decrease in survival, and prevented as many as 70% of patients from undergoing unnecessary elective neck dissection.[100–103] The completion of additional multicentered prospective trials will determine the ultimate utility of this technique.

POSTTREATMENT SURVEILLANCE

After successful treatment of cancer in the oral cavity, appropriate posttreatment surveillance is critical to identify recurrence of cancer and second primary lesions in patients with the risk profile for oral cavity malignancy. Clinical examination at 3-month intervals is generally recommended for the first 2 years following treatment. The interval may be increased in subsequent years (4 to 6 months) for a total of 5 years.[104] Patients at high risk and with current environmental risk factors such as tobacco and alcohol use may require lifelong surveillance. In addition to basic laboratory tests, imaging studies such as a CT, PET-CT, or MRI are also critical for surveillance. The interval of imaging studies and the type of study varies depending on the initial primary site, disease factors, and the length of time elapsed since the initial therapy.[105] In general, PET-CT offers a combination of functional and anatomical imaging, which is excellent for oral cavity cancers; however, contrast CT scan may also be used. PET-CT offers excellent negative predictive value for tumor surveillance but does have issues with specificity; however, PET-CT has been shown to provide valuable data, which may alter the management of patients in this population.[106,107] MRI is helpful for patients with significant dental or hardware artifact and offers superior soft tissue resolution. The role of PET-MRI is currently under investigation.[108]

Perhaps the most important factor in the posttreatment surveillance of patients treated for malignancy of the oral cavity is the onset of new symptoms. Pain, numbness, bleeding, motor nerve deficits, infections and fistula without obvious sources, and new-onset dysphasia or dyspnea should

prompt the clinician to entertain the possibility of recurrent disease and perform the necessary workup.

CONCLUSION

Oral cavity cancer continues to challenge physicians worldwide. Locoregional control continues to be a difficult task, and improvements on disease-free survival over the last 50 years have been minimal. Patients continue to suffer from the effects of these malignancies and the therapy currently used to treat them. Future investigations should yield strategies that provide improved cure rates, with improved quality of life, for this challenging patient population.

14 Cancer of the Oropharynx

David M. Neskey Katherine A. Hutcheson Michael E. Kupferman

Nearly 10,000 cases of cancer of the oropharynx are diagnosed each year in the United States.[1] Previously, these cancers had a strong association with chronic alcohol and tobacco use, but over the past decade, the increasing incidence of the human papillomavirus (HPV) has been identified as a major etiologic agent of the oropharynx cancer.[1,2] HPV-associated squamous cell carcinoma (SCC) is now the predominant histologic type found in the oropharynx although non–HPV-associated SCC subtypes and minor salivary gland cancers are seen but less frequently.

Cancer of the oropharynx represents a diagnostic and therapeutic challenge because of the key role that the anatomic region plays in the normal function of speech, swallowing, and breathing, which requires an individualized, multidisciplinary approach for management. Head and neck surgeons, radiation and medical oncologists, speech pathologists, and dental oncologists must work in concert toward the goals of eradicating the disease, preserving function, and, when needed, functionally rehabilitating these patients after treatment. Because these cancers are frequently deeply invasive and/or present with extensive regional lymph node metastases, local–regional control is the primary therapeutic goal. Patients with HPV-associated SCC have improved survival rates compared to their non–HPV-associated counterparts, for whom overall survival rates have not improved dramatically over the past 30 years.[3,4] Advances in both radiation therapy (RT) with the advent of intensity-modulated RT and surgical approaches with laser microsurgery and robotic surgery will hopefully continue to improve survival rates while decreasing the short- and long-term morbidity. Finally, as prognostic and predictive biomarkers become validated in clinical practice, the management of oropharyngeal cancers will hopefully become more individualized.

ANATOMY

Boundaries

The oropharynx is a three-dimensional structure bounded anteriorly by the anterior tonsillar pillars (the palatoglossus muscle), the circumvallate papillae (sulcus terminales), and the junction of the hard and soft palate. Posterior and lateral boundaries are formed by the muscular pharyngeal wall (superior and middle constrictors). The superior extent is the level of the soft palate (some define this as the level of the hard palate). The inferior extent is to the vallecula at the level of the hyoid. The oropharynx is further subdivided into five areas, which include the lateral pharyngeal walls, tonsillar regions, posterior wall, base of the tongue, and soft palate. Additionally, the pharynx consists of six major muscles, the superior pharyngeal constrictor, middle pharyngeal constrictor, inferior pharyngeal constrictor, stylopharyngeus, salpingopharyngeus, and palatopharyngeus.

Cancer arising in the oropharynx can extend laterally or posteriorly to involve the parapharyngeal or retropharyngeal spaces, respectively. Lateral extension through the superior constrictor muscle can involve any of the structures of the poststyloid compartment of the parapharyngeal space including the carotid artery, jugular vein, cranial nerves IX through XII, and the sympathetic chain. The posterior pharyngeal wall begins at the Passavant ridge of the superior constrictor. The layers of the posterior pharyngeal wall are critical to the understanding of the spread of cancer in this area and include mucosa, submucosa, superior constrictor, pharyngobasilar fascia, and prevertebral fascia. The pharyngobasilar fascia is a natural barrier to the spread of cancer and is separated from the prevertebral fascia by areolar tissue. Posterior extension of cancer through the muscles and into the pharyngobasilar fascia, but not the prevertebral fascia, can still allow a complete surgical resection with clear margins. In contrast, once the prevertebral fascia is involved, or is fixed to the vertebral bodies, the cancer is no longer considered to be resectable (**Fig. 14.1A–C**).

C

Figure 14.1. A–C: Anatomic boundaries of the oropharynx.

The base of the tongue extends from the circumvallate papillae to the vallecula at the base of the epiglottis and encompasses the glossoepiglottic and pharyngoepiglottic folds. Superiorly and laterally, the base of the tongue

extends to the glossopalatine sulcus and the glossopharyngeal folds inferiorly and laterally.

Innervation

Most of the sensory innervation of the pharynx is derived from the glossopharyngeal nerve (cranial nerve IX), specifically through its pharyngeal and tonsillar branches. The pharyngeal branch arises prior to the glossopharyngeal nerve traveling intimately with the stylopharyngeus muscle. The pharyngeal branch then merges with the pharyngeal branch of the vagus nerve (cranial nerve X), which then proceeds to the pharyngeal plexus located within the external fascia of the pharynx. Although the pharyngeal branch provides most of the sensory innervation, the tonsillar branch of the glossopharyngeal nerve directly supplies the oropharyngeal isthmus as it communicates with the lesser palatine nerve (from cranial nerve V2). The soft palate receives its innervation from the lesser palatine branch of the maxillary nerve. The six major muscles of the pharynx all derive motor input from pharyngeal and superior laryngeal branches of the vagus nerve (cranial nerve X) through the pharyngeal plexus, except the stylopharyngeus. Instead, the stylopharyngeus muscle derives motor innervation from the glossopharyngeal nerve (cranial nerve IX) from fibers of the nucleus ambiguus (**Fig. 14.2**).

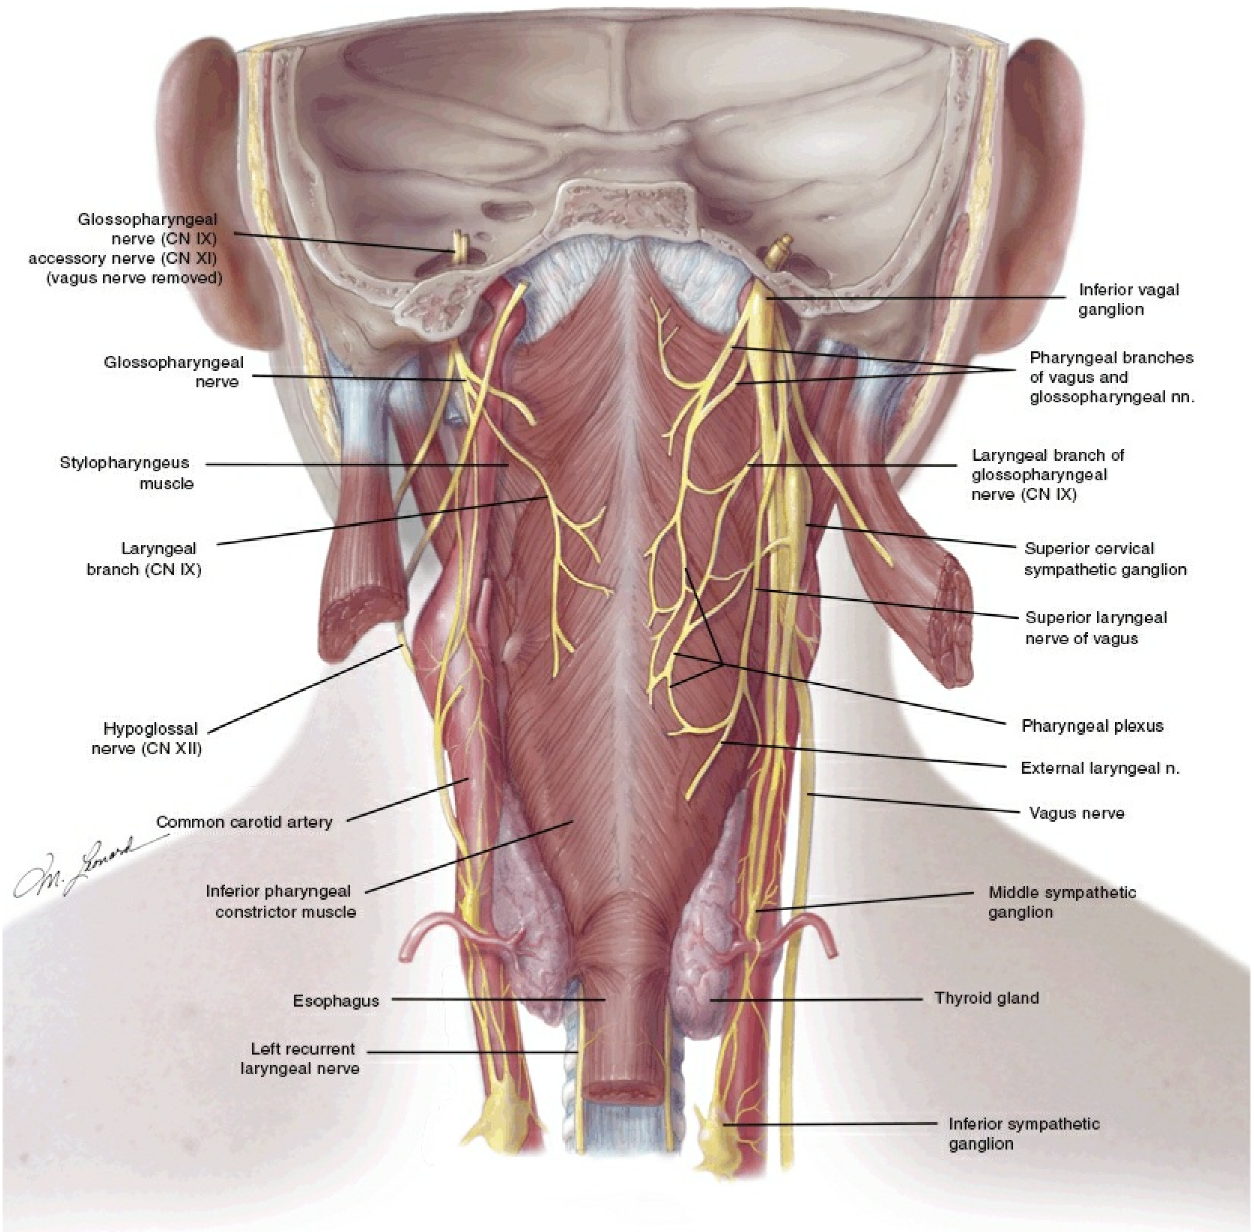

Figure 14.2. Innervation of the oropharynx.

Vasculature

The pharynx receives its blood supply from several sources. The superior aspect of the pharynx receives blood from the pharyngeal branch of the ascending pharyngeal artery and descending branches of the lesser palatine arteries. The inferior aspect of the pharynx receives blood supply from the inferior thyroid artery and superior thyroid artery. The rest of the pharynx receives blood from the ascending palatine and tonsillar branches of the facial

artery as well as from the maxillary artery. The internal carotid artery, which is an essential surgical landmark, lies deep to the superior constrictor muscles and medial to the medial pterygoid muscle. It is generally covered in adipose tissue within the prevertebral fascia[5] (**Fig. 14.3**).

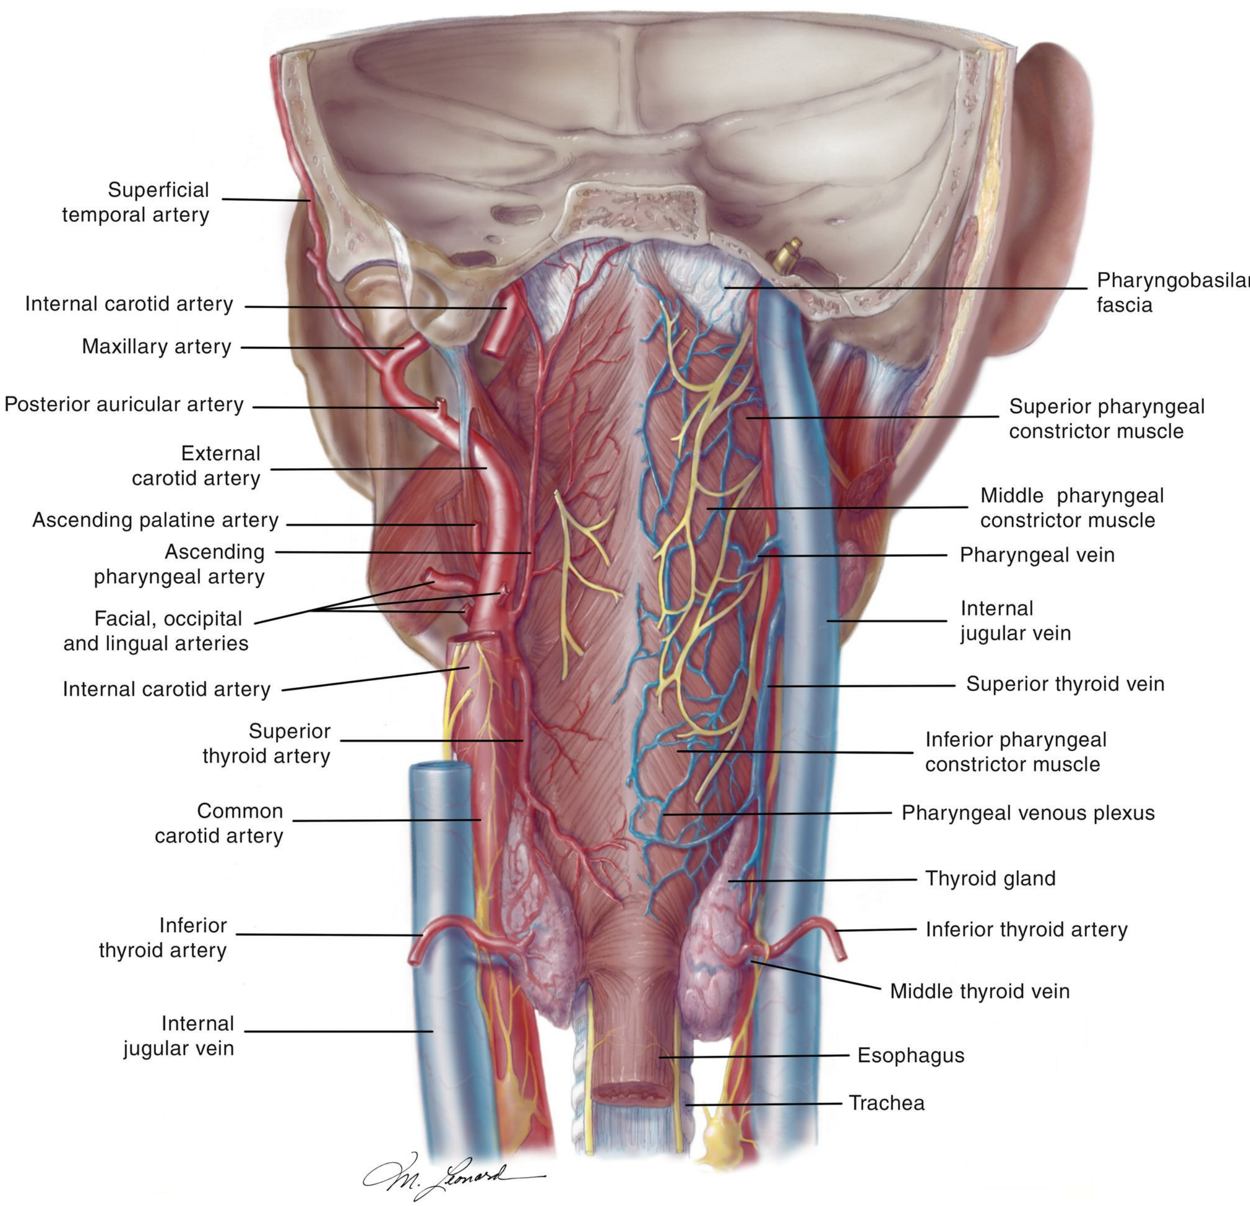

Figure 14.3. Vascular supply of the oropharynx.

Lymphatics

The lymphatic drainage of the oropharynx varies greatly across the different subsites, but the two lymph node basins most frequently involved are the

internal jugular nodes and the retropharyngeal nodes. The base of the tongue has both superficial and deep lymphatic networks that are bilateral in up to 30% of patients. The primary lymph nodes involved in primary cancer of the base of the tongue are levels II–IV. The tonsil drains to the lateral retropharyngeal lymph nodes and ipsilateral level II–III nodes. The soft palate has three distinct drainage systems, anterior, middle, and posterior. The anterior system drains primarily the hard palate and the anterior aspect of soft palate and involves the level I lymph nodes. The middle system can drain bilaterally, most commonly to level II at the posterior belly of the digastric. The posterior system can also drain bilaterally to the retropharyngeal nodes via penetration of the lymphatics through the superior constrictor muscles.[6]

EPIDEMIOLOGY, RISK FACTORS, AND PREVENTION

SCC of the oropharynx, like tumors from other head and neck subsites, has been traditionally associated with tobacco and alcohol consumption. In contrast to nonoropharyngeal cancers, the incidence of oropharyngeal squamous cell carcinoma (OPSCC) has increased in recent decades, specifically among younger age groups.[7–11] This decline in incidence of nonoropharyngeal cancers may be attributed to reductions in tobacco use in the United States, whereas the rising incidence of oropharyngeal cancers is due to a higher incidence of infection with HPV.[1,12]

The prevalence of HPV in OPSCC in the United States has steadily increased from <20% in the 1980s to over 70% in 2004, with palatine and lingual tonsils most frequently involved.[1,3] With a conservative estimate that 70% of OPSCC are HPV positive, it is projected that over 11,300 new cases will be diagnosed in the United States in 2020, and by 2030, 47% of all HNSCC will originate from the oropharynx[1] (**Fig. 14.4**). This increase in OPSCC has also been observed in other countries, specifically Canada, Slovakia, the Scandinavian countries, and Greece.[13–17] The risk factors associated with HPV-associated OPSCC are distinct from HPV-negative tumors and include oral sexual behaviors and marijuana use, whereas HPV-negative tumors are associated with poor dental hygiene and tobacco and alcohol use.[18] Furthermore, a dose–response relationship has been identified

between the risk of developing HPV-positive OPSCC with number of oral sex partners and joint years of marijuana use.[18]

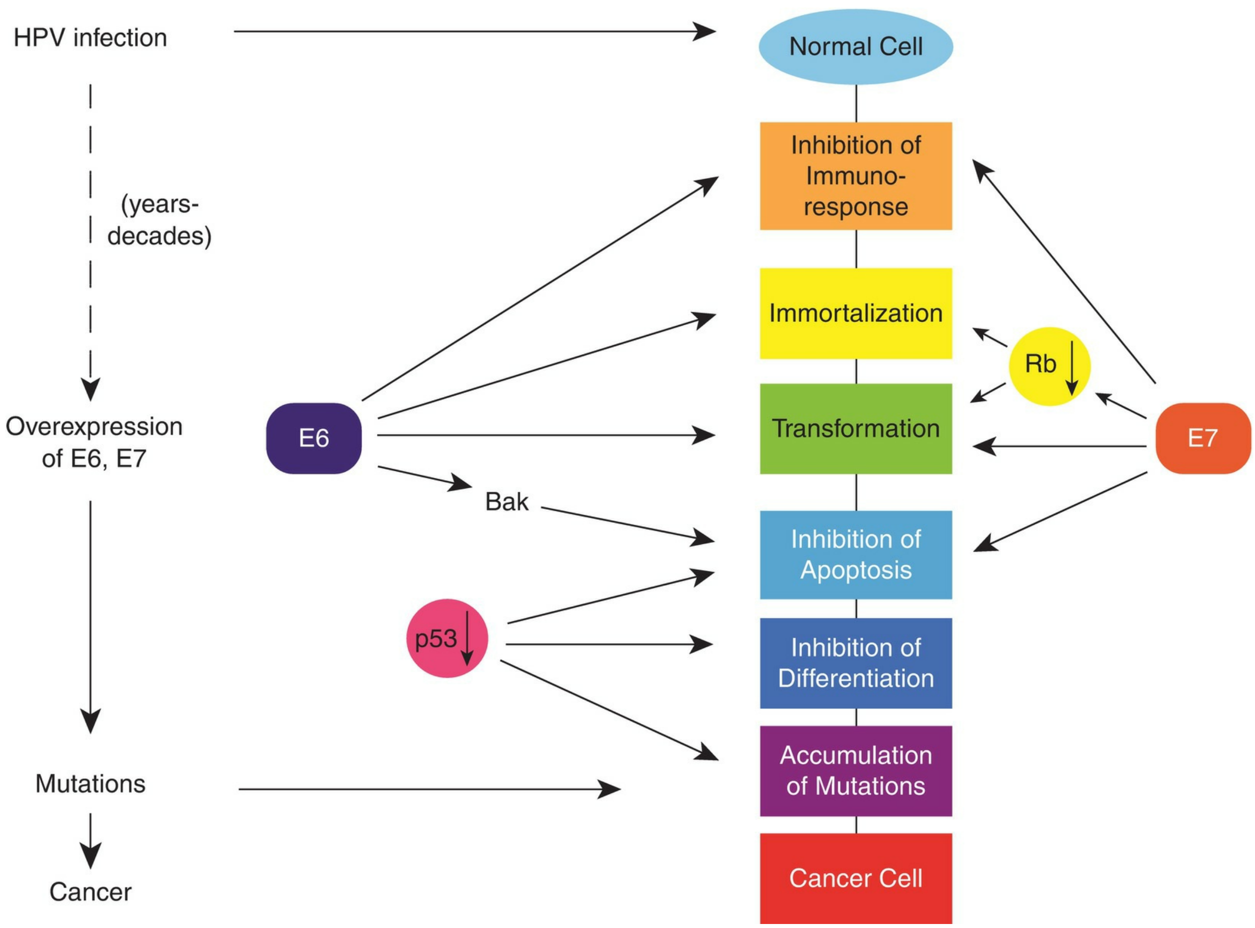

Figure 14.5. The mechanisms of HPV oncogenes E6 and E7 in cancer development.

HPVs are DNA viruses with a unique affinity for human epithelia, and HPV-associated cancers typically arise from the palatine or lingual tonsillar crypts de novo without clear evidence of epithelial dysplasia. Over 120 different HPV types have been isolated, with low-risk types (e.g., HPV 6, 11) inducing benign hyperproliferation of the epithelium, leading to lesions such as papillomas and warts. High-risk types (e.g., HPV 16, 18, 31, 33, 35) are defined by epidemiologic associations with cervical cancer.[19] The prototypical oncogenic types 16 and 18 account for over 90% of HPV-related OPSCC and are capable of malignant transformation of primary human keratinocytes from either genital or upper respiratory tract epithelia.[20] This transforming potential is attributed to two HPV oncoproteins, E6 and E7, that

inactivate two human tumor-suppressor proteins, p53 and pRb, respectively. These viral oncoproteins lead to transformation through the stimulation of cellular proliferation, delay of cellular differentiation, increase in the frequency of spontaneous and mutagen-induced mutations, and promotion of focal and broad chromosomal instability in transfected cell lines[21] (**Fig. 14.5**). Furthermore, in order to maintain a malignant phenotype, a transcriptionally active viral genome appears to be necessary.[22]–[25]

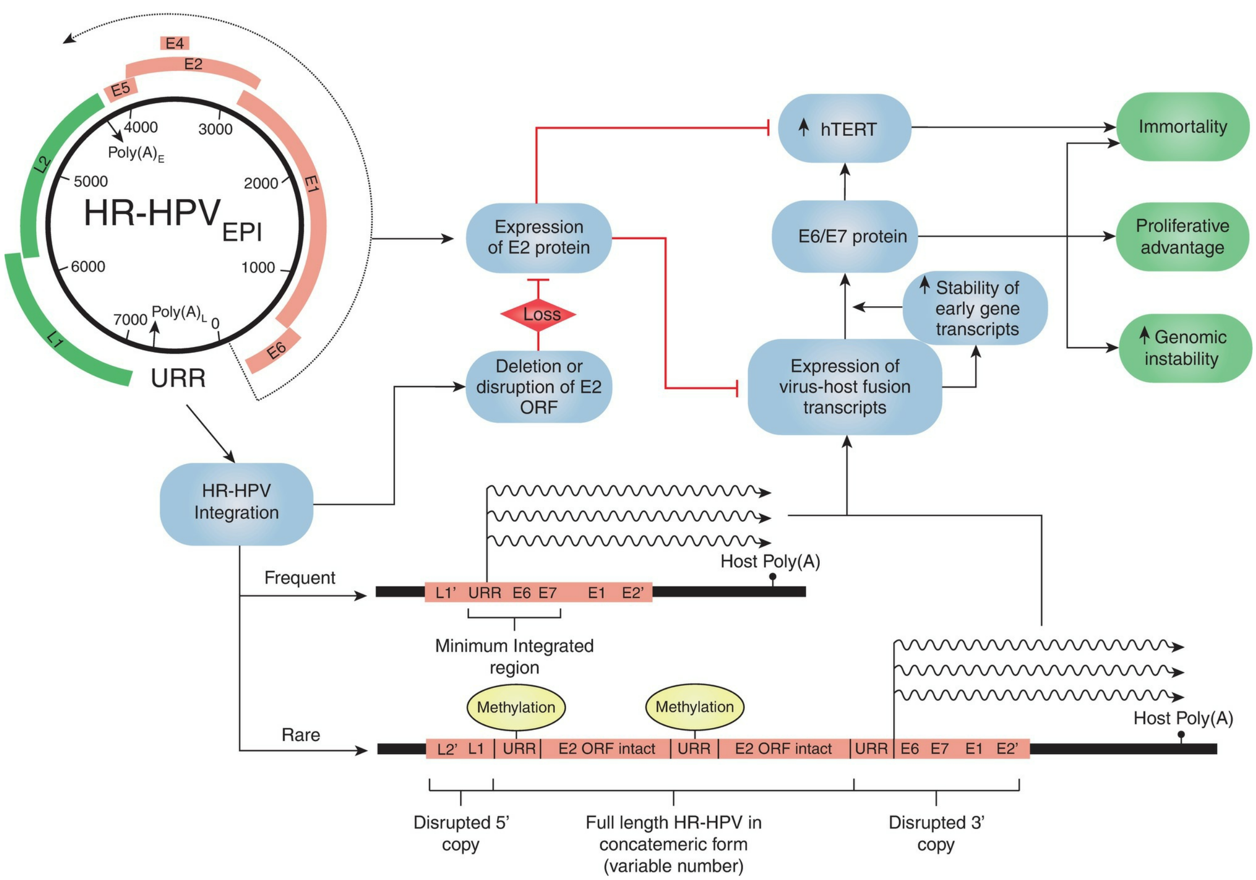

Figure 14.6. Significance of HR-HPV integration events detected in cervical carcinomas. The majority of integrants that derive from insertion of HR-HPV episomes ($\text{HR-HPV}_{\text{EPI}}$) into the host genome are detected at low copy number and retain at least the E6 and E7 oncogenes together with the viral upstream regulatory region (URR). Integrant copy number is often increased through amplification of viral and flanking host DNA. Typical integrants also have complete or partial disruption of the ORF for E2, the viral gene that regulates viral replication and which, by binding sites in the URR, can inhibit expression from integrated virus. Disruption of the viral genome also dissociates viral early (E) gene transcription from the viral early

polyadenylation signal, leading to use of host poly(A) signals and transcription of virus–host fusion transcripts with a longer half-life. These events lead to increased levels of E6 and E7 proteins, which, together with loss of additional inhibitory effects of E2, result in cellular immortalization, deregulated proliferation, and increased genomic instability. More rarely, concatemeric integrants are observed, where viral copies (including intact E2) are arranged in a head-to-tail fashion with partially deleted copies at the 5 and 3 ends. Note that the dashed line in the figure represents transcription from the early promoter of HR-HPVEPI (P97 in HPV16). (Adapted from Pett M, Coleman N. Integration of high-risk human papillomavirus: a key event in cervical carcinogenesis? *J Pathol.* 2007;212(4):356–367, with permission.)

In the normal viral life cycle, the genome replicates as episomally.[26] In cervical lesions, the HPV genome is consistently retained in the episomal state in early dysplasia and low-grade lesions, but integration of the viral genome into the host chromosome is associated with high-grade lesions and the majority of HPV-associated cervical carcinomas.[27–29] This integration appears to be a direct consequence of host chromosomal instability and is an important molecular event in the progression from high-grade lesions to invasive carcinoma.[30] A possible explanation for this disease progression is the dysregulation of the viral oncogenes following integration due to complete or partial loss of E2 open reading frame (ORF).[30] This hypothesis is supported by the finding that E6 and E7 confer a much stronger transforming capacity in primary cells following integration compared to episomal transcripts.[31] The HPV integration sites are randomly distributed throughout the host genome with a clear preference for genomic fragile sites. Viral integration is a consequence of an overall destabilization process of the chromosomal integrity in replicating epithelial cells that express the viral E6 and E7 genes. Therefore, alterations in the viral genome secondary to integration and the impact of the host cellular sequences on transcriptional regulation of the viral genes appear to be more important than cellular alterations due to the HPV integration[26,30] (**Fig. 14.6**).

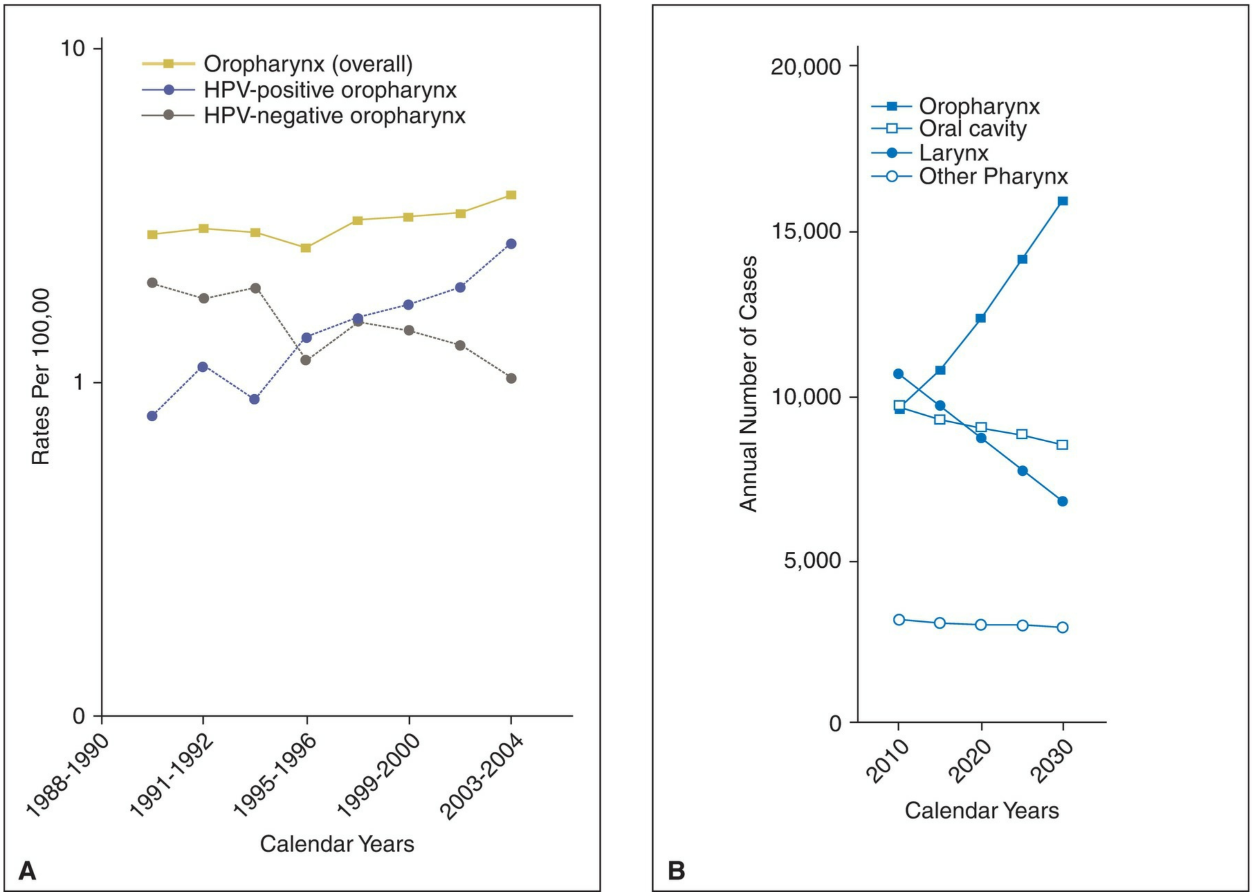

Figure 14.6. A: Incidence rates for oropharyngeal cancer (overall), HPV-positive oropharyngeal cancer, and HPV-negative oropharyngeal cancer. **B:** Projected annual number of patients with oropharyngeal, oral cavity, laryngeal, and other pharynx cancers through the year 2030. Observed incidence rates during 1973 to 2007 from nine registries within the Surveillance, Epidemiology, and End Results (SEER) program were used in age-period-cohort models to project expected incidence through the year 2030. (Adapted from Mehanna H, et al. Prevalence of human papillomavirus in oropharyngeal and nonoropharyngeal head and neck cancer-systematic review and meta-analysis of trends by time and region. *Head Neck.* 2013;35(5):747–755. http://dx.doi.org/10.1002/hed.22015. PubMed PMID: 22267298, with permission; and data from Chaturvedi, AK, et al. Human papillomavirus and rising oropharyngeal cancer incidence in the United States. *J Clin Oncol.* 2011;29(32):4294–4301.)

The increasing incidence of HPV-positive OPSCC raises important public health considerations, which utilizes health promotion and primary prevention strategies aimed to decrease the incidence of this disease. The

prevalence of oral HPV-16 infection is 1% in the United States and has been associated with a 50-fold increased risk for HPV-positive OPSCC.[18,32] In the primary care setting, risk factor modification including reduction in high-risk sexual behavior, decreased oral HPV infection, and smoking cessation should be discussed with patients.

Because HPV-positive OPSCC is related to only a few high-risk HPV subtypes, the potential exists for prevention of this disease through vaccination targeting those subtypes.[32,33] Unfortunately, vaccination is effective only prior to infection, because it induces neutralizing antibodies that prevent virion entry but does not halt the progression of existing lesions; therefore, vaccination must occur at a young age.[34,35] The two vaccines (HPV bivalent29 and quadrivalent30 vaccines) approved by the U.S. Food and Drug Administration (FDA) prevent persistent cervical HPV-16 infection.[35] The bivalent vaccine is indicated for the prevention of cervical cancer in women, whereas the quadrivalent vaccine has an additional approval for the prevention of genital warts and genital cancers in both genders up to 26 years of age. The Advisory Committee on Immunization Practices first recommended in 2007 that girls 11 to 12 years of age be vaccinated with the quadrivalent HPV vaccine. The recommendation was updated in 2011 that boys aged 11 or 12 years should also be vaccinated with three shots.[36] Females 13 to 26 years of age and males 13 to 21 years of age who were not previously vaccinated are recommended to be vaccinated. Because there is no screening strategy for OPSCC, vaccination may have higher impact in OPSCC than in cervical cancer, given that the incidence is estimated to surpass that of cervical cancer by 2020.[1] Parents of children of both sexes should be informed that vaccination is available, and, although not approved for this indication, it may reduce the risk of other HPV-related cancers, including OPSCC.

PATHOLOGY

As mentioned previously, the oropharynx is divided into subsites that are lined with distinct epithelial types. The posterior pharyngeal wall, which begins at Passavant ridge, transitions from ciliated respiratory epithelium of the nasopharynx to nonkeratinizing stratified squamous epithelium of the oropharynx. The lymphoepithelium of Waldeyer ring is formed by the fusion

of the overlying stratified squamous epithelium that extends into the deep tonsillar crypts within the underlying lymphoid tissue.[37] Minor salivary glands are located throughout the submucosa of the oropharynx.

SCC accounts for over 90% of the malignant neoplasms in the head and neck. Although SCC of the head and neck has classically been considered a homogeneous disease, recent epidemiologic trends and molecular profiling have identified distinct subtypes.[18,38] With the emergence of HPV-associated OPSCC, the typical differentiated keratinizing and nonkeratinizing SCC of the head and neck represents an increasingly smaller proportion of neoplasms in the oropharynx. Tumors of this histology tend to arise in older patients with a history of tobacco and alcohol abuse.[4]

Non–HPV-Related Squamous Cell Carcinoma

Keratinizing SCC tends to be fungating and ulcerative with limited submucosal spread but infiltrating margins. The presence of intracellular and extracellular keratin is common, and the cells are large and have the characteristic intracellular bridges.[36] Nonkeratinizing SCCs occur less frequently than do their keratinizing counterparts and grow in broad connecting bands resembling a plexus with cells that contain prominent nucleoli.[36]

Basaloid SCC is a rare but aggressive subtype of SCC that primarily arises in the base of the tongue. This cancer has a propensity for submucosal spread with central ulceration and is composed of tightly packed moderately pleomorphic cells that form cords and nests. Patients typically present with late-stage disease including regional and distant metastases.[36]

Spindle cell carcinoma is a fusion between classic SCC with spindle cells and can be referred to as sarcomatoid carcinoma. The spindle cell component tends to form the bulk of the tumor with the SCC being restricted to the stalk or base. These cancers will stain for both epithelial markers including keratin and mesenchymal markers including vimentin.[39]

Lymphoepithelial carcinoma is histologically identical to undifferentiated nasopharyngeal carcinoma (WHO III). Cancer cells are typically surrounded by lymphocytes and have large vesicled nuclei that are positive for cytokeratin. Like NPC, these cancers tend to arise in younger patients, are not

associated with alcohol or tobacco, and are radiosensitive.[40]

HPV-Related OPSCC

The pathologic features of HPV-related SCC of the oropharynx are distinct from those of the keratinizing differentiated SCC that arises from the other head and neck sites. The unique histologic features include lesions that arise from the tonsillar crypts without associated dysplasia of the epithelial surface. Additionally, these cancers exhibit lobular growth and are infiltrated with lymphocytes. Finally, the cells lack significant keratinization and demonstrate a prominent “basaloid” morphology.[41] There are two microscopic features of HPV-related oropharyngeal cancers that are frequently misunderstood. First, these cancers are frequently described as poorly differentiated based on immature appearance of the cells, when in fact these cells closely resemble the reticulated epithelium of the tonsillar crypts and are actually highly differentiated.[42] Second, the “basaloid” descriptor can be misleading and associate these cancers with aggressive basaloid SCC subtype. Although these two SCCs look similar morphologically, the detection of HPV results in significantly improved survival outcomes relative to the HPV-negative basaloid SCC.[43]

Minor Salivary Gland

Tumors of the minor salivary glands represent fewer than 10% of neoplasms in the oropharynx, but unlike tumors of the major salivary glands, the majority of tumors are malignant.[44,45] The majority of minor salivary gland tumors arise in the base of the tongue, followed by the soft palate and palatine tonsil.[46] The histologic heterogeneity in the minor salivary glands mirrors that of the major salivary glands, with adenoid cystic and mucoepidermoid carcinomas being the most frequent. There are conflicting data as to which neoplasm is actually the most frequent, but a recent series that focused on minor salivary gland malignancies of the oropharynx identified mucoepidermoid carcinomas as the most frequent, followed by adenoid cystic carcinoma, polymorphous low-grade adenocarcinoma, and carcinoma ex-pleomorphic adenoma.[46]

DIAGNOSIS

History

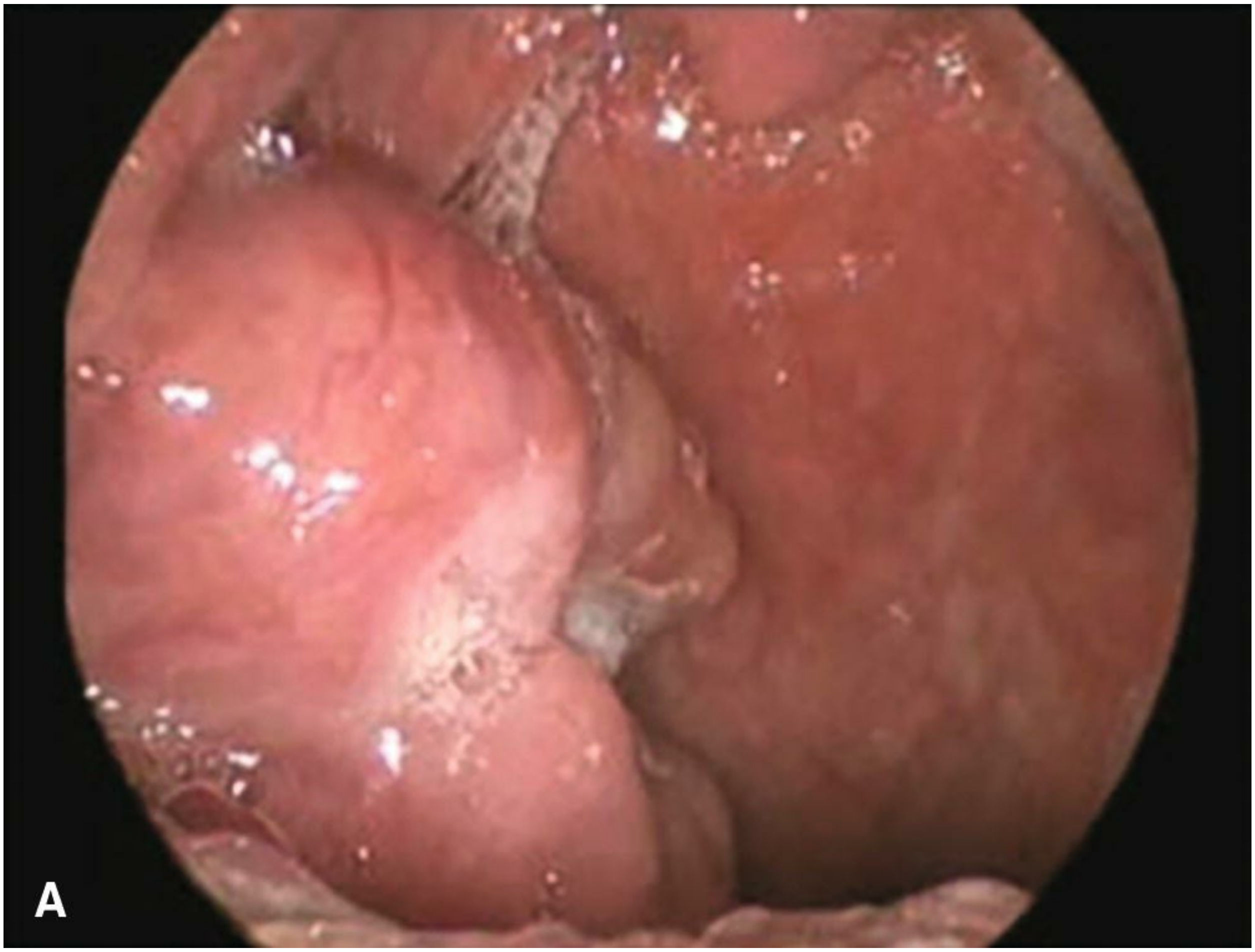
A complete history including review of systems, personal and family history of cancer, social history, and sexual history needs to be documented. As mentioned previously, the risk factors associated with HPV-positive tumors are distinct from HPV-negative tumors. Marijuana use of >1 cigarette per day for at least 5 years and >11 vaginal sex partners or 6 oral sex partners are most closely associated with HPV-positive OPSCC.[18] In contrast, the risk of developing HPV-negative OPSCC is associated with being a current smoker, a >20 pack-year history of tobacco smoking, and >14 drinks per week for 50 years.[18] Because of these differences in risk factor profiles, a thorough history needs to be gathered because of the HPV status of the cancer at presentation.

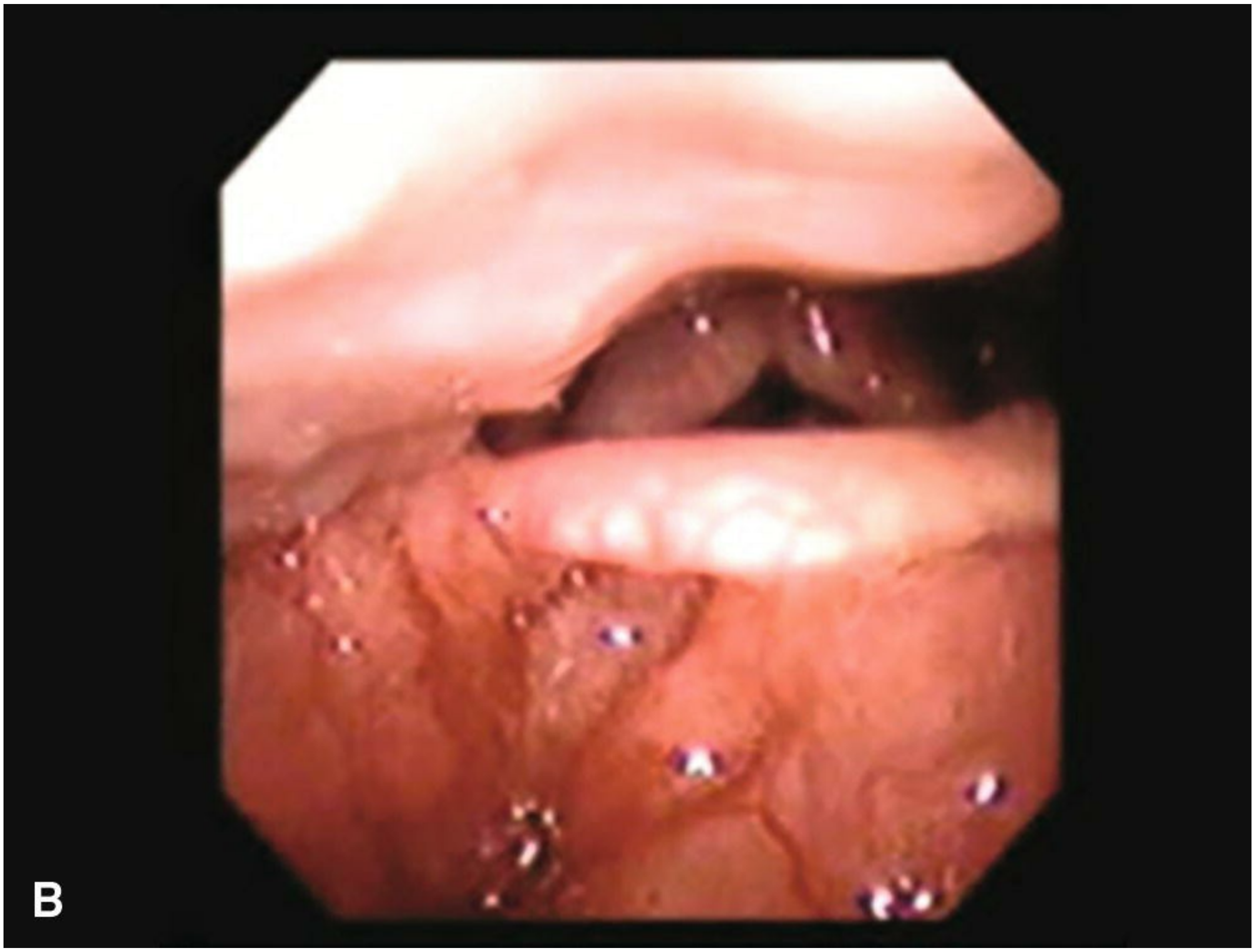
The presenting symptoms also differ between HPV-positive and HPV-negative tumors. Patients with HPV-positive tumors typically have smaller primary cancers and therefore rarely have local symptoms at presentation but will often have a painless mass in the neck secondary to regional metastases.[47] In contrast, patients with HPV-negative cancers tend to have a greater disease burden at the primary site, which results in more local symptoms of pain, otalgia, and dysphagia.

Physical Examination

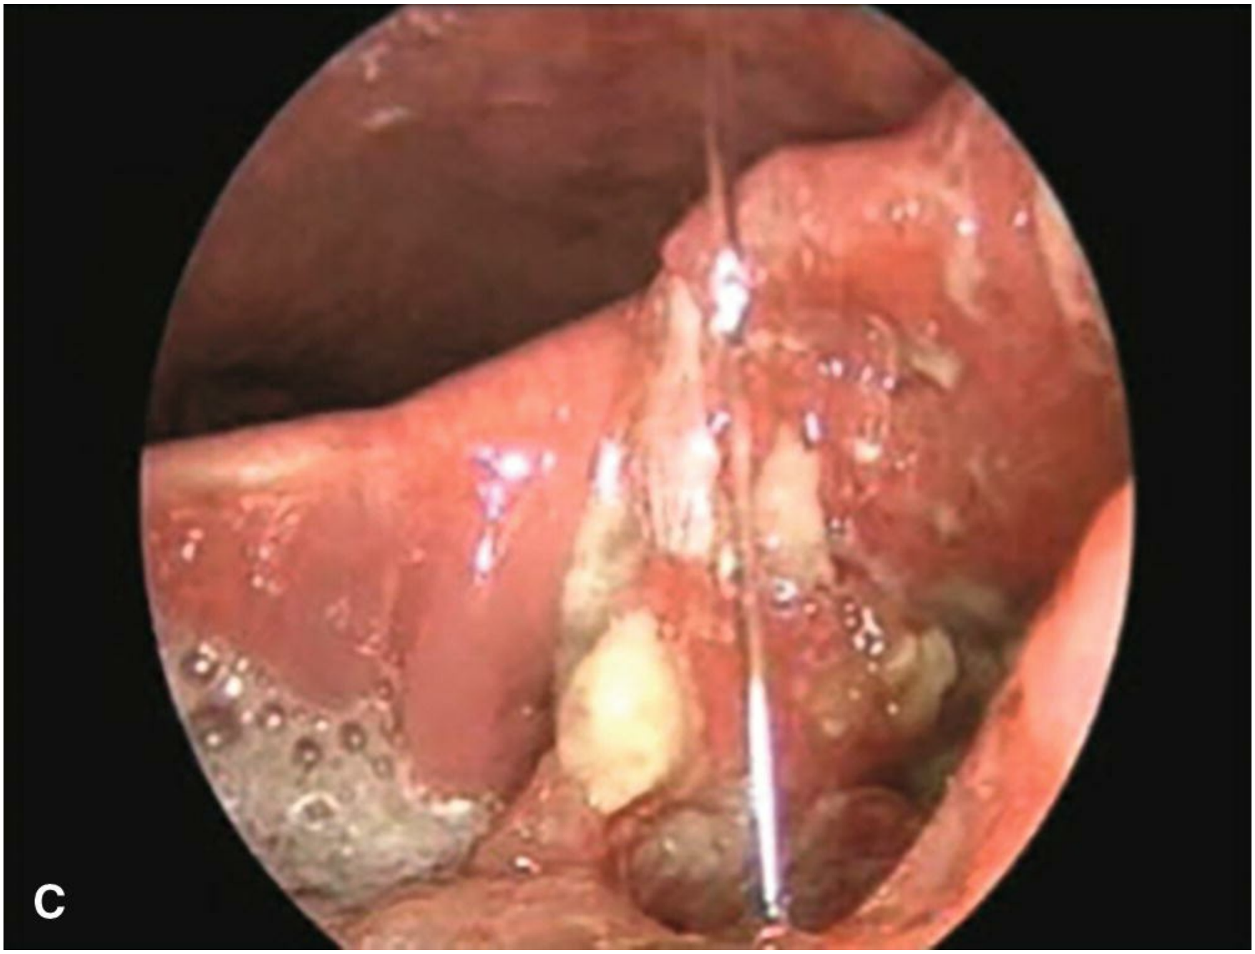
A complete examination of the head and neck should be performed on all patients. Systematic inspection of all the mucosal surfaces of the upper aerodigestive tract is necessary because of the field cancerization phenomenon that can lead to synchronous primaries, particularly in the patient with non-HPV–associated cancer.[48] Visual inspection of the base of the tongue and larynx is greatly facilitated with a fiberoptic nasopharyngoscope (**Fig. 14.7A–D**). In addition to inspection of the mucosal surfaces, the tonsils and base of the tongue must be palpated to assess the extent of the tumor and for any submucosal spread. Moreover, the extent of the lesion into the deep tissues of the base of the tongue, vallecula, and glossopharyngeal sulcus is often only evident upon palpation. Assessment of the mandible range of motion and a thorough examination of the cranial nerves also must be performed, with an emphasis on sensation of the lower face and tongue, along with mobility of the tongue and palate. Cranial nerve

deficits or the presence of trismus implies local invasion into the mandible or masticator spaces. All levels of the neck must be evaluated bilaterally, given the rich lymphatic network that drains the oropharynx and the high incidence of metastasis to the cervical lymph nodes.





B



C

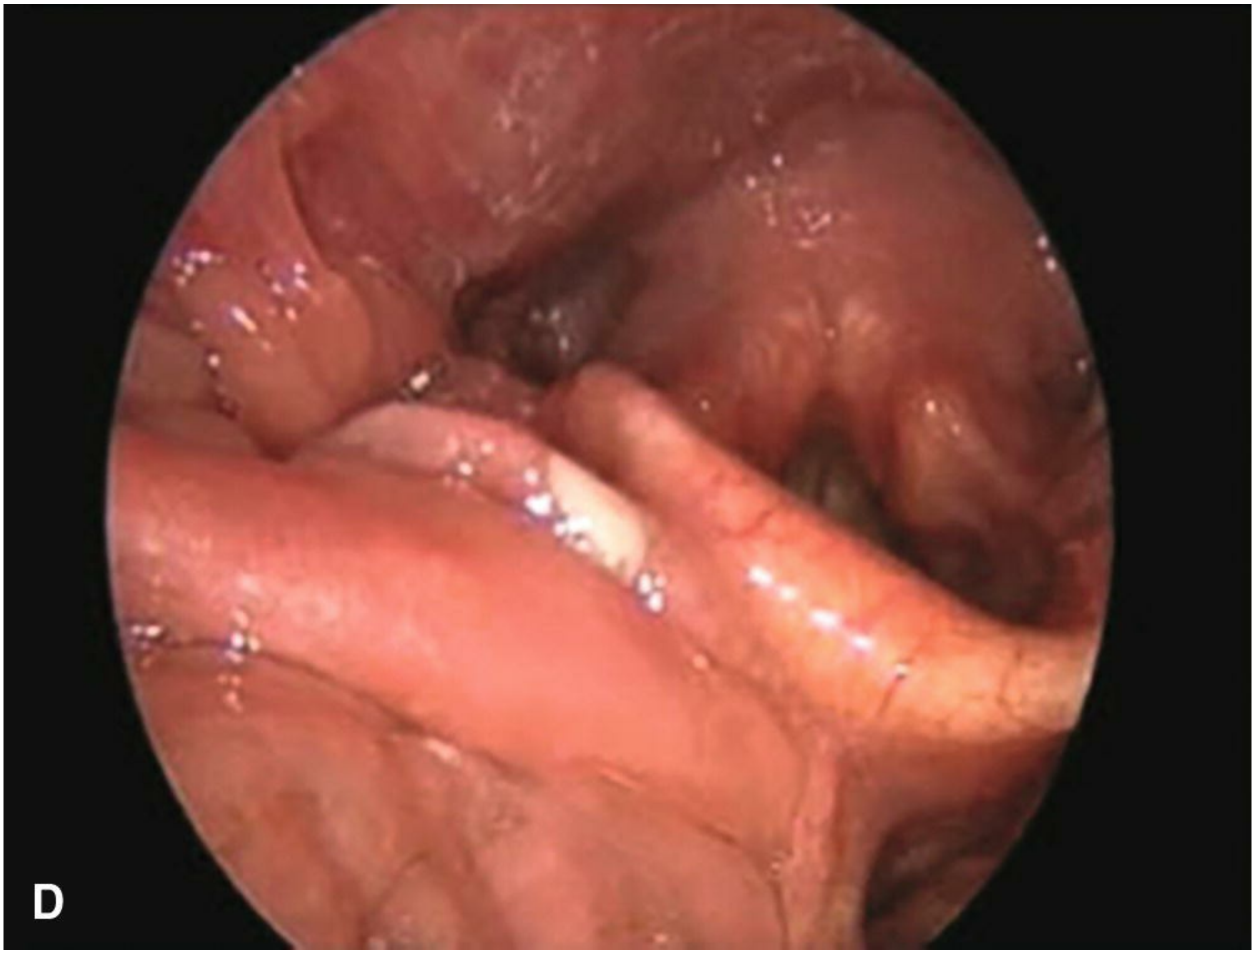


Figure 14.7. Examination of the oropharynx through direct transoral visualization (**A**) or flexible nasopharyngoscopy (**B–D**). Normal appearance of the base of the tongue and vallecula (**B**). Exophytic neoplasm along the glossopharyngeal sulcus (**C**). Small exophytic lesion of the vallecula (**D**).

Diagnostic Imaging

1. Computed tomography (CT) and magnetic resonance imaging (MRI) are helpful in determining the extent of disease at the primary site or regionally. They are primarily indicated in the assessment of advanced-stage cancers where there is concern for involvement of the mandible, parapharyngeal space, prevertebral fascia, cervical nodes, or retropharyngeal nodes. CT scans are better able to evaluate bony structures and cervical lymphadenopathy, whereas MRI is better at evaluating soft tissue, such as the base of the tongue, parapharyngeal space, or prevertebral fascia.
2. Chest radiograph is useful as a screening for metastasis to the lungs,

second primary cancers, and chronic changes associated with the use of tobacco. If a patient presents with significant lymphadenopathy that is in the inferior aspect of the neck (levels IV or VB) or bilateral in nature, a CT of the chest to detect lung metastases should be considered.

3. A panorex is a study complementary to the CT scan for the detection of mandibular involvement, and it is also critical in the assessment of the dentition prior to radiation therapy.
4. Positron emission tomography (PET) in conjunction with a contrast-enhanced CT of the neck can provide accurate anatomic details along with the biologic function about the primary tumor and regional disease. Because HPV-associated SCC frequently presents with smaller primary cancers and the nodal metastases are commonly cystic in nature, the additional functional characteristics provided by the 18F-FDG PET can improve the initial staging of these patients.[3,49,50] Furthermore, although an increased frequency of distant metastases is not related to HPV status, HPV-associated OPSCC tends to disseminate to multiple organs that are not typically involved in non–HPV-associated metastatic HNSCC.[51] These metastases also can manifest later in the course of the disease between 3 and 5 years after completion of treatment.[51] Due to this atypical pattern of disease spread, initial and surveillance imaging needs to assess distant sites of disease. The benefit of PET/CT relative to a contrast-enhanced CT in the assessment of treatment response is still not clear. One of the challenges is the timing of the posttherapy PET/CT. The optimum timing after chemotherapy and radiation therapy is not known, but an interval of 12 weeks has generally been recommended to allow for a reduction in the radiation-induced inflammation and therefore improve the accuracy of the test.[52]

Laboratory evaluation of patients with cancer of the oropharynx includes a complete blood count, electrolytes, creatinine, BUN, and liver function tests.

Staging Endoscopy and Biopsy

Patients with primary epithelial cancers of the upper aerodigestive tract should undergo examination under anesthesia independent of the presenting T stage. Direct visualization and palpation of the tumor improve the assessment of submucosal spread and invasion of surrounding structures,

especially in patients presenting with trismus. A thorough examination using direct laryngoscopy for a synchronous second primary cancer is essential, as these lesions can occur in 8% to 12% of patients with history of tobacco use.[48,53] Bronchoscopy can also be performed to evaluate for small distant metastases or second primary cancers of the lung, which have been reported to occur in 2% HNSCC patients independent of stage.[54] The findings from the examination under anesthesia and endoscopy are then used to calculate clinical staging of the primary site.

Approximately 2% to 9% of patients who have cancer of the oropharynx will initially present with cervical lymphadenopathy with an unknown primary.[55] The most common sites of primary lesions are the tonsillar fossa and base of tongue, which account for 82% of cases.[56] Panendoscopy is crucial for these patients and tonsillectomy is recommended if the primary cancer is not identified as up to 25% of unknown primaries are located in this site. Bilateral tonsillectomy is merited in these cases because of a 10% rate of contralateral spread from occult tonsil lesions.[57,58] More recently, transoral robotic surgery (TORS) has been used to identify the unknown primary site in the tongue base in patients who have undergone a panendoscopy and tonsillectomy.[59] The most recent AJCC staging guidelines for SCC of the oropharynx use only tumor size, lymph node involvement, and the presence of distant metastases as predictors of overall survival (**Table 14.1**). Future alterations to the AJCC system will likely include HPV status as a major component of patient staging.

Table 14.1 AJCC Staging for Squamous Cell Carcinoma of the Oropharynx

Tumor (T) Stage			
T1	≤2 cm		
T2	2–4 cm		
T3	>4 cm or extension to lingual surface of epiglottis		
T4a	Invades larynx, extrinsic muscles of tongue, medial pterygoid, hard palate, or mandible		
T4b	Invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, skull base, or encases carotid		
Lymph Node (N) Stage			
N0	No regional lymph node metastasis		
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest diameter		
N2a	Metastasis in a single ipsilateral lymph node, >3 cm in greatest diameter		
N2b	Metastases in multiple ipsilateral lymph nodes, none >6 cm in greatest diameter		
N2c	Metastases in bilateral or contralateral lymph nodes, none >6 cm in greatest diameter		
N3	Metastasis in a lymph node >6 cm in greatest diameter		
Overall Stage			
Stage	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
IVA	T4a	N0-N2	M0
	T1–T3	N2	M0
IVB	T4b	Any N	M0
	AnyT	N3	M0
IVC	AnyT	Any N	M1

Laboratory Diagnosis of HPV-Related Tumors

Because the HPV has recently emerged as an important etiological factor in the increasing incidence of oropharyngeal cancer, and as a highly relevant biomarker of treatment outcomes for cancer of the oropharynx, a systematic method of detection is essential. The ideal diagnostic detection methods will either localize the genome of high-risk HPV genome to tumor cell nuclei or demonstrate the expression of viral oncogenes, E6 or E7.[60] The most commonly used methods to achieve these aims are p16 immunohistochemistry and in situ hybridization.[61] p16 immunohistochemistry has emerged as a reliable surrogate marker of HPV-

induced neoplasia of oropharynx. In HPV-positive oropharyngeal carcinomas, transcription of the viral oncoprotein E7 is known to functionally inactivate the *retinoblastoma* (*Rb*) gene product. Disruption of this pathway leads to an upregulation of p16 expression that can be detected by immunohistochemistry.[42] In situ hybridization probes are type specific, and therefore multiple probes are necessary to test a complete tumor genotype. Because 90% to 95% of cancers of the head and neck are related to HPV 16 and to a lesser extent HPV 31, 33, 35, the false negative rate of ISH is low.[62] Direct comparison of p16 immunohistochemical staining and HPV-16 ISH for large numbers of HNSCCs reveals a 24% discordance rate. The discrepancies consistently involve cancers that are negative by HPV16 ISH but p16 positive by immunohistochemistry. About 45% of these cases can be attributed to the presence of some other (non-16) HPV type, as confirmed by wide spectrum ISH. The remaining discrepancies are probably due to false-positive staining of p16, which can be seen in basaloid carcinomas that are not related to HPV infection.[62] To optimize HPV detection, a combination of p16 staining with ISH is the most effective. Because the sensitivity of p16 IHC approaches 100%, this is a reasonable first-line test to confidently eliminate those cases that are HPV negative. HPV16 ISH can then be run as a second-line assay for the p16-positive cases, and given a specificity of nearly 100%, the number of false positives from p16 staining alone will be reduced. The combination of these two assays identifies a subset of cancers that require a more rigorous analysis for non-HPV 16 oncogenic types. This third-line assay can either be consensus ISH probe set or PCR for the detection of transcriptionally active virus. This algorithm accurately detects HPV in the majority of cases, and although some tumors may require a more extended analysis, the overall expense is reduced because these cases are preselected.

TREATMENT

Management of cancers of the oropharynx is very challenging, given the essential role this anatomic site plays in breathing, speech, and swallowing. Alterations in any of these functions can significantly impact quality of life. Therefore, the goal of treatment is to not only achieve an oncologic cure but also preserve the multimodal function of the oropharynx. Traditional surgical approaches to the oropharynx are associated with significant morbidity, which prompted a shift toward nonsurgical modalities in the 1990s,

specifically using radiation or chemoradiation, which have been the mainstay therapeutic approaches for the past 15 to 20 years. Although the oncologic results for radiation-based therapies have been shown to be equivalent to traditional surgical approaches, the short-term and long-term sequelae can significantly impact quality of life.[63,64] However, recent technological innovations have led to a renewed enthusiasm for surgical options in the oropharynx through a transoral approach. These transoral approaches potentially allow for the adjuvant therapy to be modified based on the pathological findings of the resection specimen. This novel paradigm can reduce the radiation doses and may theoretically decrease the long-term side effects. These advantages become more imperative considering the large emerging population of young patients with HPV-related cancer who are expected to survive for many years.

Surgical Techniques

Open Surgical Approaches

Lateral and Suprahyoid Pharyngotomy.

The lateral pharyngotomy, originally described by Trotter in 1920, requires resection of the mandible, hypoglossal nerve, and lingual artery in order to achieve adequate visualization of the resection margins. Since that time, the technique has been modified in an effort to preserve these vital structures. The modern lateral pharyngotomy begins with a selective neck dissection of levels I–IV. After the specimen is removed, the lateral horn of the hyoid bone, superior laryngeal nerve, hypoglossal nerve, branches of the external carotid artery including the facial, lingual, and superior thyroid arteries are identified and preserved. The tendon of the digastric muscle is then divided exposing the stylohyoid and mylohyoid muscles, which are subsequently released from the hyoid at their insertion. The hypoglossal nerve and lingual artery, the two most important structures, are then isolated. At this point, the extent of parapharyngeal space involvement can be accurately assessed, and the ascending pharyngeal artery can be identified and ligated to allow the posterior belly of the digastric muscle, the stylohyoid muscle, and external carotid artery system to be retracted and rotated. This maneuver provides optimal exposure for entry into the pharynx. The point of entry into the pharynx is determined by the location of the tumor and most frequently is at

the level of the vallecula. Alternatively, the pharyngotomy can be performed more superiorly in the oropharynx at the level of the tonsillar region, but this requires transection of the styloglossus muscle. If the tumor extends to the vallecula, a third entry point is at the ipsilateral piriform sinus. Once the pharyngotomy is performed, the incised mucosa is retracted superiorly to allow adequate visualization of the lesion and circumferential margins, and the cancer is resected en bloc. For smaller defects, mobilization of the posterior wall of the pharynx from the prevertebral fascia can facilitate primary closure. In the cases of larger defects, a microvascular free tissue transfer is the preferred method for anatomic restoration for optimal speech and swallowing outcomes.[65]

Contraindications to this surgical approach include cancer arising from the vallecula, posterior pharyngeal wall, lateral epilarynx, nasopharynx, piriform sinus, or soft palate extending to lateral oropharynx. Additionally, extensive involvement of the parapharyngeal space, invasion of the nasopharynx, or involvement of more than half of the base of the tongue are considered contraindications.[65]

Similar to the lateral oropharyngotomy approach, the suprahyoid approach to the base of tongue has not gained significant popularity because of concerns raised throughout the 1900s that these approaches were oncologically unsound due to poor exposure and violation of the preepiglottic space.[66–68] More recently, the utility of the suprahyoid approach for T1 and T2 lesions has been confirmed, with favorable functional and oncologic outcomes.[69] The surgical approach begins with ipsilateral or bilateral neck dissections depending on the nodal status and the location of the primary. Once the neck dissection is completed, the suprahyoid muscles are transected 5 mm above the hyoid bone. Preserving this cuff of muscle facilitates the closure of the pharynx. The hypoglossal nerves are identified near the greater cornu of the hyoid bilaterally and preserved along with the superior laryngeal nerves and the lingual arteries. The preepiglottic space is then identified, and dissection is carried down to the vallecula. The pharyngotomy is facilitated by placing a retractor through the mouth into the vallecula, and the pharynx is entered at this level through the vallecula. The mucosal edge is retracted superiorly to allow visualization of the base of the tongue and the cancer. Under direct visualization, the specimen is removed with adequate margins. In most cases, the wound can be closed primarily by suturing the mucosa of

the base of the tongue to the vallecula. The remaining wound is closed in layers by reapproximating the musculature of the base of the tongue to the periosteum of the hyoid and the suprahyoid musculature to the cuff of muscle left on the hyoid.[69] The multilevel closure prevents fistula formation and allows for resuspension of the larynx, which will facilitate rehabilitation from postoperative dysphagia.

Ideal lesions for this approach are those that are confined to the base of the tongue, although cancers that extend laterally can be addressed with combination of suprahyoid and lateral pharyngotomy approaches. Contraindications to this approach include extension of the cancer to the circumvallate papillae, as the defect would be difficult to close primarily and the exposure is poor, and involvement of the epiglottis or larynx, as laryngeal resection would also be required.[69]

Mandibulotomy.

Mandibulotomy with paralingual extension into the floor of mouth provides excellent exposure to the tonsillar fossa, soft palate, and the base of the tongue. The mandibulotomy can be performed either in the midline or paramedially, between the lateral incisor and canine tooth. Lateral mandibulotomy is not recommended because the dynamic forces on the mandible are not symmetric, and intermaxillary fixation may be necessary to maintain appropriate occlusion. Additionally, the lateral mandibulotomy site is routinely within the radiation fields, which may lead to problems with wound healing and potentially osteoradionecrosis. A paramedian mandibulotomy offers the advantages of a median mandibulotomy and avoids the transection of the genioglossus muscles.

The skin incision is made from the lower lip to the hyoid bone, and a curvilinear extension can be used to include a neck dissection. The skin, subcutaneous tissue, and lip musculature are incised until the mandible is exposed. The paramedian mandibulotomy is performed through the socket of the extracted lateral incisor juxtaposed to the canine, after the mandible is preplated. Following transection of the mandible, the two segments are retracted laterally, and the mucosal incisions are made in the floor of mouth. In order to facilitate closure, a 6- to 8-mm cuff of mucosa should be left attached to the lingual gingiva. The mucosal incision can be extended to the retromolar trigone or into the vallecula if exposure to the base of the tongue

is necessary. The genioglossus muscles are preserved by dividing the mylohyoid muscle, and the lingual nerve permits the lateral swing of the mandible. Additional exposure to the base of the tongue can be achieved dividing the pharyngeal constrictors at the junction of the base of the tongue and the lateral pharyngeal wall. After the tumor is resected and the defect is reconstructed, the mandibular segments are approximated and replated with reconstruction plates, and the mylohyoid muscle and floor of mouth mucosa are closed in layers.[70]

A segmental mandibulectomy may be necessary when the mandible is directly involved with cancer or in the setting of recurrent cancer after radiation therapy where the vascular integrity of the periosteum is compromised. The exposure for a mandibulectomy is identical to the approach for the mandibulotomy. The extent of mandible to be resected is dictated by the extent of the cancer, but frequently the condyle can be preserved and the ascending ramus is divided at the level of the sigmoid notch.[70] Preservation of the condyle facilitates the reconstruction because a fibular osseous cutaneous free flap can be fixated to this residual fragment and maintains appropriate articulation of the temporomandibular joint. Alternatively, when only the ascending ramus or posterior aspect of the body of the mandible requires resection, a soft tissue reconstruction may be used with excellent cosmetic and functional outcome especially in edentulous patients. When a mandibulectomy is required, it is important to have an appropriate preoperative assessment for immediate reconstruction. The decision to reconstruct with a fasciomyocutaneous or osseocutaneus free tissue transfer or a regional pedicled soft tissue flap must be individualized for each patient and surgical defect. Regardless of the reconstructive option selected, all of the potential reconstructive options should be discussed preoperatively with the patient.

Transoral Approaches.

The transoral approach for radical excision of tonsillar cancers was originally described by Huet in 1951.[71] This procedure begins with palpation to confirm that the involved tonsil region is mobile because fixation to the deep fascial layers is a contraindication to this technique. Once mobility is confirmed, the raphe between the superior constrictors and buccinator muscles is identified, and the overlying mucosa is incised. The incision is made superiorly along

the maxillary dentition and inferiorly at the level of the posterior floor of mouth. The tonsil is grasped and retracted medially, which also brings the superior constrictor muscle medially. This opens the submuscular plane, which includes the palatopharyngeus muscle, palatoglossus muscle, and superior constrictors as the deep margin of the oncologic specimen. The plane is further developed to the prevertebral fascia using blunt dissection. With the prevertebral fascia exposed, the internal carotid artery can be identified posterolaterally to the deflected posterior tonsillar pillar. The anterior tonsillar pillar is transected superiorly. The posterior tonsillar pillar is also transected posteriorly and separated from the posterior pharyngeal wall. The inferior extent of the resection is at the level of the tongue where the anterior tonsillar pillar is transected and followed along the glossopharyngeal fold. With strong retraction superiomedially, the inferior margin is visualized at which point the stylopharyngeus and styloglossus muscles are transected. The posterior pharyngeal incision is then connected with this inferior margin to complete the resection.[5,72]

Contraindications to the procedure include trismus, fixation of the tonsil to the lateral oropharyngeal wall, and invasion of the mandible. Each of these features suggests infiltration of the cancer into the masticator and/or parapharyngeal space or into the prevertebral fascia. In addition, cancers that extend outside of the tonsillar fossa and into the nasopharynx, glossopharyngeal fold, base of the tongue, vallecula, pharyngoepiglottic fold, and/or pyriform sinus are not optimal for traditional transoral approaches. Lastly, poor exposure of the oropharynx due to individual patient anatomic or dental considerations is also considered a major contraindication.[72]

Transoral Robotic Surgery.

TORS was first described by Hockstein et al.[5,73] In using the robot for excising cancer of the tonsil, the cancer is initially examined with the patient under general anesthesia, and the margins of the cancer are marked. The cancer is then exposed using either the FK or the Crowe Davis retractor. At this point, the robot is docked at a 30-degree angle at the level of the patient’s axilla. Using the zero-degree telescope and electrocautery, an incision is made at the pterygomandibular raphe, and the buccal mucosa is retracted medially. The constrictor muscles are elevated off the prevertebral fascia and the styloglossus, and stylopharyngeus are identified and transected to expose

the adipose tissue overlying the prevertebral fascia. The carotid artery is then identified deep to the prevertebral fascia. At this point, the inferior incision is made along the posterior floor of mouth into the base of the tongue. The vascular pedicle of the inferior tonsillar pole is well visualized, and the vessels are controlled with either endoscopic hemoclips or electrocautery. If the dissection includes the base of the tongue, the lingual nerve and subsequently the lingual artery are identified. The lingual artery should be controlled with hemoclips. Once the lingual artery is controlled, the dissection of the base of the tongue continues down to the level of the vallecula. The specimen is now mobilized by resecting it away from the posterior pharyngeal wall.[74] Although the role of this surgical technique is still being determined, early oncologic results from several case series are comparable to the outcomes observed with radiation or concurrent chemoradiation (**Table 14.2**). However, many patients who undergo TORS also receive postoperative adjuvant radiation therapy or chemoradiation therapy, and therefore it is difficult to determine if TORS adds oncologic benefit or improved QOL in the patients with lesions amenable to TORS but with extensive primaries or regional nodal metastasis who will need adjuvant treatment.

Table 14.2 Oncologic Outcomes in Transoral Robotic Surgery

Study	No. of Patients	Post-Op XRT	Post-Op Chemo-XRT	Follow-Up (Months)	Locoregional Control	Overall Survival
Hurtuk et al.[75]	54	91%	63%	12	n/a	n/a
Genden et al.[76]	36	83%	46%	18	91%	90%
White et al.[77]	89	63%	48%	24	86%	89%
Weinstein et al.[78]	31	38%	38%	24	96%	100%
Weinstein et al.[79]	47	57%	57%	27	96%	96% (III)
						82% (IV)

Cancer-related contraindications for TORS include unresectable cervical lymphadenopathy, invasion of the mandible, pharyngeal wall or base of the tongue involvement requiring resection of >50% of these sites, radiologic evidence of involvement of the carotid artery, and fixation to the prevertebral fascia. The other limitation of transoral surgery is access, and therefore a thorough preoperative assessment of the patient and the characteristics of the cancer is essential. This assessment should include an evaluation of the dentition, presence of trismus or tori, size of the tongue, degree of neck

extension, sequelae of previous treatment, and the extent of the cancer. The oncologic outcomes for robotic surgery have been favorable thus far with overall and disease-free survival rates ranging from 82% to 100% and 86% to 96%, respectively (Table 14.2).

Transoral Laser Microsurgery.

Initially described by Vaughan, Strong, and Steiner in treating cancer of the larynx, this technique has been expanded to manage cancers of the oropharynx.[80,81] To adequately expose the primary cancer, a modified mouth gag or a modified expandable laryngoscope is used. Once exposure is achieved, an operating microscope or rod telescope is used to illuminate and magnify the operative field, which helps to identify healthy and neoplastic tissues at the perimeter of the resection. For exophytic cancers, the lesions are cored out and reduced in size, and the rind of cancer that remains is subsequently managed using a series of transtumoral incisions. The cancer is deliberately transected at a series of locations to map the deep extension along the invading front. A reasonable margin of 1 to 1.5 cm is excised beyond the invading front of the cancer. These margins are then inked to determine orientation and then analyzed by a pathologist. Frozen sections are used to direct further laser resection of residual microscopic or submucosal disease. Defects from these resections that expose the mandible or the great vessels of the neck or arefull thickness through the soft palate will require a soft tissue reconstruction using either local or free tissue flaps.[82] The oncologic outcomes for transoral laser microsurgery have been favorable thus far with overall and disease-free survival rates ranging from 82% to 100% and 86% to 96%, respectively (Table 14.2).

Radiation Therapy

Radiation therapy is a standard approach for definitive treatment for the oropharynx, which combines the goal of an oncological cure with organ preservation.[83] The current RT regimens are the results of several large randomized trials that have demonstrated favorable overall and disease-free survival rates,[84–89] although permanent dysphagia and gastrostomy tube usage rates remain substantial. Total radiation dosages and overall treatment times are regarded as important variables for oncologic response and for tissue toxicity. Therefore, alterations in fractionation schedules have been

investigated in an effort to improve locoregional control rates compared to conventional RT. Several studies have shown that altered fractionation improved the locoregional rate, and a meta-analysis of 15 trials demonstrated a survival advantage with altered fractionation regimens.[86,88,89] Because cancers of the oropharynx are adjacent to several critical structures, the ideal dose distributions would tightly conform to the target area and spare the nonaffected surrounding tissue. Traditional RT was restricted to lateral x-ray beams, which limited the ability to spare nearby unaffected tissue. Intensity-modulated radiation therapy (IMRT) allows for several treatment fields of nonuniform beam intensities, which generate more conformal dose distributions. One of the primary benefits of IMRT is the ability to conform the dose distributions around the cancer with relative sparing of the parotid glands, which has led to decreased xerostomia and improved functional and quality of life outcomes.[90,91] Although the benefits of IMRT are well established, there are tradeoffs with this technique. More specifically, the use of multiple oblique beams increases the volume of radiation, and therefore more tissues are being radiated, albeit at lower doses. The two regions that are associated with IMRT unique side effects are the far posterior structures, including the occipital scalp and brainstem, leading to increased occipital alopecia and nausea and vomiting, and at the anterior mandible, which correlates with oral cavity mucositis.[92] Additionally, IMRT has increased doses to the skin, larynx, and esophagus, which has some potential negative effects.

More recently, proton therapy has been implemented in the treatment of OPSCC. Protons confer advantages over more traditional forms of photon-based RT. IMRT uses photons (x-rays), which deposit the greatest radiation dose near the surface of the skin, and the dose slowly diminishes in intensity with increasing depth. In contrast, intensity-modulated proton therapy (IMPT) involves the use of protons, which deposit minimal dose near the surface of the skin but deliver most of the radiation dose to the tumor bed.[93]

Since 2011, radiation oncologists at the UTMD Anderson Cancer Center have treated 26 patients with OPSCC using IMPT, with a median follow-up time of 10 months (range, 0 to 22 months). Of the patients treated, 50% had never smoked and all had HPV-positive tumors. Systemic therapy was a component of treatment for 20 patients (77%), and the prescribed radiation dose was 70 Gy in 33 fractions. During treatment, five patients (19%)

developed grade 3 dysphagia requiring a gastrostomy tube, which is less than half the recently published rate for IMRT.[94] At last follow-up, all patients were disease free. Based on these encouraging preliminary findings of reduced toxicity and consistent disease response with IMPT, a phase II/III randomized trial comparing the toxicities of IMPT versus IMRT for advanced-stage OPC has been initiated.

Chemotherapy

Neoadjuvant Treatment.

Induction chemotherapy (neoadjuvant) in locally advanced cancer of the head and neck offers several theoretical benefits including the administration of more intensified chemotherapy than with concurrent therapy, with a potential for reducing the risk of distant metastases by treatment of micrometastatic disease.[63,95] Additionally, it can be used to reduce tumor bulk before a definitive approach to therapy and has been used to select patients for organ preservation. Despite these advantages, clinical trial data have not definitively demonstrated a survival benefit for induction chemotherapy, and its use remains controversial. Initial studies of induction chemotherapy showed improvement in locoregional control and overall survival and decreased development of distant metastases.[96,97] Unfortunately, a large meta-analysis that summarized the experience with induction chemotherapy demonstrated that only a 2.4% improvement in survival was offered by induction treatment, an effect that is inferior to the absolute survival benefit seen with concurrent chemoradiation therapy.[98] Iteractive analysis of these data revealed that platinum/fluoruracil (PF)-based induction regimens were associated with a 4.3% reduction in the rate of distant metastases.[99] In an effort to enhance the effect of the platinum/fluorouracil-based regimens, docetaxel was added as a third agent. The addition of docetaxel to PF resulted in a significant improvement in overall survival (71 vs. 40 months, $p = 0.0006$) compared to PF alone, but the rate of distant metastatic disease was not significantly different between the groups.[100] Although the addition of docetaxel to PF is a superior induction regimen than PF alone, the optimal concurrent treatment has not been identified, and the superiority of induction versus concurrent chemoradiation has not been demonstrated. Furthermore, HPV-related cancers have been shown to have high survival rates when

treated with induction chemotherapy, but it remains to be determined whether HPV status can be used as a predictive biomarker of response to treatment. In summary, to date, no trials have shown a clear survival benefit for induction chemotherapy over concurrent chemoradiation. Because of this, concurrent chemoradiation with cisplatin is still considered the standard of care for most patients with locally advanced SCC of the head and neck. As locoregional treatment continues to improve, distant metastatic failure is becoming a more frequent cause of disease-related death. Although induction chemotherapy could reduce this risk, the patients who would derive the greatest benefit remain largely unknown.

Concurrent Chemoradiation.

The classic pattern of relapse after RT in OPSCC has been local–regional recurrence, which has been attributed to the development of radioresistant cancer cells that persist after treatment. To overcome this resistance, chemotherapy has been added to sensitize the cancer cells to the damaging effects of ionizing radiation. For patients with locally advanced oropharyngeal cancer, a pivotal randomized phase III trial by the French GORTEC group revealed an improvement in both progression-free survival and overall survival for patients receiving combined modality therapy (42% and 51%) versus radiation therapy alone (20% and 31%) and improvement in locoregional control rates in the chemoradiation arm (66%) versus radiation therapy alone (42%) (**Fig. 14.8**). Despite these benefits, similar rates of distant metastases were observed in both arms (11%), and more significant side effects, including hematologic toxicities and grade 3 and 4 mucositis, were observed in the chemotherapy arm.[101] These toxicities led to a higher rate of temporary gastrostomy tube usage in the combination arm compared to the radiation therapy–alone arm. Taken together, these results suggest that the addition of chemotherapy concurrently to radiation therapy improves locoregional control, which translates into both an overall and progression-free survival benefit for these patients, at the expense of more acute toxicities.

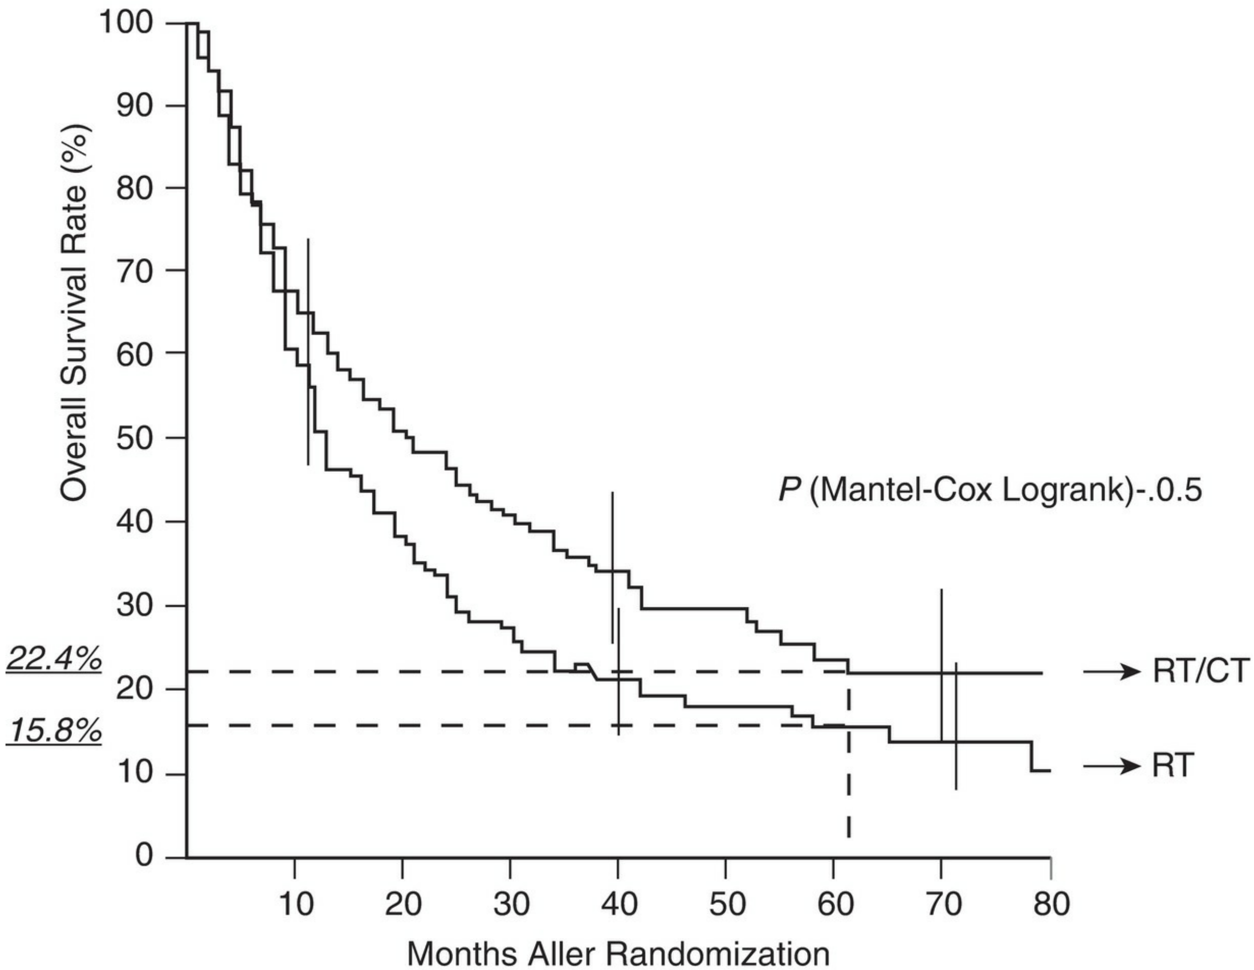

Figure 14.8. Overall survival among patients with cancer of the oropharynx treated with radiation therapy (RT) or with radiation therapy with concomitant chemotherapy (RT/CT) as analyzed by Kaplan-Meier method. (From Denis F, et al. Final results of the 94-01 French Head and Neck Oncology and Radiation therapy Group randomized trial comparing radiation therapy alone with concomitant radiochemotherapy in advanced-stage oropharynx carcinoma. *J Clin Oncol.* 2004;22(1):69–76, with permission.)

To assess the benefit of concurrent chemotherapy for patients with either resectable or unresectable head and neck cancer, a meta-analysis of 87 randomized trials between 1965 and 2000 was performed. This analysis showed that the addition of chemotherapy led to an 9.3% reduction in locoregional recurrence at 5 years but the improvement in survival was modest, at only 5%.[99,101] The oncologic benefits of concurrent chemotherapy and radiation must be weighed against the associated increase in acute side effects with this treatment. For example, high-grade mucositis has been seen

in up to 71% of patients treated with concurrent therapy versus 39% in a radiation-only cohort.[87] In addition to cytotoxic chemotherapy agents, cetuximab, a monoclonal antibody inhibitor of EGFR, has been shown to improve locoregional control and overall survival relative by nearly 10% at 5 years to radiation alone (**Fig. 14.9**).[84] The role of cetuximab with radiation therapy for HPV-positive OPSCC, in place of cisplatin, is currently under investigation through a multi-institutional clinical trial.

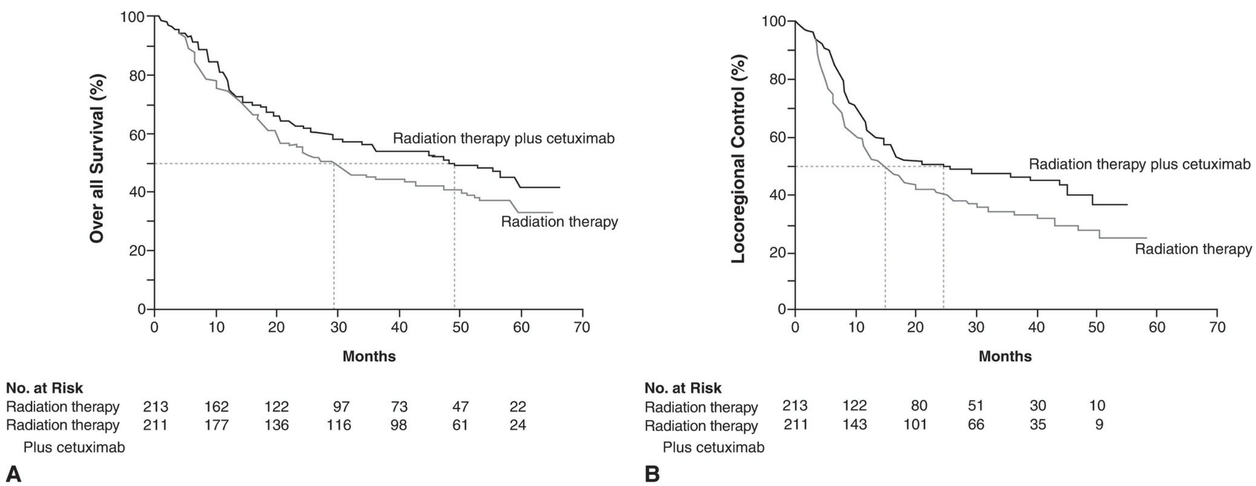

Figure 14.9. Kaplan-Meier estimates of overall survival (A) and locoregional control (B) among all patients randomly assigned to radiation therapy plus cetuximab or radiation therapy alone. (From Bonner JA, et al. Radiation therapy plus cetuximab for squamous-cell carcinoma of the head and neck. *N Engl J Med.* 2006;354(6):567–578.)

Adjuvant Chemotherapy.

The risk of recurrence for locally advanced OPSCC following surgical resection has traditionally been high. For patients with high-risk features, including perineural invasion, multiple positive metastatic nodes, and advanced T stage, postoperative radiation has been shown to decrease locoregional recurrences.[102] Furthermore, it has been shown that the addition of chemotherapy given concurrently can improve locoregional control rates in patients with high-risk features that include positive surgical margins, extracapsular extension, multiple positive lymph nodes, or perineural invasion.[103,104] There were conflicting results on an overall survival benefit between these two studies, which may have been due to the differences in

their inclusion criteria. A collaborative comparative analysis of these two trials identified positive surgical margins and extracapsular extension as the only two variables associated with improved outcomes with the addition of chemotherapy to radiation.[105] Thus, patients who undergo surgical resection of oropharyngeal cancer should be considered for adjuvant chemoradiation therapy when adverse pathological features are present. Whether this treatment paradigm is necessary for HPV-positive patients is currently under investigation.

Management of the Neck

In carefully selected cases of lateralized cancer of the tonsil, the treatment can often be restricted to the primary site and ipsilateral cervical and retropharyngeal lymph nodes. This management can be executed with surgery or definitive radiation. In the case of radiation, excellent locoregional control, low contralateral cervical lymph node failure rates, and a lower toxicity profile compared to bilateral neck treatment have been achieved.[106,107] Compared with bilateral neck irradiation, this approach substantially reduces the dose to the contralateral major salivary glands, uninvolved upper aerodigestive tract mucosa, and important swallowing structures.[108] The ideal patients for the unilateral approach had T2 or lower primary site disease with minimal soft palate involvement and no involvement of the base of the tongue. Locoregional control rates for both the primary site and ipsilateral neck were 100% at 5 years in this series of 102 patients, and at a median follow-up interval of 39 months, only 2 patients had developed a contralateral recurrence. With regard to toxicity, only 9 patients required placement of a feeding tube during therapy, and no patient experienced long-term dependence on a feeding tube.[108] With these promising findings observed with unilateral radiation therapy, the potential for unilateral surgical management of low-volume tonsillar cancer and the ipsilateral regional lymphatics as a single modality needs to be investigated.

Assessment of Treatment Response.

Following nonsurgical treatment of OPSCC, the primary site and neck should be clinically assessed 4 to 8 weeks following the completion of treatment. If persistent or progressive disease is detected, a CT and/or MRI with contrast should be obtained to assess the extent of local and regional disease.

Additionally, a CT scan of the chest or PET/CT should be considered for the evaluation of distant metastases disease. If a clinical response is detected 4 to 8 weeks after treatment, a CT and/or MRI should be obtained, and if there is no evidence of metastases, the patient can be observed with repeat imaging within 6 months. If persistent disease is detected, a PET/CT can be obtained 12 weeks from the completion of treatment or a neck dissection can be performed. If PET/CT is obtained, there are four treatment scenarios:

1. If no lymph nodes are detected or the lymph node is <1 cm but not FDG avid, then the patient can be observed with repeat imaging with 6 months.
2. If there is a lymph node <1 cm and FDG avid, then the patient can either be observed closely with repeat imaging in 4 to 8 weeks, undergo an ultrasound-guided fine needle aspiration, or proceed with a neck dissection.
3. If a lymph node is >1 cm but not FDG avid, then the patient can either be observed closely particularly if there has been significant nodal regression from pretreatment imaging, or an ultrasound-guided fine needle aspiration, or proceed with a neck dissection.
4. If a lymph node is >1 cm and FDG avid, then proceed with a neck dissection.

The addition of PET/CT imaging to the clinical evaluation of posttreatment surveillance of patients with OPSCC in the National Comprehensive Cancer Network Clinical Practice Guidelines is the result of several studies demonstrating the predictive value of this study. The negative predictive value for posttreatment PET/CT ranges from 85% to 99%.[109–116] Additionally, some studies have shown that patients with a negative first posttreatment PET/CT have an improved survival compared to those patients who have a positive PET/CT.[110–116]

Management of Local–Regional Recurrence

Despite the development of complex multimodality therapy for patients with OPSCC, 25% to 50% will recur.[117,118] Patients who develop recurrent OPSCC have long-term survival rates ranging from 23 to 35%.[119] Given the low survival rates and potentially high morbidity, multidisciplinary head and neck oncology teams must carefully weigh the risks versus benefits when considering treatment options. Although radiation therapy with or without

chemotherapy has become the preferred method of treating the majority of primary OPSCC, salvage options are limited for patients that have failed initial treatment.[120,121] Traditionally, salvage surgery has been considered the only potentially curative option, while chemotherapy and reirradiation have been reserved for unresectable disease or adjuvant therapy after salvage surgery.[122–126] Unfortunately, of the patients who recur, only 10% to 20% are favorable candidates for salvage surgery.[118,127] These patients are typically younger, have a longer disease-free interval after receiving definitive therapy, have small recurrent tumors where negative surgical margins can be achieved, and do not have recurrent neck disease.[118] Patients with recurrent disease harboring these characteristics and undergo salvage surgery with negative margins have an estimated 3- and 5-year overall survival of 42% and 28% respectively.[118] Given these low survival rates, it is important to consider all treatment options for recurrent OPSCC.

Reirradiation has been proposed as another curative approach for recurrent OPSCC with 5-year survival rates ranging from 13% to 22%, but it is associated with severe or fatal complications in 9% to 32% of patients.[128] Two Radiation Therapy Oncology Group trials evaluated reirradiation for recurrent head and neck SCC, which included 40% to 50% recurrent OPSCC. These trials reported greater than grade 4 acute toxicity in more the 25% of patients, treatment-related death in 8% of patients, and a median survival of 8 and 12 months, respectively.[129,130] In a retrospective review of patients with recurrent OPSCC, Zafereo et al.[118] reports a 5-year survival rate of 32% for patients who received definitive reirradiation or brachytherapy with or without chemotherapy.

Chemotherapy can be implemented as a palliative treatment but is not a curative option. Approximately one-third of patients with recurrent OPSCC have a partial response to platinum-based chemotherapy, with a median survival ranging from 4 to 6 months and 2-year overall survival rates of 5% to 10%.[119,131] Additionally, the addition of cetuximab to platinum–fluorouracil chemotherapy has shown a survival benefit compared to platinum–fluorouracil chemotherapy alone in patients with untreated recurrent or metastatic SCC.[132] Although a spectrum of treatment options is available for recurrent OPSCC, very few patients are able to achieve long-term survival; therefore, the successful management of the initial disease is crucial to improve outcomes for OPSCC.

BIOMARKERS AND RISK STRATIFICATION

Biomarkers aim to identify patients at high risk for recurrence and death from their disease (prognostic) and can also be used to predict patient response to specific therapies (predictive). Numerous studies have demonstrated that HPV-related oropharyngeal cancers are associated with improved outcomes.[3,133,134] Unfortunately, the presence of HPV alone is insufficient to stratify patients, and complementary biomarkers are now being identified to identify patients at highest risk for recurrence. To date, explored biomarkers include EGFR, p16, p53, Bcl-xL, and *p53* mutations. In a study of advanced OPSCC, patients with favorable expression profiles (low EGFR and high HPV titer/p16 or low p53 with low Bcl-xL) showed significantly improved overall and disease-free survival (**Fig. 14.10**).[133] Furthermore, a retrospective analysis of RTOG 0129 identified distinct risk categories for patients treated with concurrent chemotherapy and radiation based on HPV status, pack-years of smoking, along with the N stage for HPV-positive tumors and T stage for HPV-negative tumors. Using this stratification, low-risk patients defined as HPV-positive tumors and <10 pack-years of smoking and high-risk patients defined as HPV-negative tumors and >10 pack-year smoking history had 3-year overall survival rates of 93% and 46.2%, respectively. Intermediate-risk patients, with HPV-positive tumors with smoking history, had a 3-year overall survival of 70.8% (**Fig. 14.11**).[135] Bcl2 combined with HPV status has also been analyzed retrospectively and has identified a subset of patients at high risk for recurrence and more specifically for the development of distant metastases. Because high Bcl2 expression is associated with decreased survival outcomes, small molecule inhibitors are currently under investigation.[134]

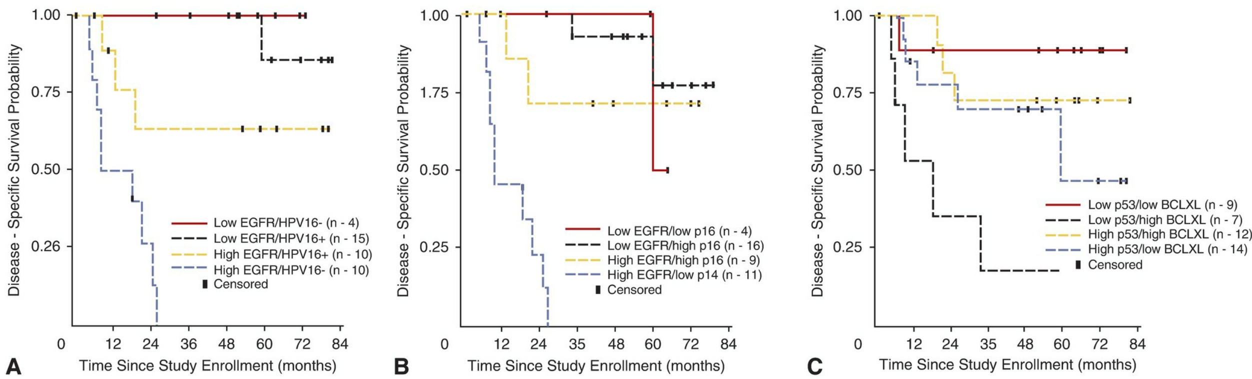

Figure 14.10. Kaplan-Meier curves for disease-free survival on risk stratification by EGFR, HPV-16, p16, p53, and Bcl-xL. **A.** Disease-specific survival according to epidermal growth factor receptor (EGFR) intensity and HPV16. **B.** Disease-specific survival according to EGFR intensity and p16 proportion. **C.** Disease-specific survival of patients on the basis of tumor p53 and Bcl-xL expression. (From Kumar B, et al. EGFR, p16, HPV Titer, Bcl-xL and p53, sex, and smoking as indicators of response to therapy and survival in oropharyngeal cancer. *J Clin Oncol*. 2008;26(19):3128–3137.)

FUNCTIONAL OUTCOMES

Although swallowing outcomes highly depend on tumor burden, baseline functionality, treatment intensity, and supportive care, after primary radiation therapy or chemoradiation for OPSCC, it is estimated that on the whole, 7% to 31% develop chronic aspiration,[136,137] 11% develop aspiration pneumonia,[138] and are chronically feeding tube dependent.[139] To date, surgical series have been published in highly selected cohorts, and functional outcomes have been explored primarily with questionnaire data (rarely with instrumental studies). Acknowledging these limitations, after primary TORS for OPSCC, it is estimated that 0% develop chronic aspiration, 0% to 7% develop postoperative pneumonia, 20% to 40% require gastrostomy placement, and 0% to 7% are chronically feeding tube dependent after treatment.[140] Dose-dependent effects are robustly demonstrated with risk of dysphagia increasing after roughly 50-Gy mean dose to pharyngeal constrictors and 20-Gy mean dose to the larynx.[137]

Preventive swallow therapy is best practiced for patients receiving radiation therapy as a component of therapy for OPSCC and is supported by numerous randomized trials and large observational studies.[141–143] The central premise of proactive swallowing therapy is “Use It or Lose It” to mitigate muscular wasting and remodeling that occurs after even brief intervals of disuse. Preventive or proactive swallowing therapy encourages maximal use of the swallowing musculature during treatment by (1) avoiding NPO intervals, and (2) adhering to swallowing exercise regimes. To implement in the clinical setting, routine pretreatment referral to a speech pathologist is recommended.

SUMMARY

SCC of the oropharynx has classically been associated with tobacco and alcohol consumption. Unlike other aerodigestive tract subsites, the incidence of OPSCC has increased in recent decades due to increased infection with high-risk types of HPV. The integral role of the oropharynx in speech, swallowing, and breathing prompted a shift from the substantially morbid open surgical procedures toward nonsurgical organ preservation therapies. These radiation therapy-based approaches offer similar survival outcomes to surgery. Over the past two decades, numerous studies have attempted to determine the optimal regimen for head and neck squamous carcinoma, and

currently, the standard remains concurrent platinum-based chemotherapy with radiation. Yet, long-term dysphagia, gastrostomy tube usage, and osteoradionecrosis remain substantial survivorship issues for patients. The emergence of HPV-related OPSCC and novel surgical technologies has reignited an interest in surgical approaches to the oropharynx, and ongoing prospective clinical trials are exploring the oncologic and functional outcomes of TORS with radiation. Because HPV-related OPSCC is associated with improved survival outcomes, clinical trials are exploring whether low- and intermediate-risk patients can undergo treatment de-escalation, while achieving acceptable oncological outcomes. As the incidence of OPSCC continues to increase, the results from novel trials will hopefully provide evidence for the appropriate management of both low- and high-risk patients.

15 Cancer of the Larynx

Richard O. Wein Kathryn A. Gold, G. Brandon Gunn, Randal S. Weber

The incidence of cancer of the larynx has stabilized at ~10,000 cases reported in the United States per year. The larynx is composed of three subsites that are unique in their predilection for regional spread, response to therapy, and capacity for laryngeal preservation with treatment. The major goals of therapy are to offer cure while preserving quality of life (QOL) and function. Posttreatment speech and swallowing capacity weigh heavily on a patient's selection from the variety of treatment options. With early-stage cancers, the monomodality treatment options of surgery or radiation offer the possibility of good locoregional control and maintenance of function. For advanced-stage lesions, the collaborative multimodality options of surgery with adjuvant radiation or primary chemoradiation (induction vs. concomitant) offer more aggressive approaches with associated toxicity and side effects while attempting organ preservation. As with all sites in the head and neck, recurrence has a poor associated overall prognosis and, when feasible, salvage options typically require radical surgical approaches with special techniques to facilitate functional rehabilitation.

Epidemiology

Approximately 0.7% of all new cancer cases and 0.6% of all cancer-related deaths are due to laryngeal cancer. It is the 21st most common cancer in the United States. The estimated 5-year relative survival for cancer of the larynx by stage at diagnosis, all stages included, was reported as 61% (for the years 2001–2007). The relative survival rate by race (all races included) for laryngeal cancer has remained stable over time with only a slight decline from 66% for 1975–1989 to 63% for 2001–2007.[1,2] In 2012, the American

Cancer Society reported 12,360 newly diagnosed cases of cancer of the larynx (male 9,840, female 2,520) and 3,650 deaths attributable to the disease.[1] In 2013, The SEER database estimated that 12,260 new cases of laryngeal cancer were diagnosed, representing 0.7% of all new cancer cases, with 3,630 attributable deaths.[2]

Statistics for patients with cancer of the larynx demonstrated a decrease in survival from the mid-1980s to the mid-1990s in a review performed by the National Cancer Data Base by Hoffman et al. It was noted that during this time frame, there was also an increase in nonsurgical approaches (chemoradiation or radiation alone) for the primary management of cancer of the larynx. This statistical decline in relative survival was most significant for patients with T1–T3 N0M0 supraglottic cancer.[3]

The male-to-female ratio is greater for glottic (9.2:1 among whites and 11.8:1 among blacks) than for supraglottic cancer (3–5:1 for both races).[4] Women are more likely to develop supraglottic cancer than glottic.[5] Cancer of the larynx has a peak incidence in the sixth and seventh decades with the median age at diagnosis of 65.[1] Less than 1% of cases occur in patients younger than 30 years of age, although it has been reported in children with no risk factors.[6,7]

Risk Factors

Multiple factors contribute to the development of cancer of the larynx. Foremost among them is the use of tobacco. Possible effects of secondhand smoking have not yet been carefully investigated for cancer of the larynx. The relationship of alcohol consumption to the relative risk is not clear; most studies show that it has a synergistic effect when combined with smoking. After controlling for factors such as tobacco exposure and average alcohol consumption, a case–control study using scoring with Michigan alcoholism and screening test (MAST) demonstrated an association between alcohol and the risk for development of glottic (OR = 1.9), supraglottic (OR = 2.3), and subglottic carcinoma (OR = 1.9). The highest risk was seen in patients consuming 42 or greater alcohol-based beverages per week (OR = 3.1).[8]

A review by the British Occupational Cancer Burden Study Group in

2012 attempted to summarize the occupational risk factors identified in Health and Safety Executive technical reports related to cancer of the larynx. Asbestos exposure and working within the rubber industry were considered to have a weak association with the development of cancer of the larynx. Contrary to this, occupational exposure to strong inorganic acids containing sulfuric acid was found to have a strong association (odds ratio = 2.90, 95% CI = 1.62 to 5.20) with cancer of the larynx and demonstrated an exposure–response relationship. The attributable fraction (AF) for all exposures combined for laryngeal carcinoma was 2.61% (95% CI = 0.83 to 4.32), largely due to the impact of strong inorganic acids, which equated to 20 attributable deaths.[9]

Dietary factors have also been postulated to have a significant influence on the development of laryngeal cancer. The International Head and Neck Cancer Epidemiology consortium investigated the impact of vitamin and mineral supplementation on the incidence of cancer of the head and neck by reviewing 12 case–control studies on the topic. The study included 1,329 patients with cancer of the larynx. Although supplementation with vitamin C (OR 0.76, 95% CI 0.59 to 0.96) and calcium (OR = 0.64, 95% CI 0.42 to 0.97) was associated with a reduced risk in the development of head and neck cancer (yet lacked a dose–response relationship), the authors ultimately failed to discern a strong association between the vitamin and/or mineral intake and risk reduction in the development of cancer.[10]

Reviews of the literature have failed to demonstrate a causal role of gastroesophageal reflux disease (GERD) as an independent risk factor in the development of cancer of the larynx. Cited confounding factors limiting the ability to confirm a statistical association include a coexisting history of habitual tobacco and alcohol use and the inherent inaccuracies in establishing the clinical diagnosis of GERD and laryngopharyngeal reflux (LPR).[11] Given that lower esophageal reflux is associated with the development esophageal adenocarcinoma and not esophageal squamous cell carcinoma, skepticism in the relationship of GERD and LPR to cancer of the larynx would appear reasonable.[12]

Given that chronic inflammation has been implicated as a potential etiology for the development of neoplasia, the question of whether anti-inflammatory therapy could be associated with a reduction in the risk of future development of specific cancers has provoked investigation. In a

nested case–control study, performed through the Seoul National University College of Medicine, the association between the use of inhaled corticosteroids and cancer of the lung and larynx was examined. Patients with a documented history of cancer of the larynx (*n* = 408) were matched with 1,651 controls. Although the authors noted a statistically significant reduction in the risk of developing lung cancer with the use of inhaled corticosteroids, there was no effect noted on the incidence of cancer of the larynx (positive or negative) with habitual use.[13]

The ARCAGE (alcohol-related cancers and genetic susceptibility) project was a multicenter case–control study performed in 10 European countries. As part of the study, investigators examined type-specific human papillomavirus (HPV) antibodies in 1,496 patients with an upper aerodigestive tract (UADT) cancer. The results of the study revealed only a marginal role for HPV6 (OR = 3.25, 95% CI+1.46 to 7.24 for HPV6 E7 seropositivity) in laryngeal cancer.[14]

A separate aspect of the ARCAGE study, examining the effect of medication and medical history on the development of UADT carcinomas demonstrated that the regular use of aspirin was associated with a reduced risk in the future development of cancer of the larynx (OR 0.74, 95% CI 0.54 to 1.01).[15]

Anatomy and Embryology

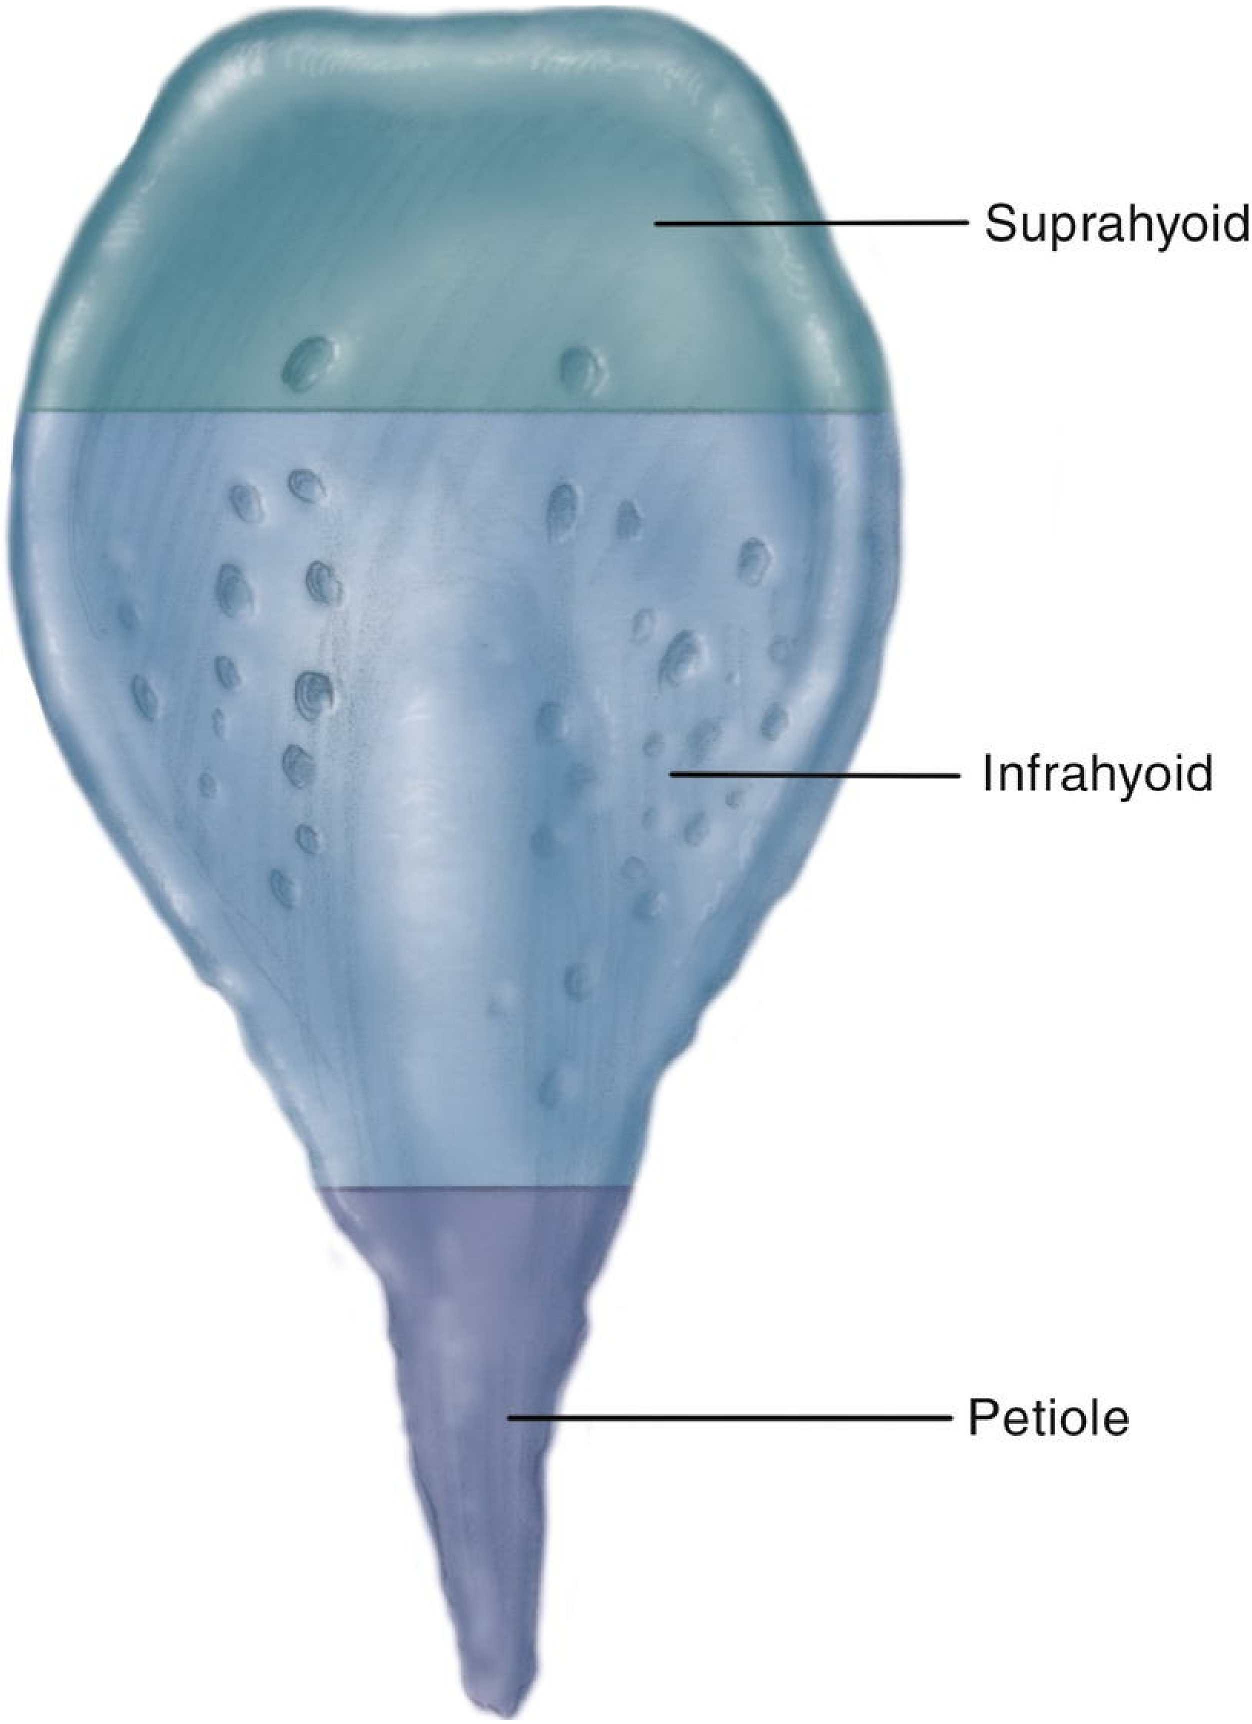
The larynx is divided into three anatomical subsites. Beyond the embryologic differences, the supraglottis, glottis, and subglottis have different lymphatic drainage pathways and therefore varied risk for regional metastasis in the setting of carcinoma. Clinically, neoplastic lesions in each of these subsites tend to present with a characteristic set of symptoms unique to the anatomic location of involvement.

Supraglottic Larynx

The supraglottis subunit includes the lingual and laryngeal surfaces of the epiglottis, the aryepiglottic folds, the arytenoid cartilages, the false vocal folds, and the ventricle. During embryologic development, these structures

are derived from the buccopharyngeal anlagen of branchial arches three and four. The glottic and subglottic subunits develop from the tracheobronchial anlagen of the fifth and sixth branchial arches. The embryonic fusion plane between the supraglottic subunit and the glottic and subglottic subunits is represented by a horizontal line drawn through the ventricle. This horizontal plane provides the anatomic and oncologic basis of supraglottic laryngectomy.

The supraglottic larynx is comprised of the suprahyoid epiglottis (both lingual and laryngeal surfaces), the infrahyoid epiglottis, the preepiglottic space, the laryngeal aspects of the aryepiglottic folds, the two arytenoids, and the ventricular bands (false cords). The inferior portion of the epiglottic cartilage is the petiole (**Fig. 15.1**). The inferior boundary of the supraglottis is a horizontal plane passing through the apex of the ventricle of the larynx. The supraglottis is intimately associated with the preepiglottic and paraglottic spaces, which can provide a pathway for transglottic spread (**Figs. 15.2 and 15.3**). The anatomic division is located at the arcuate line, which marks the change from respiratory to squamous epithelium and is reliably located at the apex of the ventricle. Thus, the roof of the ventricle is included in the supraglottis, and the floor belongs to the glottis.[16]



Suprahyoid
Infrahyoid
Petiole

Figure 15.1. The three portions of the epiglottis.

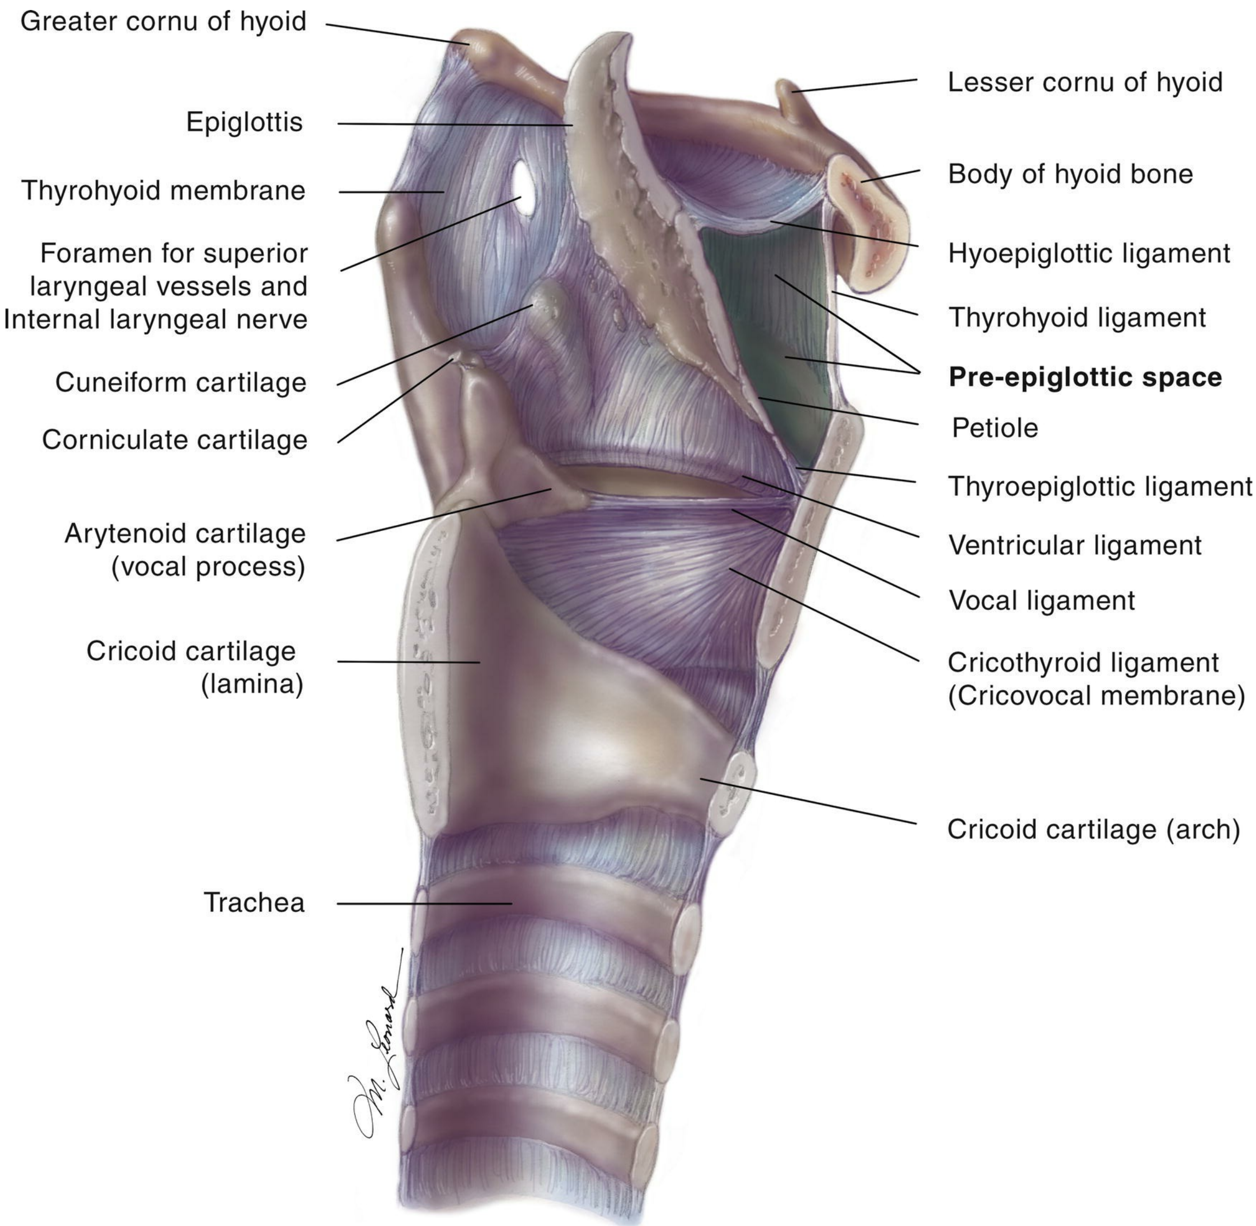


Figure 15.2. Sagittal cut of the larynx demonstrating the relative anatomy, highlighting the preepiglottic space.

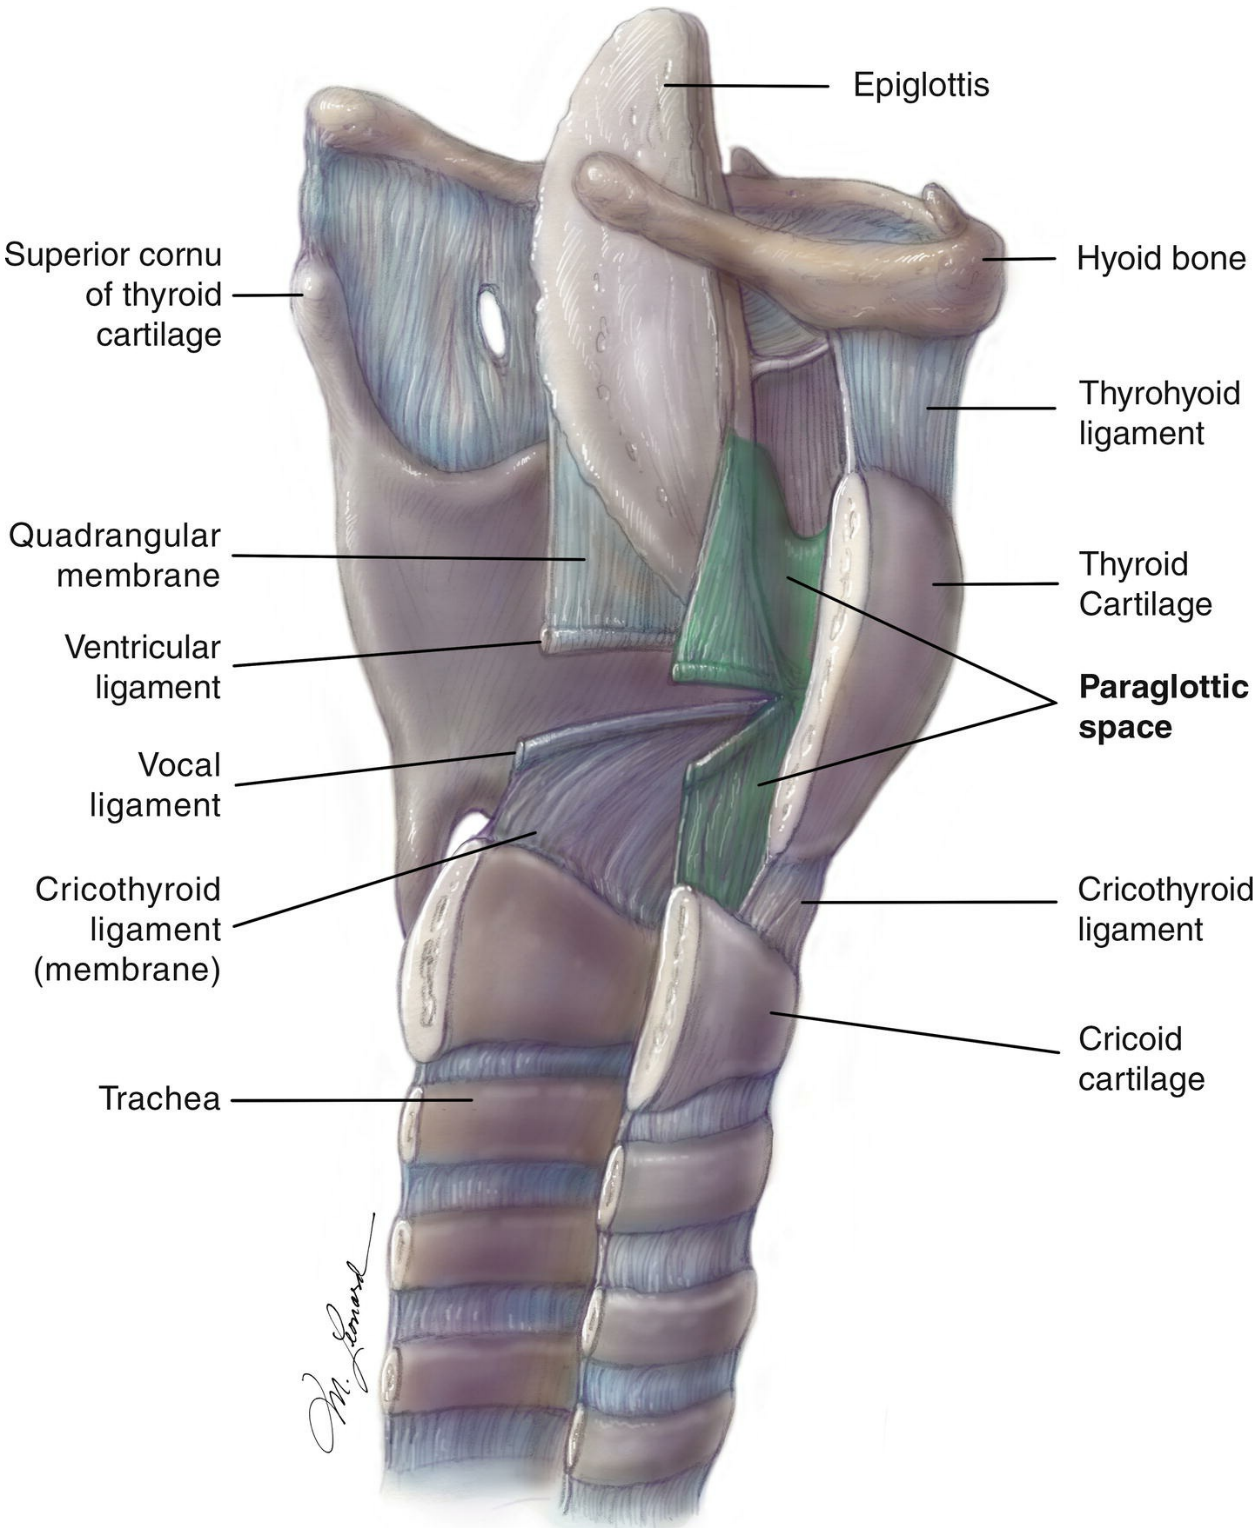

Figure 15.3. Sagittal cut of the larynx demonstrating the relative anatomy, highlighting the paraglottic space.

Histologically, the supraglottis is lined by ciliated columnar epithelium, as is

the majority of the upper respiratory tract. Exceptions are the free edges of the epiglottis and the aryepiglottic folds, which are lined with stratified squamous mucosa. Mucous glands are abundant and are of greatest density in the saccule and the periarytenoid areas. The predilection for lymphatic spread of supraglottic cancer is explained by the rich vascularity and lymphatics associated with this anatomic region.

Glottis

The glottic larynx includes the true vocal cords and the anterior and posterior commissures. The inferior border is the horizontal plane passing 1 cm below the apex of the ventricle. Histologically, the vocal cords are covered by stratified squamous epithelium around the edges and pseudostratified ciliated epithelium at the superior and inferior aspects, where the glottis merges with the supraglottis and the subglottis, respectively. The lamina propria has (1) a superficial layer composed of loose fibrous tissues that makes Reinke space and (2) intermediate and deep layers of elastic and collagenous fibers that form the vocal ligament. Blood vessels and lymphatics are almost absent in Reinke space, creating a resistance to the spread of early cancer of the glottis. No mucous glands are found on the free edge of the vocal cord, and only sparse glands are noted on the superior aspect. The conus elasticus extends upward from the superior border of the cricoid cartilage to merge with the inferior surface of the vocal ligament; it has the capacity to resist the extralaryngeal spread of glottic and subglottic cancer.

Subglottis

The subglottic larynx has no subsites and is the area of the larynx inferior to the glottis down to the inferior rim of the cricoid cartilage. It is a rare site of origin but is commonly involved by extension of glottic and supraglottic cancers. Cancer arising in the subglottis has a higher incidence of extralaryngeal spread owing to the proximity of the cricothyroid membrane and the rich postcricoid lymphatics.

Diagnosis

History, Physical Examination, and Laboratory Tests

Common presenting symptoms can include progressive hoarseness, chronic sore throat, referred otalgia, odynophagia, dysphagia, dyspnea, chronic cough, hemoptysis, and unexplained weight loss. Cancer in the glottis is seen in an earlier stage more frequently because of the notable finding of change in vocal quality not seen immediately with the other subsites. Patients with cancer of the supraglottis are more likely to present with advanced-stage cancer secondary to palpable regional metastases to the lymph nodes and a history of an ill-defined discomfort in the throat. The history should also assess for the current and prior use of tobacco products, average alcohol consumption, medical comorbidities (in particular chronic cardiovascular or pulmonary diagnoses), and potential occupational exposures.

A complete examination of the head and neck including detailed examination of the oral cavity, oropharynx, larynx, hypopharynx, and neck is critical. Indirect laryngoscopy (mirror examination) should be performed and supplements the findings of fiberoptic examination. Flexible fiberoptic laryngoscopy and/or videostroboscopy provide superior information about the anatomical and functional findings within the larynx and pharynx, which assist in treatment planning and staging. Careful palpation of the neck bilaterally is important with documentation of the location (group or level I to VI), size, mobility, and relationship of the node(s) to adjacent structures. Staging of the primary and the cervical lymph nodes is necessary prior to considering a patient's treatment options.

The diagnosis of a cancer of the larynx usually requires direct laryngoscopy and biopsy with the patient under general anesthesia. Direct laryngoscopy not only helps the clinician in making a diagnosis; it is also an important tool in proper mapping of the cancer for further management planning. Some authors advocate additional bronchoscopy and esophagoscopy in all patients with cancer of larynx for full pretreatment assessment and in evaluating for concurrent second cancers. Although the empiric performance of "panendoscopy" remains controversial, it is indicated when symptoms mandate additional evaluation. A typical example warranting this approach would be a patient who complains of dysphagia/odynophagia with supraglottic cancer spreading to the hypopharynx. Esophagoscopy would be performed to rule out extension to the cervical esophagus. For patients with enlarged lymph nodes in the setting

of a laryngeal cancer, fine-needle aspiration biopsy (preferably with ultrasound guidance) should be considered and can have a significant impact on staging and treatment.

Office-based transnasal flexible fiberoptic biopsy of laryngeal pathology has represented an alternative to conventional operative direct laryngoscopy with biopsy. Cohen et al. reported a low sensitivity of 69.2% with a specificity of 96.1% for office-based flexible fiberoptic laryngeal biopsy. Adequate tissue to establish the diagnosis of carcinoma was obtained in 35.4% of the 102 patients and allowed for early referral for treatment. The study's algorithm included follow-up operative biopsies for patients with initial benign or carcinoma in situ (CIS) biopsy results found with office-based biopsy. The authors expressed concern that pathologists were more reluctant to confirm a diagnosis of cancer with small tissue samples typically resulting from flexible fiberoptic office-based laryngeal biopsy.[17]

Laboratory testing at the time of initial assessment can be directed by the findings from the patient's history and physical examination. Preoperative pulmonary function testing should be considered along with history of activity level and exercise tolerance when making decisions about the suitability of a patient for partial laryngectomy. Consultations with other services, including radiation therapy, medical oncology, dentistry, speech pathology, psychiatry, and general medical services, are obtained as indicated.

Radiographic Examination

Clinical/endoscopic examination alone can fail to reveal extension of the cancer into the laryngeal cartilages and the extralaryngeal soft tissues. The combination of clinical/endoscopic and radiologic examination, by either computed tomography (CT) or magnetic resonance imaging (MRI), results in significantly improved staging accuracy (CT scan improves imaging in 80% of patients, and MRI in 87.5%). MRI is significantly more sensitive but is less specific than CT in detecting cartilage invasion. MRI can overestimate cartilage invasion and lead to overtreatment, whereas CT tends to underestimate cartilage invasion and may result in inadequate therapy.[18] A chest radiograph should be obtained to rule out concurrent cancer of the lung or metastatic disease.

Park et al. demonstrated that pretreatment Mean Tumor Volume (MTV) assessed by PET–CT correlated with 3-year LRC and OS for patients with locoregionally advanced laryngeal and hypopharyngeal carcinoma. The median SUVmax for patients was 10.3 and the MTV was 15 mL. MTV of >18 mL was seen to be a cutoff value that correlated with prognosis. The 3-year LRC and OS for patients with MTV ≤ 18 was 85.3 % and 91.4%, whereas for a MTV > 18, these values fell to 50.8% and 60.6%, respectively.[19]

The recommended timing of posttreatment PET–CT varies; however, most authors advocate that an accurate reading can be achieved at 10 to 12 weeks after CRT. However, it should be noted that a mild to moderate intensity of tracer uptake may persist for several months as a result of inflammation or radionecrosis and is typically diffuse and nonfocal. In addition, standardized uptake values (SUVs) cannot differentiate reliably between residual cancer and inflammation. Although SUV cutoffs have been reported to correlate with malignancy in a single institutional experience, these values have not been validated as reproducible at other institutions. The high NPV associated with PET–CT in the posttreatment setting is considered to be the most significant impact of this imaging modality on care.[20]

Staging

Primary Site

The specifics of the primary staging system for the supraglottic, glottic, and subglottic larynx are listed later in the discussion of the TNM staging system.

Metastases to Regional Lymph Nodes

The incidence and distribution of metastases to the cervical nodes from cancer of the larynx vary with the specific site of origin of the primary cancer and the stage of the primary cancer. The true vocal cords are nearly devoid of lymphatics so that early-stage glottic cancer rarely spreads to regional nodes. In contrast, the supraglottis has a rich and bilaterally interconnected lymphatic network. Advanced-stage glottic cancer may spread to adjacent soft tissues and to prelaryngeal, pretracheal, paralaryngeal, and paratracheal

nodes, in addition to upper, middle, and lower jugular nodes. Supraglottic cancer commonly spreads to upper and middle jugular nodes and only occasionally metastasizes to retropharyngeal nodes. Primary cancer of the subglottic spread initially to adjacent soft tissues and prelaryngeal, pretracheal, paralaryngeal, and paratracheal nodes and may metastasize to the middle and lower jugular nodes.

In clinical evaluation, the size of a mass in the neck should be measured and recorded in the medical record. It is recognized that most masses larger than 3 cm in diameter are not single nodes but multiple, confluent nodes with extracapsular spread. Clinically positive nodes are classified into three categories: N1, N2, and N3. In an N1 neck, the single enlarged lymph node is <3 cm in size. N2a represents a neck with a single ipsilateral lymph node larger than 3 cm but not larger than 6 cm in greatest dimension; N2b represents multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension; N2c represents bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension. Midline nodes are considered ipsilateral nodes. An N3 neck has a lymph node >6 cm in size and often represents unresectable cancer.

In addition to the components used to describe the N category, regional lymph nodes should be described according to the level of the neck involved. Imaging studies showing amorphous margins of involved nodes or involvement of internodal adipose tissue strongly suggest extracapsular (extranodal) spread of the cancer. No imaging study can yet identify microscopic foci in regional nodes. In addition, a distinction cannot be made between small reactive nodes and small malignant nodes unless central radiographic inhomogeneity is present.

Metastatic Sites

Distant metastases are more common among patients who have bulky (N2b, N2c, N3) lymph node metastases. Distant spread to the lungs is most common, whereas metastasis to the bone and/or liver occurs less often. Patients with extracapsular spread have a higher rate of metastasis to distant sites than those without extracapsular spread. Mediastinal lymph node metastases are considered distant metastases for the purposes of staging.

Staging

Clinical Staging

The larynx is assessed primarily by inspection, with the use of indirect mirror and direct endoscopic examinations. The cancer must be confirmed histologically, and any other data obtained by biopsy may be included. Cross-sectional imaging in laryngeal carcinoma is particularly recommended when the extent of the primary cancer is in question based on clinical examination. This may be accomplished with a high-resolution/fine-cut CT scan with contrast, through the larynx. In addition, it can help to distinguish between a coalescence of several lymph nodes and a single larger node, thereby making staging of the neck more precise. Endoscopic examination with the patient under general anesthesia is generally performed after completion of other diagnostic studies that accurately assess, document, and biopsy the cancer.

Pathologic Staging

All information used in clinical staging and in histologic study of the surgically resected specimen is also used for pathologic staging (**Table 15.1**). The pathologic description of any neck dissection should describe the size, number, and level of involved lymph nodes, as well as whether extracapsular spread is present. Specimens should also be examined for the presence of lymphovascular and/or perineural invasion in the primary cancer resection.

Table 15.1 Stage Grouping

Stage	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
IVA	T4	N0	M0
	T4	N1	M0
	Any T	N2	M0
IVB	Any T	N3	M0
IVC	Any T	Any N	M1

In a trial to assess for tumor biomarkers predictive of outcome in laryngeal carcinoma, Bradford et al. analyzed 58 pretreatment specimens as tissue microarrays with a panel of various biomarkers. Expression of Bcl-xL, a member of the antiapoptotic Bcl-2 family of proteins, was increased in patients with recurrent/persistent tumors. Overexpression of EGFR was correlated with an increase in risk of death from laryngeal carcinoma. When BAK (a proapoptotic protein) was expressed in low levels, cancers were more likely to respond to neoadjuvant chemotherapy. Lack of cyclin D1 expression and elevated cytoplasmic expression of CD24 were the best predictors of overall survival ($p \leq 0.05$) within the tested panel.[21]

In patients with advanced cancer of the larynx, individuals with high

circulating levels of CD4-positive T lymphocytes (both absolute count [$p = 0.006$] and percentage [$p = 0.04$]) demonstrated a better response to induction chemotherapy and experienced an improved survival. The results of these studies suggest that a peripheral blood draw could someday be used to identify patients with advanced-stage cancer that may be more likely to respond to an organ preservation protocol that uses induction chemotherapy (**Table 15.2**).[22]

Table 15.2 Definition of TNM

Primary Tumor (T)
TX Primary tumor cannot be assessed
T0 No evidence of primary tumor
Tis Carcinoma in situ
Supraglottis
T1 Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2 Tumor invades mucosa of more than one subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of the base of the tongue, vallecula, medial wall pyriform sinus) without fixation of the larynx.
T3 Tumor limited to the larynx with fixation of the vocal cord and/or invades any of the following: postcricoid area, preepiglottic tissues, paraglottic space, and/or inner cortex of the thyroid cartilage
T4a Moderately advanced local cancer Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (trachea, soft tissues of the neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, and esophagus)
T4b Very advanced local disease Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Glottis
T1 Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T1a Tumor limited to one vocal cord
T1b Tumor involves both vocal cords
T2 Tumor extends to supraglottis and/or subglottis and/or occurs with impaired vocal cord mobility
T3 Tumor limited to the larynx with vocal cord fixation and/or invasion of the paraglottic space and/or inner cortex of the thyroid cartilage
T4a Moderately advanced local disease Tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx (trachea, soft tissues of neck, including the deep extrinsic muscle of the tongue, thyroid, and esophagus)
T4b Very advanced local disease Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Subglottis
T1 Tumor limited to the subglottis
T2 Tumor extends to vocal cord(s) with normal or impaired mobility
T3 Tumor limited to the larynx with vocal cord fixation
T4a Moderately advanced local disease Tumor invades through the cricoid or thyroid cartilage and/or invades tissues beyond the larynx (trachea, soft tissues of neck, including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus).
T4b Very advanced local disease Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures.
Regional Lymph Nodes (N)
NX Regional lymph nodes cannot be assessed
N0 No regional lymph node metastasis
N1 Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2 Metastasis in a single ipsilateral lymph node, larger than 3 cm and <6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension
N2a Metastasis in a single ipsilateral lymph node larger than 3 cm and <6 cm in greatest dimension
N2b Metastasis in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension
N2c Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension
N3 Metastasis in a lymph node larger than 6 cm in greatest dimension
Distant Metastasis (M)
MX Distant metastasis cannot be assessed
M0 No distant metastasis
M1 Distant metastasis
Residual Tumor (R)
RX Presence of residual tumor cannot be assessed
R0 No residual tumor
R1 Microscopic residual tumor
R2 Macroscopic residual tumor
Histologic Grade (G)
GX Grade cannot be assessed
G1 Well differentiated
G2 Moderately differentiated
G3 Poorly differentiated
G4 Undifferentiated

Natural Course of Disease

Nodal Metastases

Most lymph node metastases are found within levels II, III, and IV (**Fig. 15.4**). Levels I and V are rarely involved unless lymph node metastasis is extensive. Occult cervical lymph node metastases are often associated with cancer of the supraglottic larynx. Esposito et al. reported a rate of occult regional spread of 27% in 97 N0 patients with previously untreated supraglottic carcinoma undergoing neck dissection at the time of horizontal laryngectomy. In this group, based on the preoperative staging of the cancer, 14% of cases had occult metastases involving lymph nodes in T1 cancer, 21% in T2 cancer, 35% in T3 cancer, and 75% in T4 cancer. The incidence of occult metastases was higher for the less differentiated cancer and for primary cancer with a higher T stage. In a subset of patients with lateralized supraglottic primary tumors, contralateral occult regional spread occurs in 37% of patients. The authors stressed the importance of bilateral regional nodal treatment with supraglottic tumors even in the N0 setting.[23]

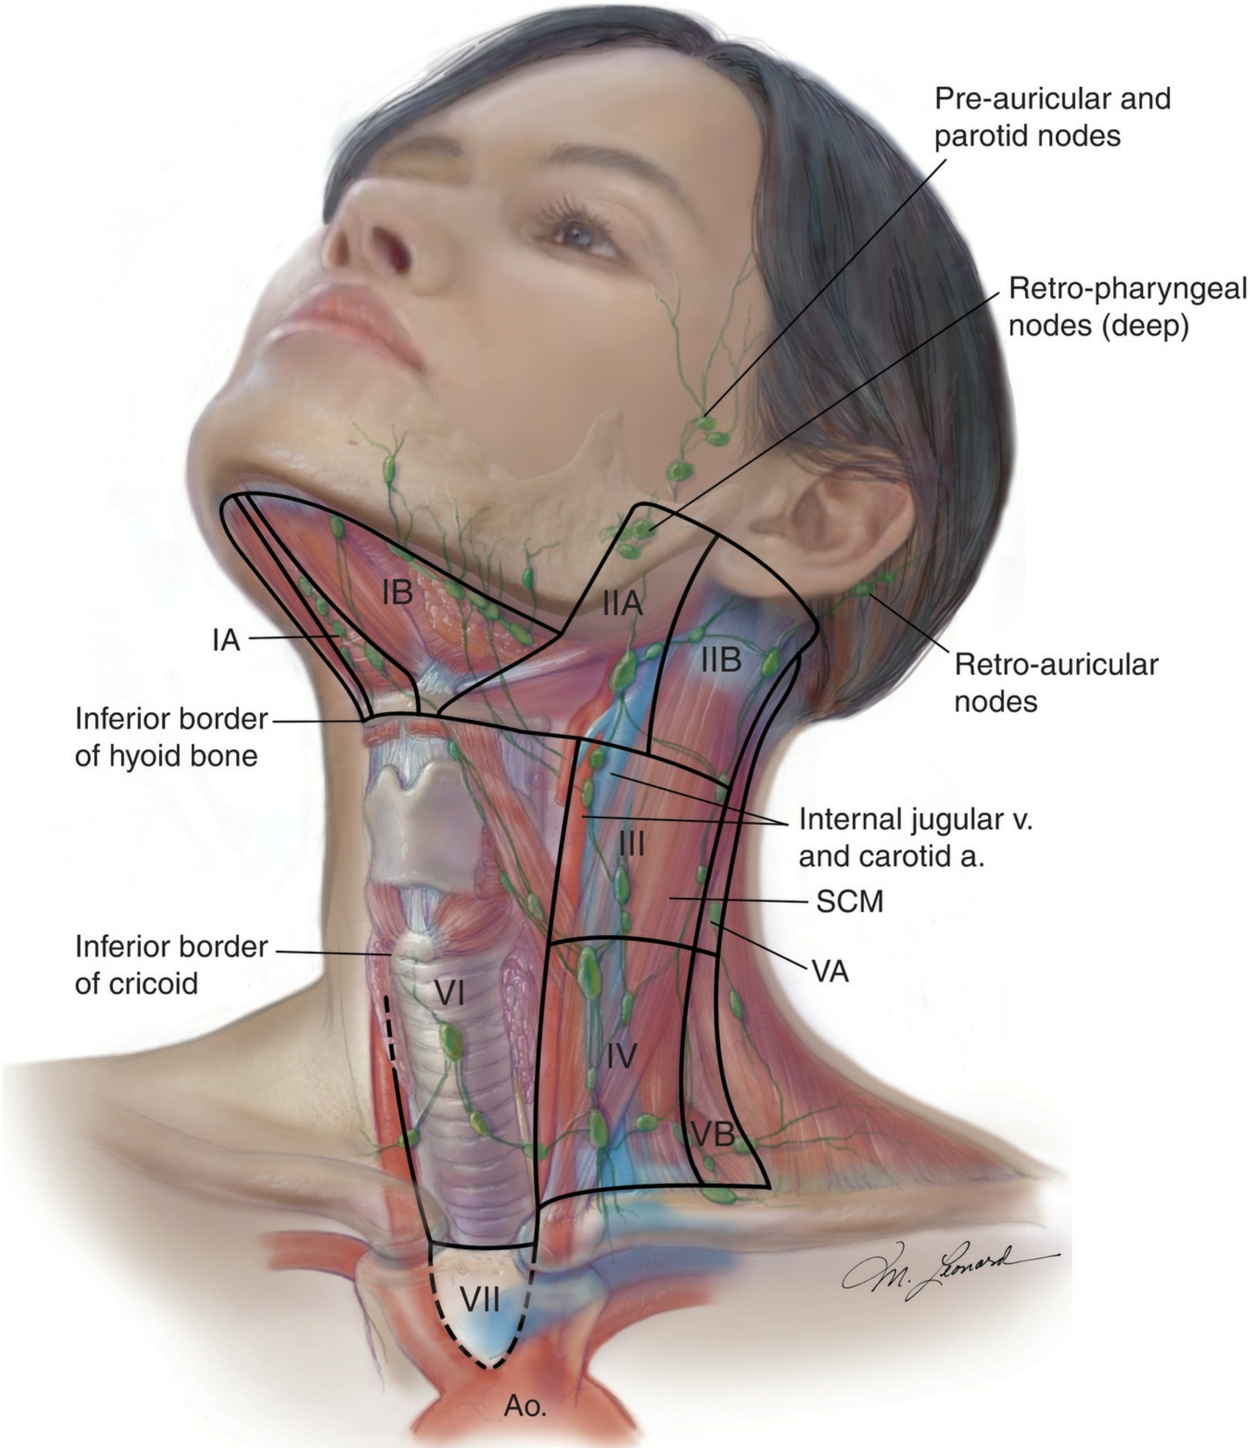

Figure 15.4. The lymph node levels of the neck.

In a study from Washington University of 2,550 patients with cancer of the larynx and hypopharynx, the overall incidence of delayed regional metastases was 12.4% (317/2,550 patients); distant metastases, 8.5% (217/2,550); and

second primary cancer, 8.9% (228/2,550). Delayed regional metastases and distant metastases were related to advanced primary cancer (T4 stage), lymph node metastases (node positive [N+]), the cancer arising in the hypopharynx as the primary site, and locoregional cancer recurrence ($p = 0.028$). Advanced regional metastases at initial diagnosis (N2 and N3 disease) increased the incidence of delayed and distant metastases threefold ($p = 0.017$). Incidences of delayed regional metastases by anatomic location of the primary cancer were glottic, 4.4%; supraglottic, 16%; subglottic, 11.5%; aryepiglottic fold, 21.9%; pyriform sinus, 31.1%; and posterior wall of the hypopharynx, 18.5%. Delayed regional metastases to the ipsilateral-treated neck had a significantly worse survival prognosis than did delayed metastases to the contralateral untreated neck.[24]

Distant Metastases

Distant metastases are associated with a poor prognosis. Among patients with cancers of the head and neck region, ~8% eventually develop distant metastases.[25] The lung is the most common site of distant metastases in primary cancer of the larynx. Staging has been helpful in predicting the likelihood of distant metastases with the highest frequency seen in patients in stages III and IV (85%). A supraglottic primary cancer is the most common subsite associated with the development of distant metastases.

The overall 5-year disease-specific survival after patients developed distant metastases was 6.4%. Distant metastases were related to advanced local cancer (T3 + T4), lymph node metastases at presentation (N+), and locoregional cancer recurrence ($p = 0.028$). A meta-analysis of variables that predispose to a higher incidence of distant metastasis identified tumor location (hypopharynx > larynx), advanced primary disease (T3 + T4), regional metastasis (N+), locoregional cancer recurrence, and advanced regional metastasis (N2 + N3).[26]

Second Primary Cancers

In a retrospective study from France including 410 patients, the incidence of second primary cancer was 23.9% (98/410). Cancer of the lung was the most common second primary and two-thirds of patients who developed a second primary cancer died of disease.[27]

In another retrospective review of 240 patients from Oregon with T1–T2 SCC of the larynx, 72% had glottic primaries, 27% had supraglottic cancer, and 1% had subglottic cancer. With a median follow-up of 68 months, 68 patients (28%) have developed 72 additional cancers. 15% were diagnosed with synchronous primaries.[28]

Pathology

Keratosis/Leukoplakia

Leukoplakia, also described as keratosis, of the larynx most commonly involves the true vocal cords and the interarytenoid area. It often occurs in smokers, singers, and professional voice users. Keratosis is grossly characterized as a white, thickened plaques. Microscopically, keratotic lesions are characterized by increased thickness of the normally present keratin layer of the epithelium. Hyperkeratosis is defined as the presence of a keratin layer in a normally nonkeratinized epithelium and may represent an early response to mucosal trauma.

Bartlett and colleagues performed real-time polymerase chain reaction analysis on the RNA of 17 specimens, originally classified clinically as glottic leukoplakia, yet subsequently diagnosed with nondysplastic keratosis, dysplasia, and invasive carcinoma on final pathology. Differential gene up-regulation and matrix metalloproteinase (MMP-1, MMP-2, MMP-9) expression was noted among the specimens suggesting a correlation between genetic changes and the progression of cancer. As a result of their findings, the authors suggest that the development of cDNA microarray genomic expression profiles could increase the sensitivity of assessment for patients with glottic leukoplakia by identifying disease progression reflected in markers of extracellular matrix degradation and the promotion of angiogenesis.[29]

Dysplasia

Dysplasia refers to a microscopic change that is characterized by cellular atypia, loss of maturity, and loss of stratification. Three grades of dysplasia are defined by the World Health Organization (WHO) classification[30]:

1. Mild—Changes are limited to the lower third of the epithelial thickness.
2. Moderate—Changes are limited to the lower two-thirds of the epithelial thickness.
3. Severe—Changes involve more than the lower two-thirds of the epithelial thickness. Cells are less crowded than with CIS and usually reveal greater differentiation.

Carcinoma in Situ

CIS may be present as the only lesion, or it may occur at the periphery of an invasive carcinoma. The standard criterion for diagnosis is the presence of atypical changes throughout the epithelium without evidence of surface maturation or invasion through the basement membrane.

Papillary CIS is a form of CIS characterized by papillary fronds with cytologic features of the classic CIS. The actual rate of malignant progression for untreated cases of laryngeal is unknown; however, some estimates have been reported to be as high as 40%. CIS of the larynx can be treated by means of biopsy, local excision, laryngofissure, stripping, or radiation.

Invasive Squamous Cell Carcinoma

Microscopically, more than 90% of cancers of the larynx are SCCs. They are graded into well-, moderately, and poorly differentiated cancers based on the degree of differentiation, cellular pleomorphism, and mitotic activity.

Persistence of SCC after radiation can be difficult to distinguish from postradiation atypia because of the similar histologic appearance. Immunoreactivity for keratin is universally present and cells also express epidermal growth factor receptors.

Various prognostic factors have been reported in the literature for invasive SCC and include clinical stage and site, histopathologic grade, lymphovascular invasion, perineural spread, lymph node spread (+/− extracapsular spread), HPV, tumor thickness/depth of invasion, and DNA ploidy.

Basaloid Squamous Cell Carcinoma

Basaloid SCC is characterized by a predominance of basaloid features in the

epithelium and is considered an aggressive variant of squamous cell carcinoma that can present in the larynx.

An association with HPV positivity and basaloid carcinoma has been seen with cancer of the oropharynx, yet similar findings have not been reported with laryngeal carcinoma.[31] Patients with laryngeal basaloid carcinoma typically present with a more advanced overall stage at diagnosis and have a worse disease-specific survival than individuals with conventional squamous cell carcinoma of the larynx. In a review of 145 cases of basaloid carcinoma of the larynx, 11.6% were found to harbor distant metastases at the time of initial presentation (vs. 2.7% for conventional squamous cell carcinoma of the larynx). The majority of basaloid carcinomas of the larynx present as supraglottic primaries (64.8%) and ~50% develop regional lymph node spread of metastases.[32]

Verrucous Carcinoma

Clinically, verrucous carcinoma is a slow-growing, locally aggressive cancer with an exophytic, fungating, warty, gray–white appearance and well-defined margins. Because it produces few early symptoms, patients often present with a bulky cancer. Histologically, this cancer is composed of elongated papillary fronds of well-differentiated squamous epithelium with extensive keratinization. Cytologic abnormalities are absent. The margins of the cancer have “pushing” rather than infiltrative growth that is usually accompanied by an exuberant host response of inflammatory cells. Regional lymph nodes may be enlarged and raise suspicion for occult malignancy, but this cancer does not metastasize, and nodal enlargement is invariably part of the host inflammatory response. The combination of the gross appearance of the cancer and the suggestive histologic findings is usually sufficient to establish the diagnosis.

Verrucous carcinoma constitutes from 1% to 3% of all cancers of the larynx. Within the larynx, a majority of these cancers arise from the glottis with the remainder diagnosed in the supraglottis. The typical patient is a male in his fifties or sixties who have been hoarse for at least a year before presentation. Smoking is a known risk factor. Overall prognosis is excellent with proper treatment, even among patients with locally advanced cancer. Fliss et al.[33] found 45% of patients with verrucous carcinoma of the larynx to have HPV detectable in their cancer by the polymerase chain reaction, all of

which cases of HPV were either type 16 or 18.

Huang et al. reviewed the experience of 62 patients with verrucous carcinoma of the larynx treated with primary radiation over a 43-year period. In the series, there were no reported episodes of posttreatment anaplastic transformation. Disease-specific survival was also noted to be comparable to those from series reporting on surgical management; however, local control (66% at 5 years) was noted to be inferior in comparison to surgery. Individuals who experienced a local recurrence (21/62) were capable of undergoing successful salvage resection of persistent cancer.[34]

Verrucous carcinoma of the larynx can be difficult to differentiate from benign papillary hyperplasia on biopsy if a limited quantity of tissue is available for histopathologic examination. Increased mean levels of expression of survivin, a member of the inhibitor of apoptosis protein family, in regions of parakeratosis have been shown to have the capacity to differentiate verrucous carcinoma from laryngeal papillary hyperplasia.[35]

Nonsquamous Tumors

Nonsquamous cancers account for <5% of all laryngeal malignancies. Among these, salivary gland tumors, cartilaginous neoplasms, sarcomas, and neuroendocrine carcinomas have been the types most commonly reported.

Adenocarcinoma

Adenocarcinomas of the larynx follow the distribution of the laryngeal mucous glands and are primarily supraglottic and subglottic in origin. Male predominance has been reported. Clinically, the cancers appear as submucosal, nonulcerated masses and symptoms are the same as for carcinomas of the larynx.

Most adenocarcinomas of the larynx present with advanced primary cancer and cervical lymph node metastases. Distant metastases to the liver and lung account for the dismal 5-year survival under 20%.[36] Secondary to the aggressive behavior of this primary, most authors have recommended radical surgery with total laryngectomy and bilateral neck dissections. Postoperative radiotherapy is usually advocated, although the numbers of reported cases are too small to know if this confers a survival benefit. Patients succumb to both locoregional failure and distant metastases.

Adenosquamous carcinoma is an uncommon but aggressive variant of head and neck squamous cell carcinoma with a propensity for regional and distant metastases with ~50% of cases presenting with a laryngeal primary. Very little has been reported concerning the risk factors or etiology of this variant. In a review by Masand et al. of 18 cases, 7 cases of primary laryngeal presentation were reported. The average age of patients was 58, all cases were male, and none of the cancers were positive for high-risk HPV.[37]

Adenoid Cystic Carcinoma

Although not exceedingly rare, a limited number of cases of adenoid cystic carcinoma have been reported and they are estimated to represent only 0.6% of all cancer of the larynx. The most common site of origin is the subglottis, followed by supraglottic primaries. These cancers produce only vague symptoms while they spread in a perineural and infiltrative growth pattern. When the primary originates from the subglottis, patients typically present with involvement of the laryngeal framework, trachea, thyroid gland, and esophagus. Metastases to the lung are common with this entity.

Adenoid cystic carcinoma of the larynx can be difficult to treat because of the predilection for perineural spread and pulmonary metastases. The mainstay of treatment, dependent upon stage and presentation, has typically been surgery (open vs. endoscopic approach) with potential adjuvant radiation therapy. Misiukiewicz et al. reported on the use of primary concomitant chemoradiation (CRT), using carboplatin and paclitaxel, as a means of organ-sparing therapy for patients who otherwise would have required laryngectomy and radiation. Locoregional control with functional laryngeal preservation was obtained with a follow-up of at least 5 years in two patients. The authors suggested that this regimen represented an alternative for selected patients with this diagnosis when laryngeal preservation is desired and salvage laryngectomy would be used for nonresponders.[38]

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma of the larynx is an uncommon cancer that typically presents in older males with the supraglottis as the most common primary site. The worst prognosis is seen with patients with high-grade

cancer. Low-grade cancers rarely spread beyond the confines of the larynx and conservation surgical approaches without neck dissection may be curative. Radiation has not been shown to be effective when used as a single modality.

The management of high-grade mucoepidermoid carcinoma is similar to that of SCC. The extent of surgery is dictated by the extent of the cancer and elective neck dissection is recommended, even for smaller cancers, because of the risk of occult neck metastases. Radiation therapy is usually administered in the adjuvant setting.[39]

The management of intermediate-grade cancer is controversial, and many authors tend to follow a more aggressive approach. Surgery is the mainstay of therapy. The use of postoperative radiation therapy varies according to the surgical margins and other factors, such as the patient's age and the presence of regional metastases.[40]

Chondrosarcoma

Chondrosarcoma is the most common sarcoma of the larynx. Its incidence is difficult to know because the low-grade form of this tumor is often confused with a benign chondroma. It predominantly affects men (3:1 male-to-female ratio) between the ages of 50 and 70 years and arises from the hyaline cartilages of the larynx.[39] The most common of these sites are the cricoid (especially the posterior lamina) (70%), the thyroid (20%), and the body of the arytenoid cartilage (10%).

Chondrosarcoma arising from the cricoid cartilage tends to grow into the airway and cause progressive obstruction, whereas chondrosarcoma arising from the thyroid cartilage typically protrudes laterally and presents as a firm mass in the neck. Endoscopically, the tumor appears as a firm, submucosal mass that is difficult to biopsy because it is so dense. On imaging, these lesions are typically hypodense, well-circumscribed masses containing mottled calcifications with smooth walls centered within the cartilage.[41]

The management of chondrosarcoma varies with the grade and extent of the tumor. The primary modality of treatment is surgery. For low-grade and some medium-grade tumors, local control is the goal. Partial laryngectomy with voice preservation and reoperation if the tumor recurs is an option in selected patients. Challenges arise with tumors arising in the cricoid, and a

variety of techniques have been described to reconstruct the larynx following partial resection with reconstruction of the cricoid, using hyoid bone, rib, and strap muscle. High-grade chondrosarcomas usually require a total laryngectomy, with neck dissection reserved for clinical or radiographic evidence of metastasis.

Five-year survival rates are not useful data for chondrosarcomas of the larynx, especially with low-grade tumors, because recurrences and subsequent mortality may occur well beyond this time point.[42]

Neuroendocrine Tumors

The second most common tumor type in the larynx takes rise from neuroendocrine family of neoplasms, which include carcinoid tumors (6.6%), atypical carcinoid tumors (53.7%), small cell neuroendocrine carcinomas (27.6%), and paragangliomas (12.1%).

Laryngeal carcinoid tumors can be mistaken as being an indolent pathology yet has reported rate of regional and distant metastasis of 33%. It typically presents in the supraglottic or transglottic lesion. Conservative surgical resection with therapeutic neck dissection (in N+ patients) has been advocated. Elective neck dissection is considered unnecessary because of the low rate of associated occult spread. Radiation is considered to be ineffective in the management of this pathology.

Atypical carcinoid tumors are aggressive lesions with regional and distant metastatic rates ranging from 43% to 67%. The reported 5-year survival is <50%. Histopathologic misclassification of atypical carcinoid as carcinoid tumor can occur and may prompt re-evaluation of tissue specimens if the clinical behavior of the tumor is uncharacteristic for a specific patient's presentation. Surgical resection is considered the treatment standard with bilateral elective neck dissection being advocated for supraglottic presentations. One series from MD Anderson reported on the use of radiation and chemotherapy (primary therapy and as an adjuvant) in the care of selected patients with mixed results.

Small cell neuroendocrine carcinoma has a poor associated prognosis with 90% of patients experiencing regional and/or distant metastasis. The 5-year survival is typically <10%. Paraneoplastic syndromes can occur in association with this diagnosis. Nonsurgical treatment is advocated for this

diagnosis and frequently requires a multidrug chemoradiation regimen.

Paraganglioma of the larynx is a benign tumor with a female predominance. Surgery is the treatment of choice for this lesion with both open and endoscopic CO_2 lesion resections described.[43]

Liposarcoma

Liposarcoma of the larynx is a rare entity that typically presents as a supraglottic lesion in males in the fourth to seventh decade of life. The tumors tend to be low grade and are rarely associated with regional or distant spread. The four most commonly described histologic variants are pleomorphic, round cell, myxoid, and well-differentiated liposarcoma. Well-differentiated liposarcoma represents ~65% of cases and can be easily confused with a basic lipoma both macroscopically and microscopically. Wide surgical excision is advocated for this tumor with little evidence of a role for radiation in this setting. Recurrence is common and occurs in over 50% of reported cases.[44]

Composite Tumors

Synchronous presentation of small cell carcinoma and squamous cell carcinoma of the larynx, also known as “composite tumor of the larynx,” is rare and represents a clinical quandary and requires a collaborative approach to management.[45] Additional reports of synchronous “double-tumor” presentations, such as with squamous cell carcinoma in the setting of laryngeal chondrosarcoma, have also been reported.[46]

Treatment of Cancer of the Larynx

Early-stage laryngeal carcinoma (stage I or II) is usually treated with a single-modality regimen involving surgery or radiation therapy. Although controversy exists regarding the relative merits of either treatment modality, the rates of cancer control are similar, and patients should be made aware of the options available. Surgical options include endoscopic laser resection, open partial laryngectomy, and total laryngectomy.

In contrast, advanced-stage cancers of the larynx typically require combined multimodality therapy to treat the primary site and regional lymphatics. Primary surgical management and adjuvant radiation therapy (with or without chemotherapy) versus chemoradiation with surgery reserved for salvage are typically the options employed in this setting.

Surgical Treatment

The options of conventional (open) conservation surgery (CCS), transoral endoscopic laser microsurgery (TLM), and supracricoid partial laryngectomy (SCPL) provide a variety of treatments that can offer the goal of cure with preservation of laryngeal function and integrity of the airway.

Although CCS has been supplanted for many early-stage lesions by TLM, centers throughout the world have reported favorable results with CCS, which may be modified to allow resection of more extensive tumors. A number of extended CCS procedures exist for the management of glottic cancer involving both vocal cords and the anterior commissure (AC), for cancer in the paraglottic space with vocal cord fixation, and for supraglottic tumors involving the glottis or hypopharynx.

TLM has proved to be an effective, minimally invasive, and functionally satisfactory procedure for management of selected T1 and T2 glottic cancers, as well as for T1–T3 supraglottic cancers (**Figs. 15.5 and 15.6**). The procedure may be effectively employed in combination with neck dissection and postoperative radiotherapy when necessary, particularly for moderately advanced supraglottic carcinomas.

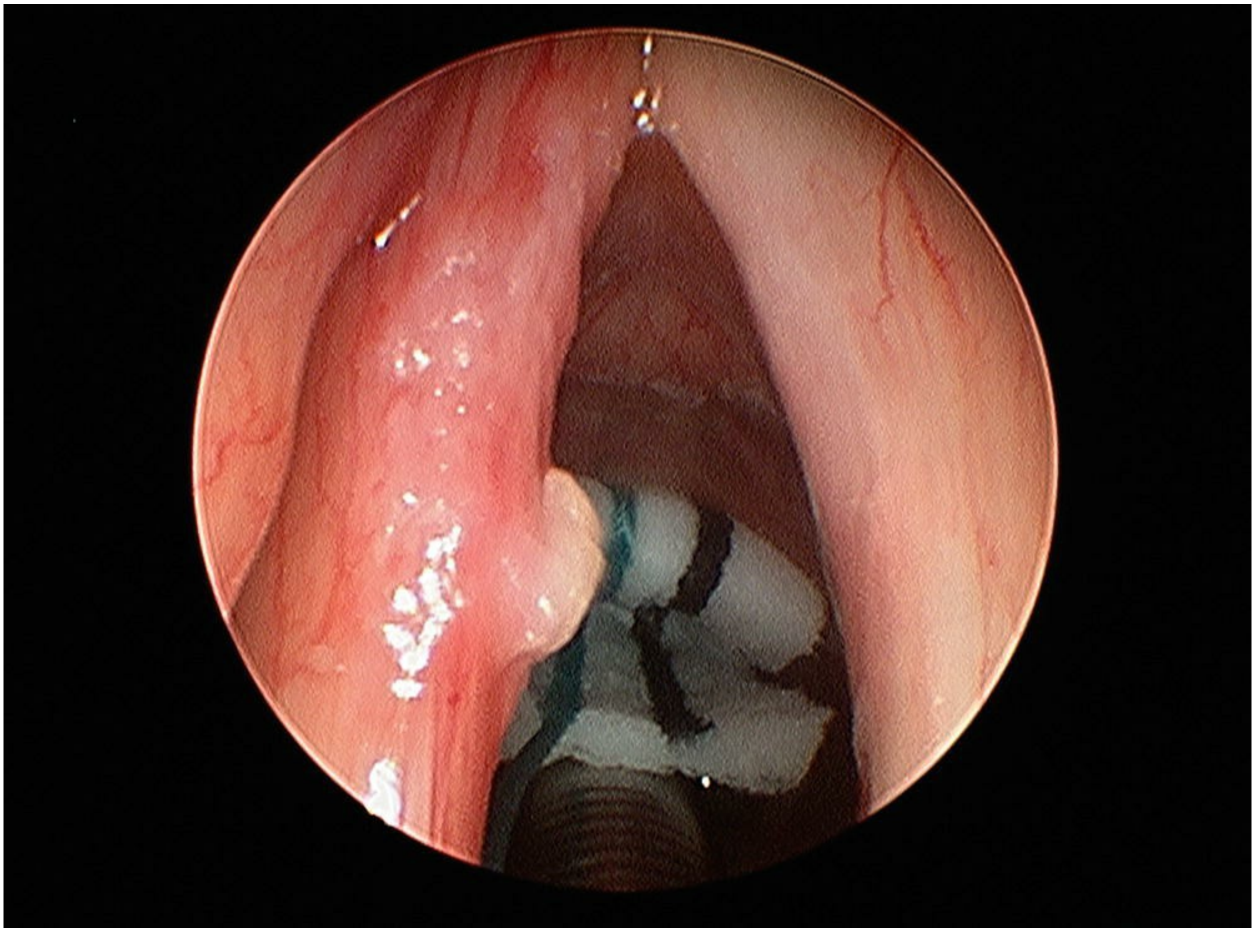

Figure 15.5. T1a glottic carcinoma prior to resection.

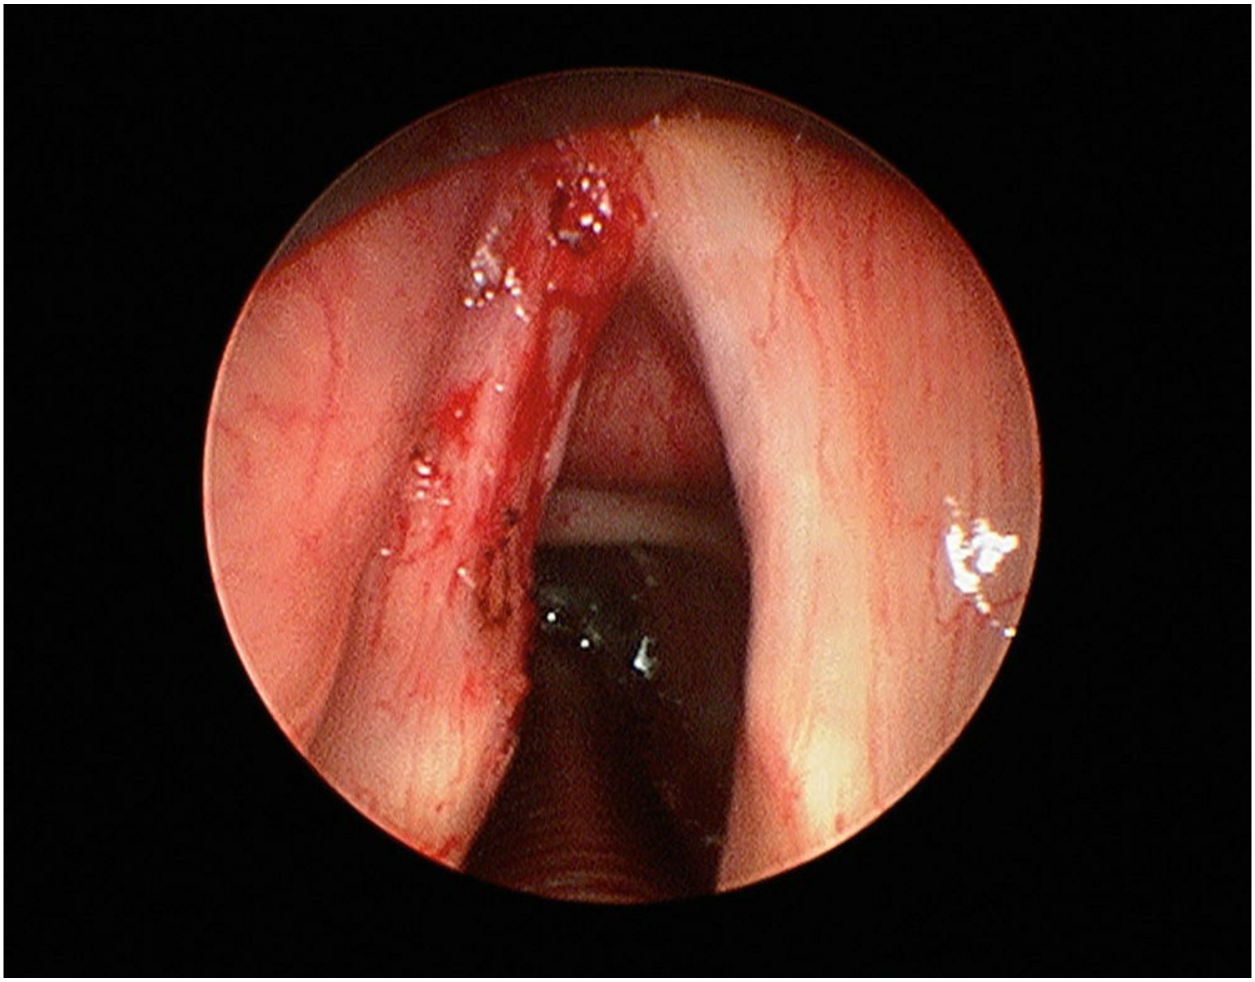

Figure 15.6. T1a glottic carcinoma after TLM (using CO_2 laser) resection of tumor potential paths of spread of tumor within the laryngeal ventricle.

SCPL has proved effective in the management of glottic and supraglottic cancers, even when involvement of the paraglottic space and the thyroid cartilage exists, provided at least one arytenoid unit could be preserved with clear margins. Invasion of the cricoid cartilage is the most significant limitation of this procedure. Voice quality results are variable.

All three surgical approaches have been employed for radiation failure but with increased failure and complication rates compared with primary surgical treatment. A decision to treat a cancer of the larynx initially with radiation may complicate the potential for a satisfactory result with salvage partial laryngectomy. The treatment of cancer of the larynx should be individualized with various treatment modalities and surgical procedures according to the size and extent of the cancer, the age and physical condition

of the patient, and the skill and experience of the treating physicians.

In 1866, Patrick Watson of Edinburgh performed the first laryngectomy. The patient was a 36-year-old man whose larynx was being destroyed by syphilis. He survived the operation but died several weeks later from pneumonia; after his death, the procedure was condemned. In 1873, Billroth of Vienna performed what is considered to be the first successful laryngectomy. Since then, surgery for cancer of the larynx has seen significant advances that have made the surgery both safe and reliable.[47]

Cancer of the Glottis

Endoscopic Resection

The European Laryngological Society proposed a classification of different laryngeal endoscopic cordectomies in order to ensure better definitions of postoperative results; the word *cordectomy* is used even for partial resections because it is the term most often used in the surgical literature. The classification includes eight types of cordectomies: (1) subepithelial cordectomy (type I), which is resection of the epithelium; (2) subligamental cordectomy (type II), which is resection of the epithelium, Reinke space, and the vocal ligament; (3) transmuscular cordectomy (type III), which proceeds through the vocalis muscle; (4) total cordectomy (type IV); (5) extended cordectomy that encompasses the contralateral vocal fold and the AC (type Va); (6) extended cordectomy that includes the arytenoid (type Vb); (7) extended cordectomy that encompasses the subglottis (type Vc); and (8) extended cordectomy that includes the ventricle (type Vd). These operations are classified according to the surgical approach used and the degree of resection. Each surgical procedure ensures that a specimen is available for histopathologic examination (**Fig. 15.7**).[48]

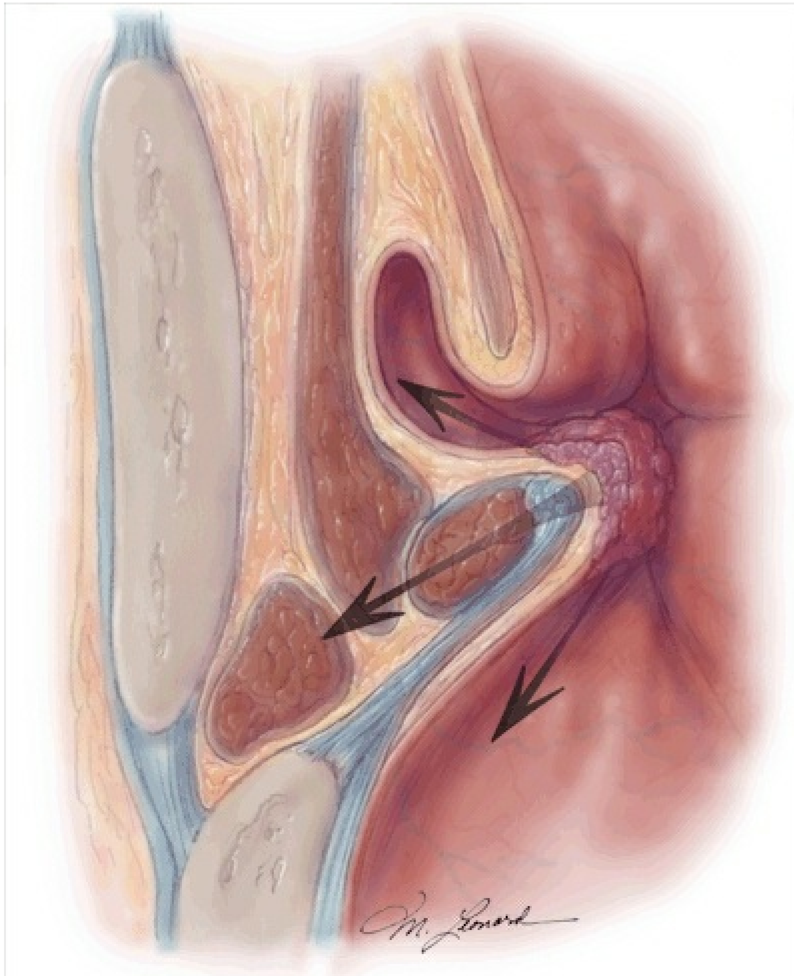

Figure 15.7. Path of potential lateral deep invasion for a primary cancer of the glottis that may affect the extent of endoscopic resection.

Hakeem et al. reviewed a group of 296 patients with early cancer of the glottis to evaluate the impact of AC involvement on disease control while using transoral endoscopic resection techniques. In the series, 61/296 had AC involvement. Negative margins were obtained at the original resection in 77.05% of patients with AC involvement versus 94.55 of the time without AC involvement. The local recurrence rate for patients with AC involvement was significantly greater than for those without involvement (29.51% vs. 18.35%, $p = 0.0001$). Of the patients with AC involvement and local recurrence, laryngeal preservation with open and endoscopic techniques or radiation therapy was possible in 68.85%. However, the laryngeal preservation rate (95.8% vs. 93.26%, $p = 0.287$) and overall survival were not affected by cancer involving the AC.[49]

Blanch et al. reviewed their experience in a series of 107 patients with transoral endoscopic CO_2 laser resection of T2/T3 glottic carcinomas with AC involvement. Tumor recurrence was statistically related to the margin status at original resection ($p = 0.01$) and the experience of the surgeon ($p = 0.02$) but was unrelated to T stage. The experience of the surgeon reflected a comparison of the first 5 years (1998–2003) in which transoral laser microsurgery was performed in the author’s department versus the subsequent 5 years (2003–2008). They reported 5-year overall and laryngectomy-free survivals of 71% and 71.4%, respectively.[50]

In a similar retrospective review by Remmelts et al., primary radiation therapy (89) was compared to TLM (159) in early-stage cancer of the larynx/CIS, for oncologic and functional outcome. The local control rates between the two groups were not statically different. The 5-year laryngeal preservation rate was noted to be superior in the TLM group (93% vs. 83%, $p < 0.05$), yet the overall voice handicap index (VHI) questionnaire scores reflecting superior voice results were experienced with radiation therapy ($p < 0.05$). Although patients with T1a lesions had similar VHI scores between the two treatment modalities, patients with T1b disease revealed a greater discrepancy favoring radiation therapy, likely reflecting the complexity of the resection encountered with AC lesions.[51]

In a retrospective analysis of 118 patients with cancer of the glottis (T1/T2) treated with TLM without adjuvant therapy, oncologic outcomes were assessed. The 5-year DFS and OS were 87.2% and 96.2%, respectively. On initial resection, 39.8% of patients were noted to have positive margins per the pathology report, yet when “2nd look” operations were performed (on 10 of the 43), residual cancer was not identified. Retreatment and adjuvant therapy were not offered to patients with positive margins because of the operating surgeon’s confidence in the initial acquired margins. The authors noted that in their series, AC, arytenoid, and subglottic extension did not have an impact on local control.[52]

The American College of Radiology (ACR) Expert Panel on Radiation Oncology–Head and Neck Cancer developed ACR Appropriateness Criteria for the management of T1 glottic cancer. Their guidelines advocate for TLM for T1a glottic carcinoma when the lesion can be completely visualized via a direct laryngoscopy approach. In patients with lesions less amenable to resection with TLM, radiation therapy is advocated with 2.25 Gy fractions.[53]

Laryngofissure and Cordectomy.

This open conservation laryngeal technique is reserved for T1 glottic cancers involving the mid true vocal cord and results in cure rates of >90% in selected patients. An endoscopy is performed before the laryngofissure is undertaken, and the cancer is mapped for the suitability of laryngofissure and cordectomy, following which a tracheostomy is performed. A horizontal incision in a major skinfold in the neck is used; this is separate from the tracheostomy incision. Superior and inferior flaps are raised and the larynx is exposed in the midline by separation of the strap muscles. A midline thyrotomy is then performed and the larynx opened. The lesion is then visualized and excised. The specimen is sent to the pathologist for examination by frozen section. The AC is reconstructed by anchoring the anterior end of the uninvolved vocal cord to the thyroid lamina. The perichondrium and the strap muscles are sutured together, and the incision is closed over suction drains. The increased use of endoscopic CO_2 resections has resulted in a significant decrease in the use of this open procedure.

Vertical Partial Laryngectomy.

This procedure is reserved for T1 and T2 cancers of the true vocal cord and success rates of more than 90% have been reported. The results of vertical partial laryngectomy (VPL) for selected T3 and T4 lesions have also provided acceptable outcomes. An endoscopy is performed before the VPL and the cancer is mapped for the suitability of the procedure, following which a tracheostomy is performed **(Fig. 15.8)**. A horizontal incision that is separate from the tracheotomy incision is made. Superior and inferior flaps are elevated. The strap muscles are retracted. The external perichondrium of the thyroid cartilage to be removed is incised; the perichondrium and musculature are elevated as a single flap, and the larynx is skeletonized. At this point, midline thyrotomy, cricothyroidotomy, and incision across the petiole are performed to provide visualization of the cancer. The cancer and the thyroid cartilage are then excised as one specimen (**Figs. 15.9 and 15.10**). The muscle/perichondrial flap are then used to create a neoglottis. The wound is closed over a suction drain.

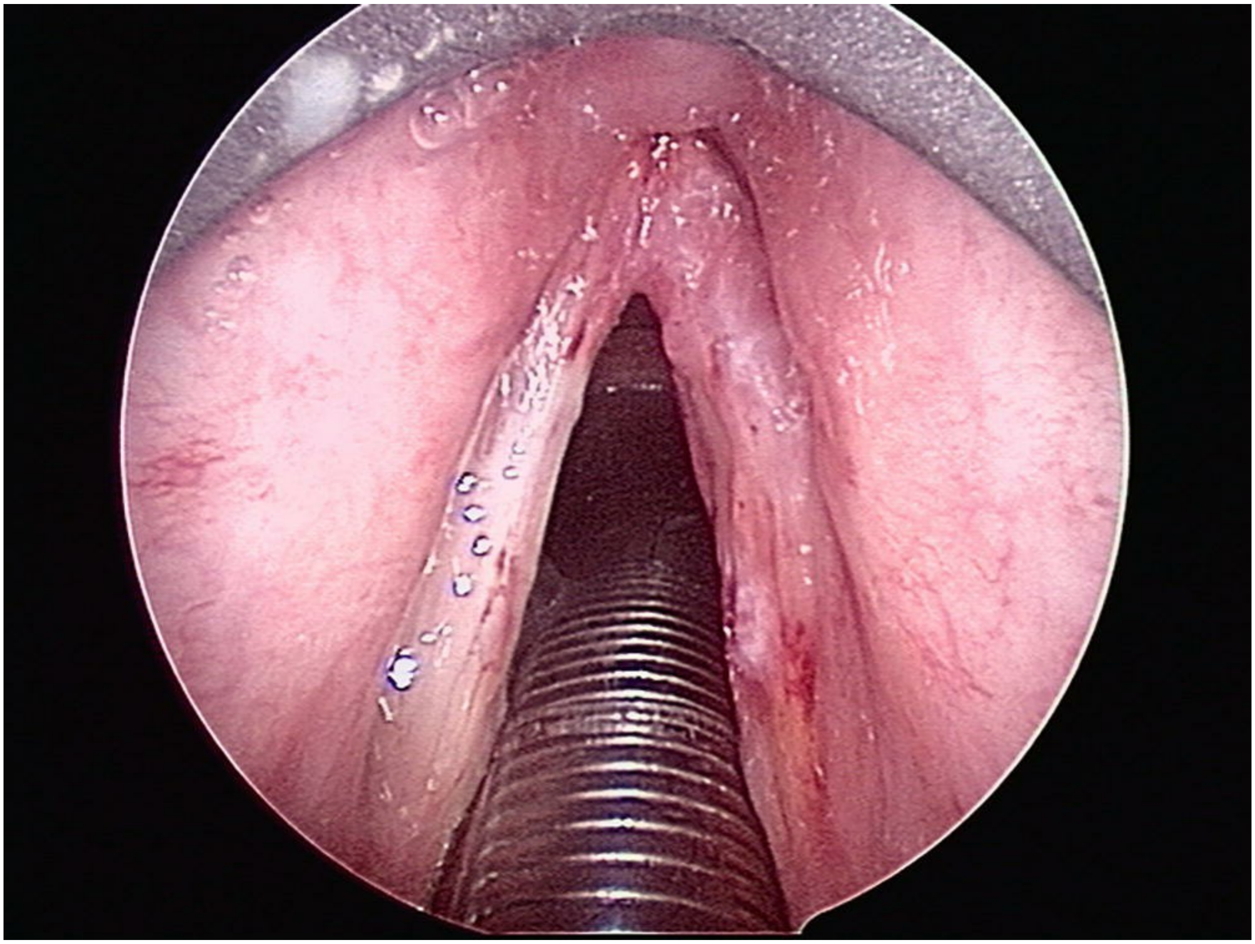

Figure 15.8. Endoscopic view of a T1b squamous carcinoma of the glottis.

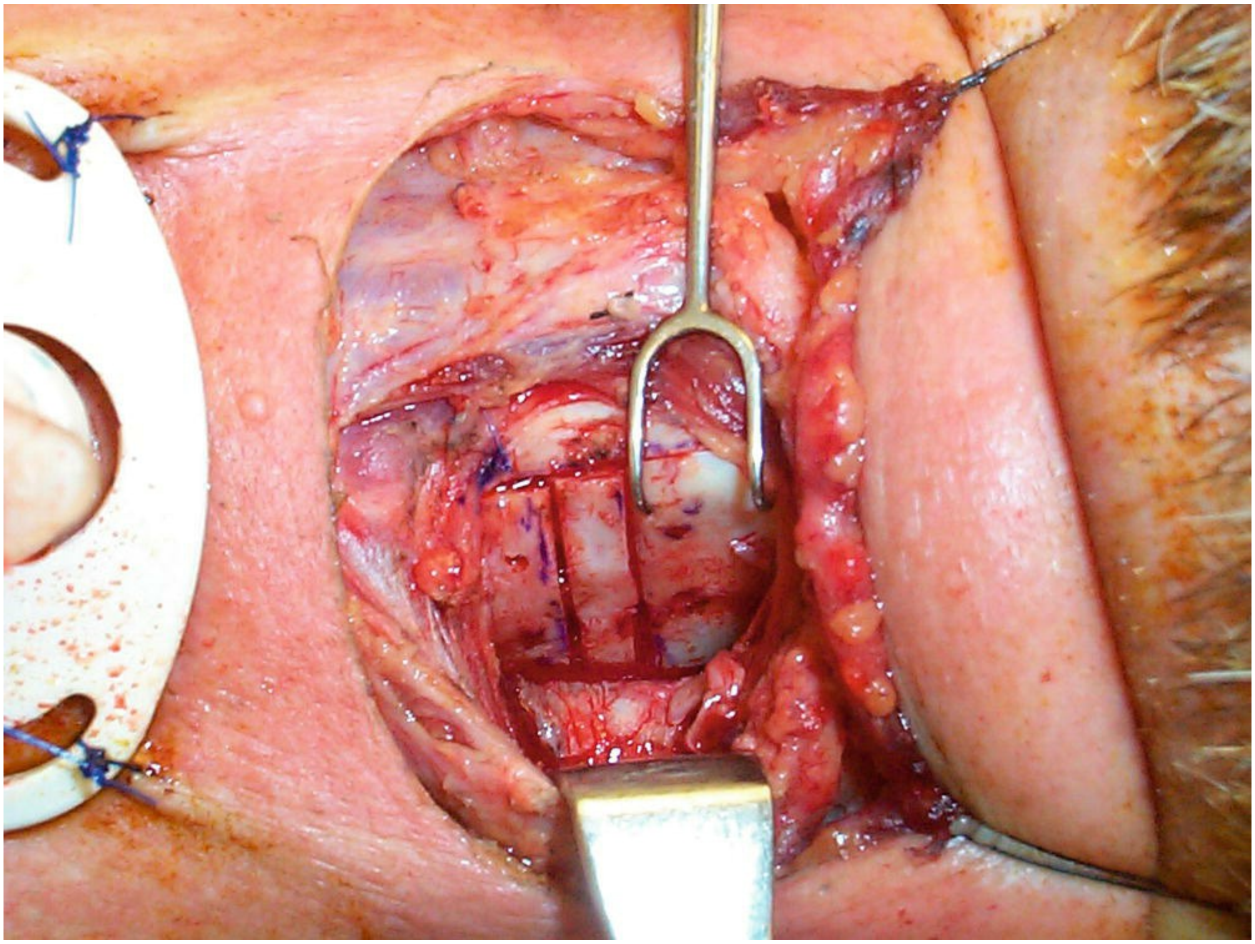

Figure 15.9. Cartilage cuts for VPL with plan for imbrication laryngoplasty.

Extended Vertical Hemilaryngectomy

1. Frontolateral vertical hemilaryngectomy—used for lesions involving the AC and the anterior contralateral cord

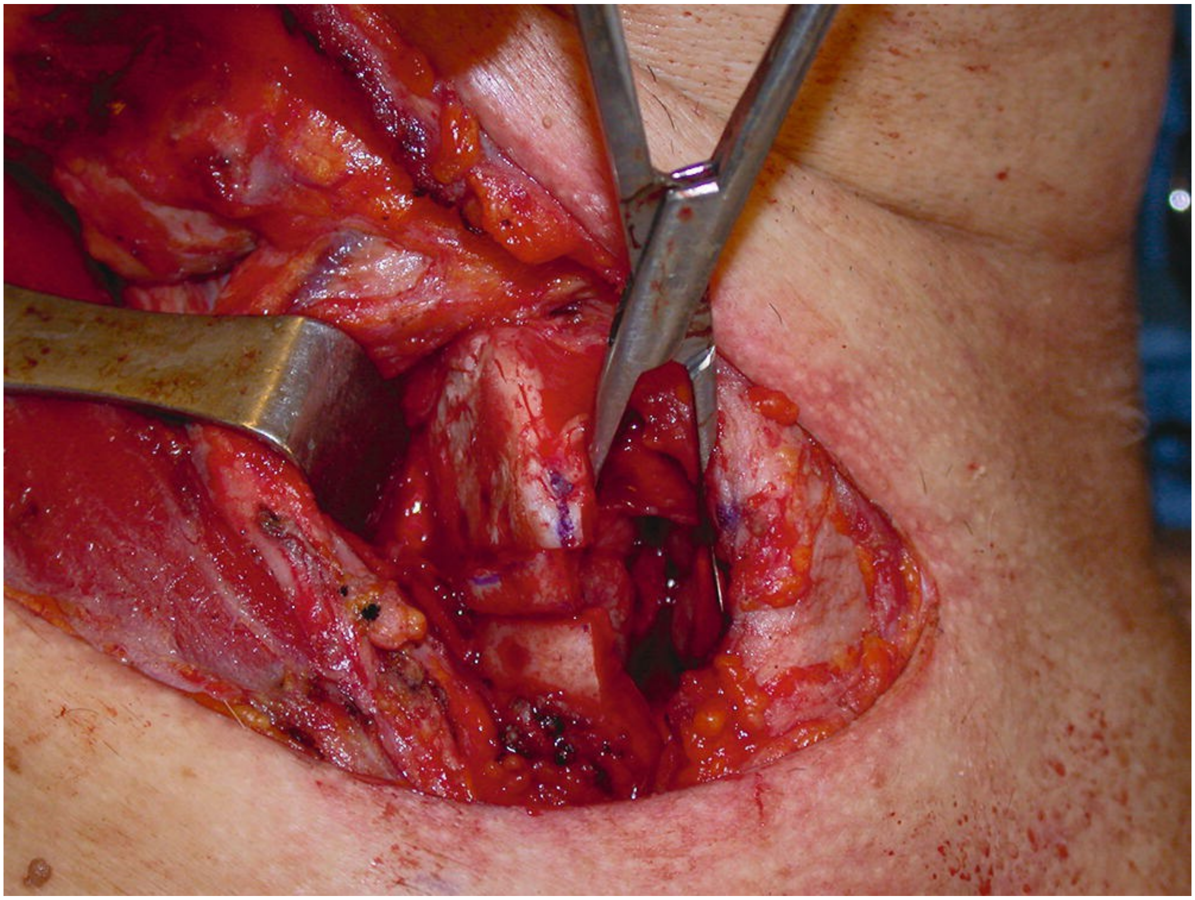

Figure 15.10. The laryngofissure performed at the time of VPL for resection of a glottic cancer provides good exposure of the larynx.

2. Posterolateral vertical hemilaryngectomy—used for lesions involving the ipsilateral arytenoid cartilage

The systematic use of frozen section control of margins cannot be overemphasized in this type of precision surgery. If frozen sections are not used and the permanent sections indicate that the margins are positive, the rate of recurrence is intolerably high.

Horizontal Glottectomy.

AC involvement has also been treated effectively with open surgical techniques. Szyfter et al. reported on their experience using open horizontal glottectomy in 108 patients with T1b disease. Negative margins were obtained in 100% of specimens with this open technique. Resection included removal of the true and false vocal cords, the lower portion of the thyroid cartilage, and the entire paraglottic space whereas reconstruction involved re-approximating the cricoid and remaining thyroid cartilage. The locoregional

recurrence rate was 16.7%, which correlated with prelaryngeal regional lymph node metastasis (6.5%). Organ preservation was possible in 90.7% of patients with a 5-year reported overall survival of 97.2%. The authors considered their results with open horizontal glottectomy comparable, if not better, than those reported by TLM and primary radiation therapy for T1b lesions.[54]

Supraglottic Carcinoma

Pressman's study of the lymphatic drainage of the subunits demonstrated that the lateral structures of the aryepiglottic folds and false cords were found to have ipsilateral lymphatic drainage and that the midline epiglottis drainage pattern was bilateral. The superficial lymphatic channels in the supraglottis had bilateral drainage, and the deep lymphatic channels were side specific. The lymphatic vessels traverse the thyrohyoid membrane, alongside the superior thyroid artery and vein, and empty into the jugulodigastric (level II) and midjugular (level III) lymph nodes.

Fibroelastic membranes within the laryngeal framework serve as functional barriers to prevent the spread of cancer from one subunit to another. These barriers include the thyrohyoid membrane, the hyoepiglottic ligament, the thyroepiglottic ligament, the conus elasticus, and the quadrangular membrane. These membranes serve to divide the larynx into two three-dimensional compartments—the preepiglottic space and the paraglottic space. Cancer initially invading the preepiglottic space can directly extend into the paraglottic space (**Figs. 15.11 and 15.12**); in this situation, the use of supraglottic laryngectomy is precluded. Involvement of these spaces has a direct effect on the selection of patients for conservative surgical management of supraglottic cancer.

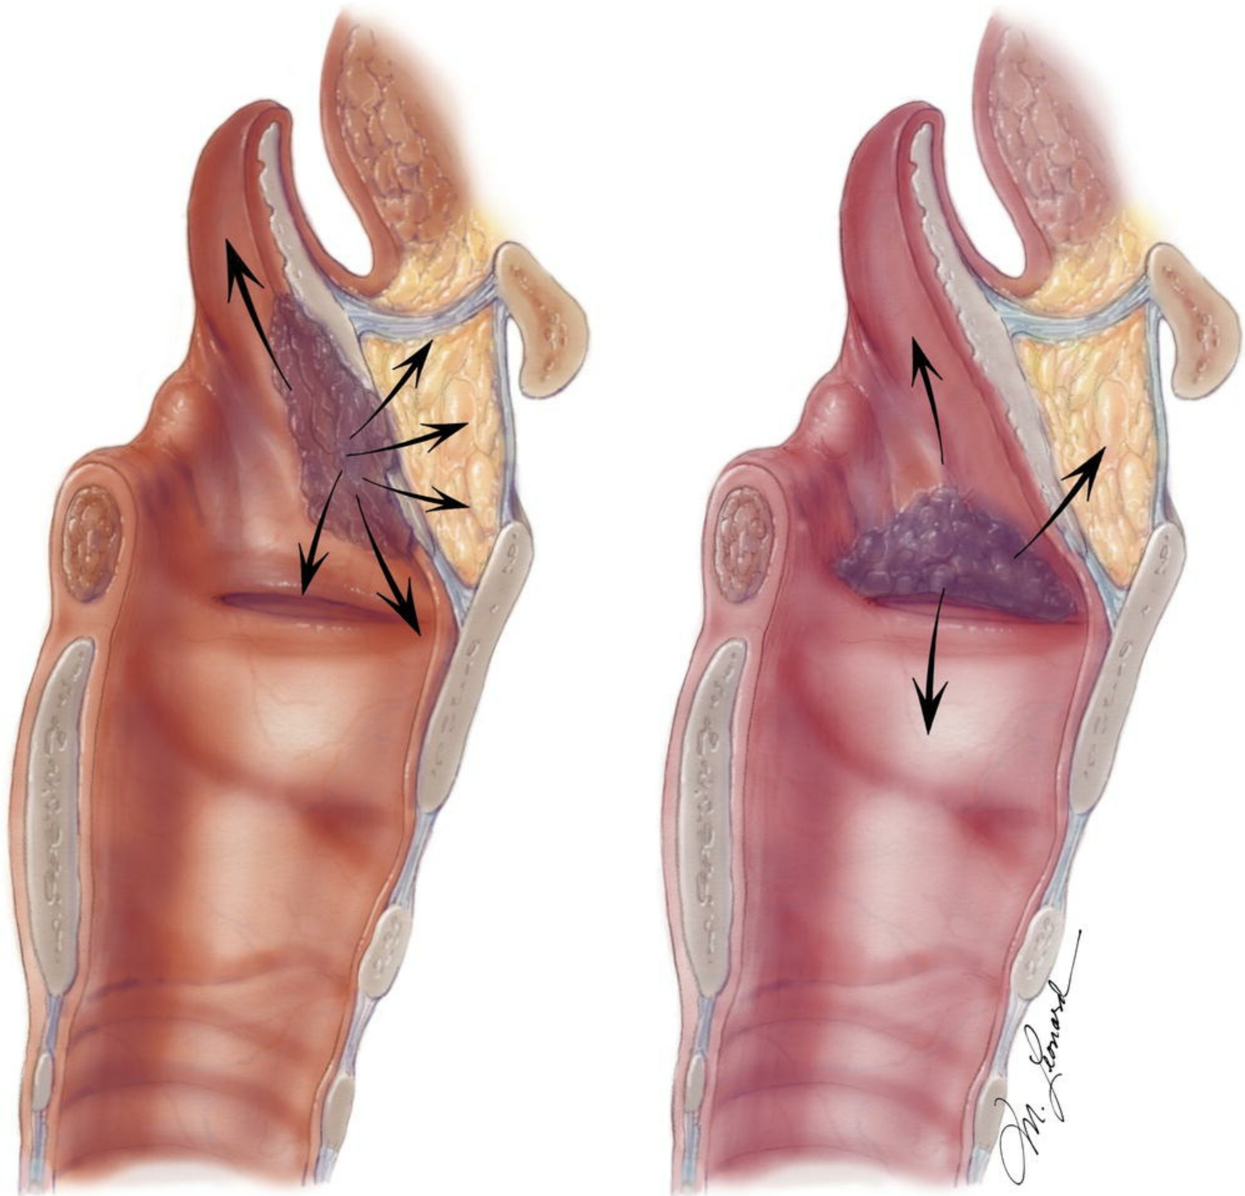

Figure 15.11. Invasion of the preepiglottic space from cancers of the laryngeal surface of the epiglottis and laryngeal ventricle.

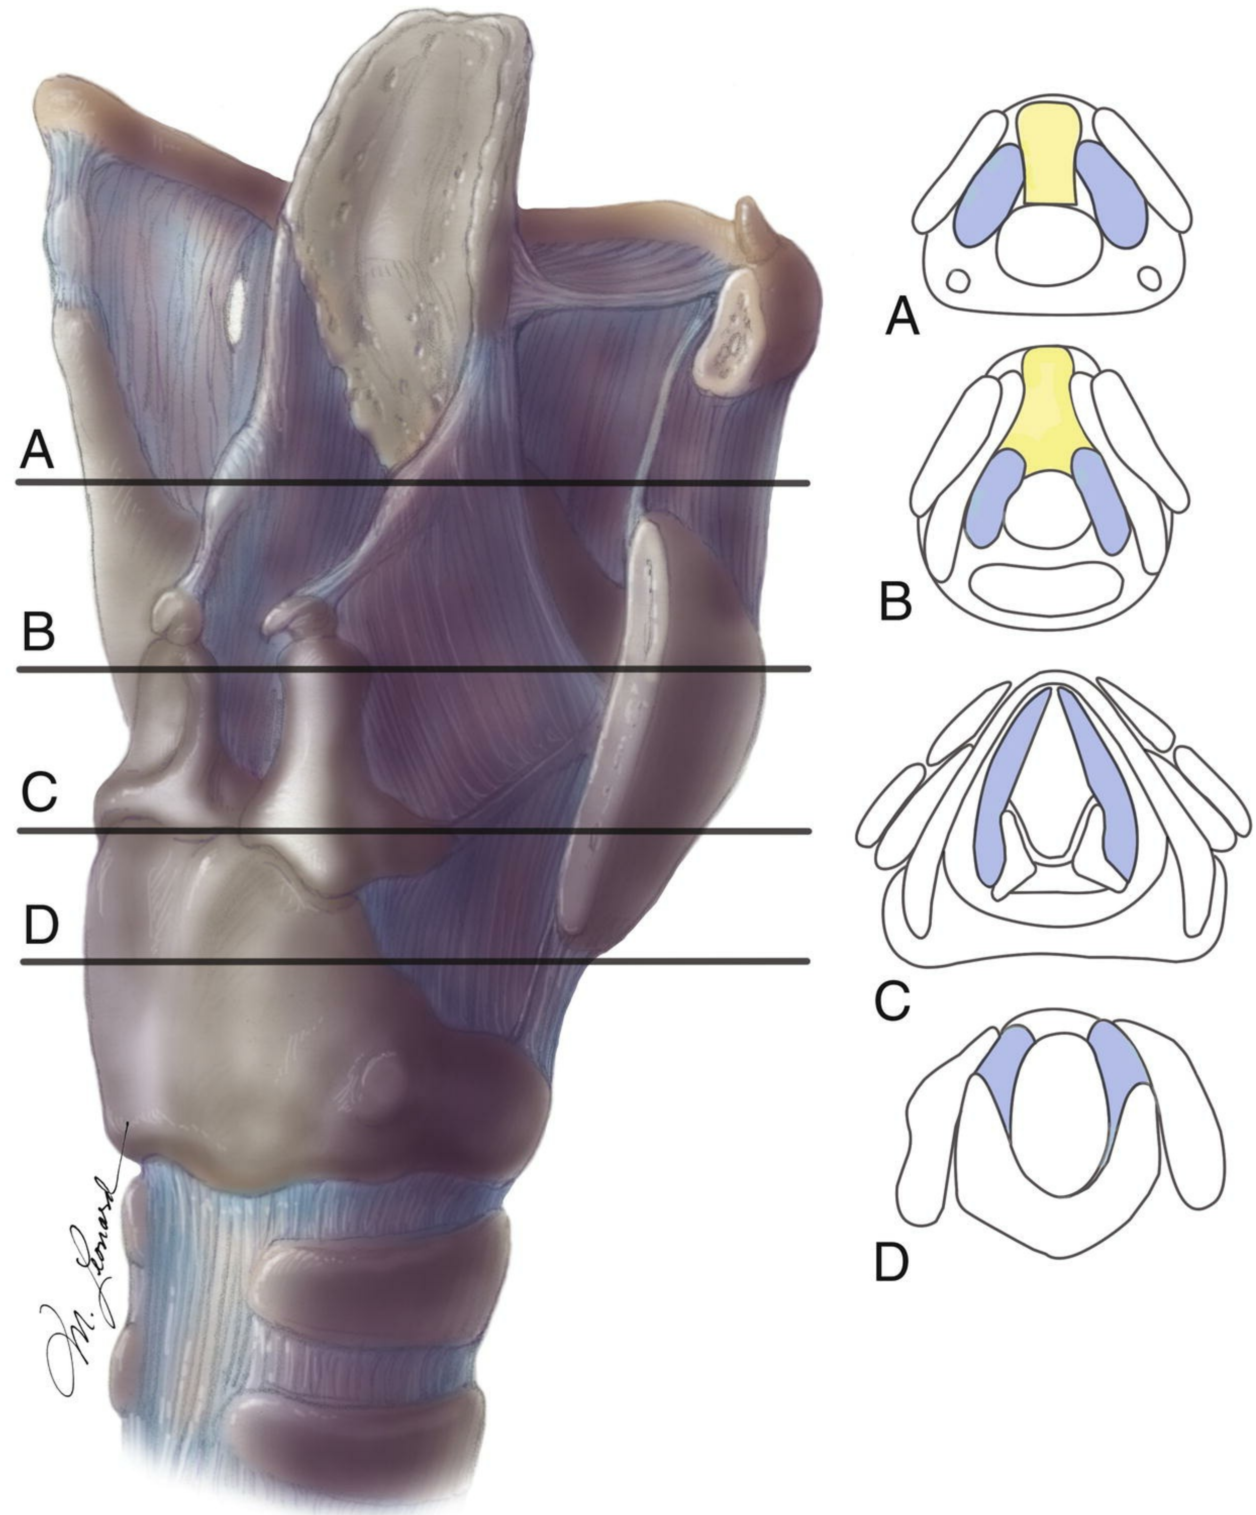

Figure 15.12. Spaces of the larynx at various axial levels. Preepiglottic space–*yellow*, paraglottic space–*blue*.

Endoscopic Resection

The concept of endoscopic management of supraglottic cancer began in 1939 when Jackson described the use of a laryngoscope and punch biopsy forceps to resect cancer of the suprahyoid epiglottis.[55] Endoscopic management fell into disrepute owing to the poor results and morbidity associated with it. The advent of the operating microscope, suspension microlaryngology, and the carbon dioxide (CO_2) laser led to the renewed popularity of endoscopic management of laryngeal cancers, both in Europe and the United States.

The potential advantages of endoscopic management over open surgery include the elimination of the need for tracheostomy, shorter operating times, and earlier rehabilitation of swallowing function. Disadvantages include the need for specialized equipment, prolonged healing time in that the defect is allowed to heal by second intention, and the potential for limited exposure that often leads to inadequate removal of the cancer. The CO_2 laser combined with an operating microscope is the most frequently used instrumentation. The quality of the voice following laser surgery for supraglottic cancer should be unchanged. Studies from Europe have shown that the results of endoscopic laser surgery are comparable to those of radiation therapy, with the latter type of treatment being more convenient for patients and less expensive overall.

The use of endoscopic laser resection is dependent on the size, location, and extent of the cancer. T1 and T2 cancers located on the suprahyoid epiglottis, aryepiglottic fold, and vestibular fold with minimal preepiglottic and no paraglottic involvement can be treated successfully with endoscopic resection. Cancers arising on the infrahyoid epiglottis and false cord can be technically challenging to resect with endoscopic resection. The most important factor in endoscopic laser surgery is adequate exposure of the cancer. The use of the Weerda bivalved laryngopharyngoscope allows optimal exposure. The superior blade is placed into the vallecula, and the inferior blade pushes the endotracheal tube against the posterior pharyngeal wall. The laryngoscope is repositioned as necessary to maintain optimal exposure throughout the procedure.

The CO_2 laser is the laser of choice for endolaryngeal surgery. Advantages of the CO_2 laser include its superficial effect, which helps to minimize damage to surrounding normal tissue, and its ability to be used as a cutting tool in the focused mode and as a coagulation tool in the defocused

mode.

Small cancers on the suprahyoid epiglottis or the aryepiglottic fold may be resected with the laser en bloc, but the majority of supraglottic cancers are excised in a piecemeal fashion. The epiglottis is split in the midline (sagittal plane) with resection of the suprahyoid division first, followed by the infrahyoid component. The preepiglottic adipose tissue is then encountered and removed until the thyrohyoid membrane is identified. Resection is then continued inferiorly to include the aryepiglottic folds and false cords as necessary. Frozen sections are taken from the specimens, and additional resection is performed until negative margins are achieved. The defect is allowed to heal by second intention (**Fig. 15.13**).

Figure 15.13. Endoscopic appearance after TLM resection of an epiglottic carcinoma with appropriate wound healing.

A retrospective study examining the feasibility of TLM in cases of T3 cancer of the larynx was reported by Canis et al. in a series of 226 patients (glottic 122, supraglottic 104). Adjuvant radiation was required in 18% of patients and 63% underwent delayed neck dissection. Endoscopic CO_2 laser resection to a margin of 2 to 3 mm was pursued with primary cancers of the glottis and expanded to 5 to 10 mm for supraglottic tumors. Postoperative bleeding

occurred after 1% of glottic resections and 12% following supraglottic procedures. The 5-year laryngeal preservation rate was 87%. The 5-year local control and overall survival rates were 71.4% and 64.4%, respectively. The authors emphasized the favorable oncologic results with limited treatment-related morbidity and capacity for organ preservation offered by TLM when compared to chemoradiation and open surgical techniques.[56]

Potential complications of endoscopic excision include intraoperative or postoperative hemorrhage and infection of the exposed laryngeal cartilage.[55] Radiation may be started ~2 to 4 weeks following resection of the primary. The patient is readmitted for neck dissections. At that time, further resection can be carried out if permanent sections reveal positive margins.

Supraglottic Laryngectomy

Supraglottic laryngectomy is indicated in patients in whom the cancer arises from the epiglottis, aryepiglottic folds, and false vocal cords. This procedure minimizes morbidity and maintains the three primary functions of the larynx—airway protection, respiration, and phonation. Supraglottic laryngectomy (as a two-stage procedure) was introduced by Alonzo in 1947 as an alternative for supraglottic tumors to the traditional total laryngectomy and radical neck dissection. Modifications made by Ogura in 1958 and later by Som in 1959 converted supraglottic laryngectomy to a one-stage procedure.[55]

The most important factor influencing the success of supraglottic laryngectomy is appropriate patient selection based on both the patient and tumor factors. Every patient undergoing supraglottic laryngectomy will experience temporary aspiration postoperatively, thus making the patient’s cardiopulmonary reserve an important factor in patient selection. Patients must have a reasonably good cough mechanism or they will not be able to swallow properly and will therefore aspirate and potentially develop recurrent aspiration pneumonia and become malnourished.

The cancer factors are equally important in the selection process; established contraindications are based on anatomic considerations, including involvement by cancer of the thyroid cartilage or the AC, vocal cord fixation due to involvement of the paraglottic space, and involvement of the sinus apex pyriform or postcricoid mucosa. Such patients are at an unacceptable risk because of the potential for recurrent cancer, as well as the potential for

postoperative dysphagia and aspiration. In patients with involvement of the base of the tongue, primary closure can be difficult, resulting in increased dysphagia and aspiration.

Supracricoid Partial Laryngectomy

SCPL remains a surgical treatment alternative for selected patients for the primary treatment and surgical salvage of glottic (with cricohyoidoepiglottopexy [CHEP]) and supraglottic carcinoma (with cricohyoidopexy [CHP]). Beyond anatomic considerations, comorbidities that would be a contraindication to the procedure include compromised pulmonary function (e.g., COPD) and disorders predisposing to poor wound healing such as insulin-dependent diabetes, selected immunologic disorders, and severe peripheral vascular disease.

Placement of a gastrostomy tube prior to surgery should be considered anticipating postoperative dysphagia and aspiration that requires a prolonged period of rehabilitation with the assistance of a speech–language pathologist. Preoperative placement of a gastrostomy tube is strongly advised for patients over 75 years of age, individuals requiring resection of one arytenoid at the time of operation, patients who have been previously radiated, and patients with CN XII, superior or recurrent laryngeal nerve dysfunction or need for sacrifice of these nerves. A temporary tracheostomy is placed at the time of surgery with the goal of early decannulation to facilitate laryngeal elevation and minimize inhibiting a patient's cough reflex as they adapt to the postsurgical changes as they regain their ability to swallow.[57]

In SPL-CHP, the entire supraglottis, the false and true vocal cords, and the thyroid cartilage, including the paraglottis and preepiglottic spaces, are removed. The procedure can be extended to resect one involved arytenoid cartilage. The cricoid cartilage, hyoid bone, and at least one arytenoid are saved. Phonatory and swallowing functions are maintained by the movement of the remaining arytenoid against the base of the tongue.

In SCL-CHEP, the false and true vocal cords and the thyroid cartilage, including the paraglottic, are removed. Reconstruction is performed by suturing the hyoid bone and the remnants of the epiglottis to the cricoid cartilage.

SCL can be used as a primary treatment modality or as a salvage option

after failure of organ preservation therapy (radiation therapy or radiation therapy with chemotherapy). SCL-CHP has a high rate of failure (aspiration and tracheotomy dependence) after radiation therapy with chemotherapy. SCL may be considered for supraglottic cancers that involve the glottis at the AC, invade the thyroid cartilage, are associated with impaired vocal cord mobility, and have paraglottic invasion and/or moderate preepiglottic space involvement or are transglottic (**Figs. 15.14 to 15.16**).

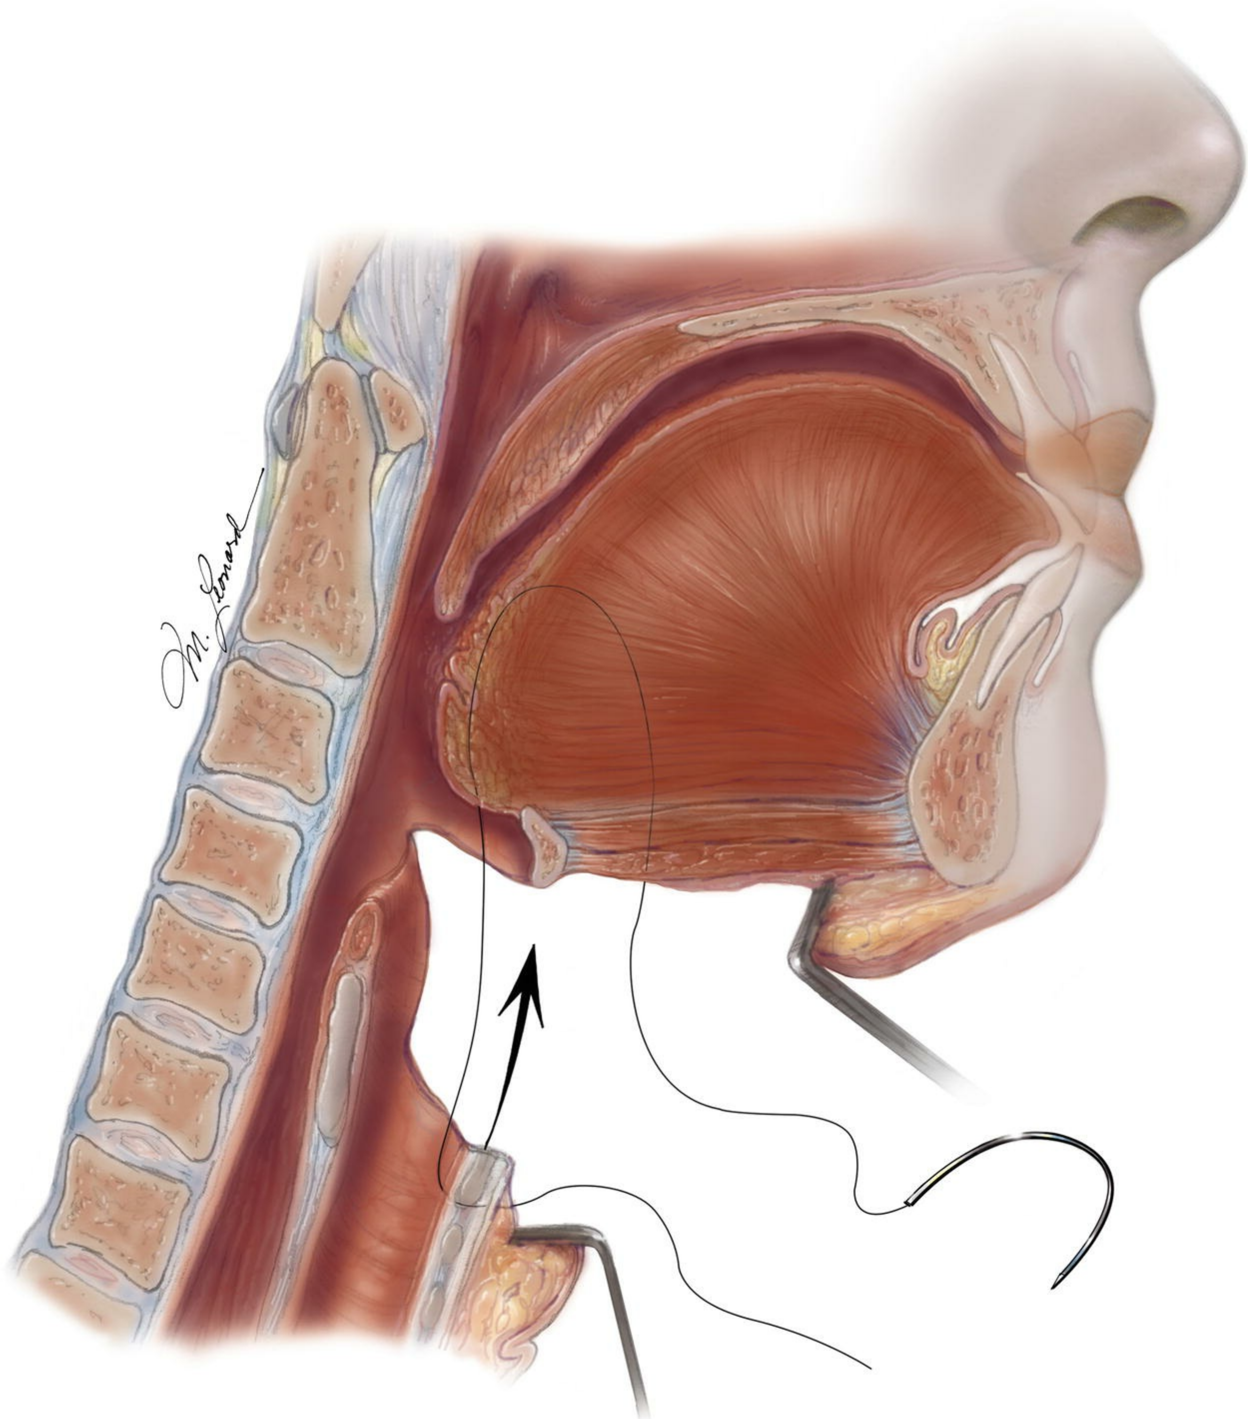

Figure 15.16. Sagittal view–suture placement, approximating cricoid to hyoid, made during reconstruction with a supracricoid laryngectomy with CHP.

Total Laryngectomy

Despite the advances made in organ preservation treatment protocols, total laryngectomy (TL) is a viable option in certain patients, including those with locally advanced cancer of the larynx with cartilage invasion, recurrent or persistent cancer after conservation treatment (surgery, radiation therapy, or chemoradiotherapy), and advanced malignant tumors of certain histologic types such as spindle cell carcinoma, adenocarcinoma, chondrosarcoma, and others that respond poorly to radiation therapy and/or chemotherapy. It is also appropriate for those with benign processes such as chronic severe aspiration or radionecrosis of the larynx refractory to more conservative management (**Figs. 15.17 to 15.20**).

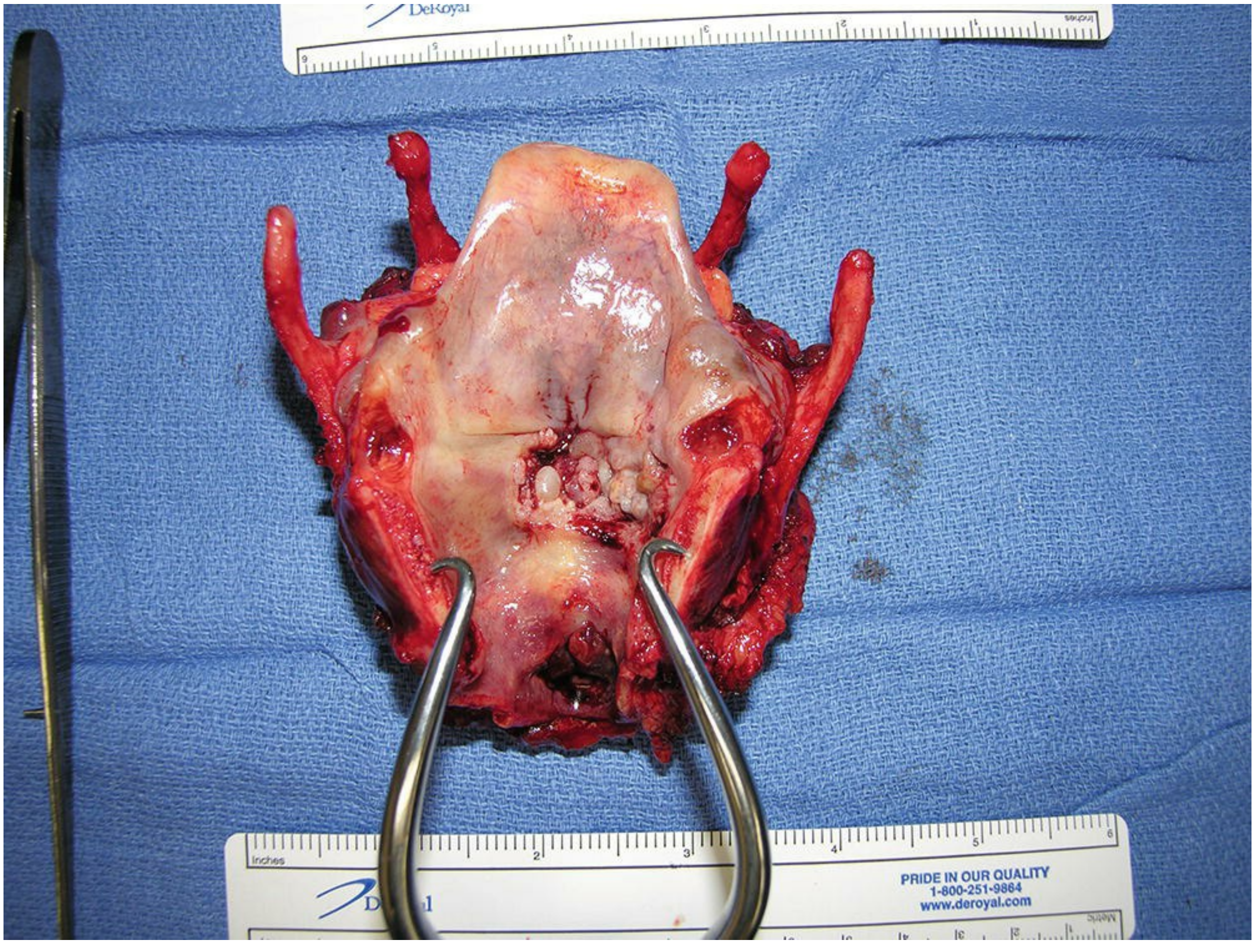

Figure 15.20. Total laryngectomy specimen with posterior cricoid cartilage bisected demonstrating extent of spread of a transglottic cancer that had preepiglottic and paraglottic space spread.

Criteria for patient selection for TL include the ability of the patient to undergo general anesthesia and to care for the stoma, as well as the psychological capability for adjusting to a laryngectomy.

Robotic Laryngeal Surgery.

Transoral robotic surgery (TORS) has been applied to resection of cancer of the larynx. Lallemant et al. reported on a series of 23 patients (13 glottic, 10 supraglottic) with predominantly early-stage cancer (T1N0-16, T2N0-4, T2N+-3) treated with primary TORS. The local recurrence rate was 8.7% (2/23) and was associated with cancer of the AC in both cases. The median operative time was 1 hour and patients were hospitalized a median of 7.5 days. There were no intraoperative complications. There were two reported

postoperative complications including one case with cervical emphysema with pneumothorax and laryngeal bleeding requiring a return to the operating room and a second case with supraglottic bleeding on postoperative day 2 requiring a return to the operating room for control. As a result of their experience, the authors recommend pre-emptive identification and clipping or coagulation of the superior laryngeal artery when supraglottic resections are performed. The oncologic results of TORS resection for this population were comparable to endoscopic CO_2 laser resection.[58]

Park et al. reported on 16 previously untreated patients who underwent primary TORS supraglottic partial laryngectomy. The majority of cancers were epiglottic (62%) with the remainder located on the aryepiglottic fold (25%) and false vocal fold (13%). The cancers were predominantly early staged (T1–T7, T2–T5, T3–T4) and 56% of patients were N0. Neck dissections (eight unilateral, six bilateral) were performed concurrent with the TORS. A temporary tracheostomy was placed in all patients. Negative margins at the time of resection were obtained in 88% of patients. One-half of patients required adjuvant therapy with 31% also requiring chemoradiation. Patients resumed the capacity to swallow after an average of 8.3 days and the average hospital stay was 13.5 days. There were no significant perioperative or postoperative complications reported. The Kaplan-Meier disease-free survival for the group at 2 years was 91%.[59]

TORS is not limited to partial laryngeal surgery; a series of patients who underwent TORS total laryngectomy was reported by Smith et al. The technique was used in a group of 7 patients with recurrent cancer (5/7) or posttreatment laryngeal dysfunction (2/7). At the beginning of the TORS approach, a transcutaneous incision is made to allow for tracheal transection and creation of the stoma. The surgical resection of the larynx and associated pharyngeal tissues is accomplished with the transoral technique in addition to the pharyngeal mucosal closure after removal of the specimen. The surgical approach requires adequate exposure to the vallecula and does require resection of the hyoid as part of the procedure. TORS total laryngectomy required conversion to an open approach in 29% of patients due to inadequate exposure with the robotic approach. Postoperative fistula occurred in 29% of patients. The authors cite that patients with a narrow mandibular arch, anterior displacement of their laryngeal anatomy, and intact dentition would not be candidates for this approach. They also state the exact indications and

limitations of the technique continue to evolve, yet they believe that the technique has a role in salvage surgery for the larynx.[60]

Complications of Laryngectomy

Early Complications

Early complications of laryngectomy include infection, stomal crusting, and pharyngocutaneous fistula. Perioperative antibiotics have significantly decreased the incidence of infection. Crusts around the stoma are removed at least once a day to prevent airway obstruction.

Fistula formation occurs in 15% to 40% of cases, depending on whether regional flaps are used for pharyngeal closure and whether the tissues have been previously radiated. The fistula itself is conservatively managed with drainage, irrigation, and packing; most heal spontaneously. Fistulas in patients who had undergone previous irradiation were larger than in patients who had not had prior treatment.[61]

Free-tissue transfer reconstruction of the hypopharynx is the preferred method of reconstruction following combined chemotherapy and radiation therapy protocols (**Figs. 15.21 to 15.23**). Surgical complications such as pharyngocutaneous fistulas are significantly reduced, and hospital stays are minimized with the use of microvascular flap reconstruction.[62]

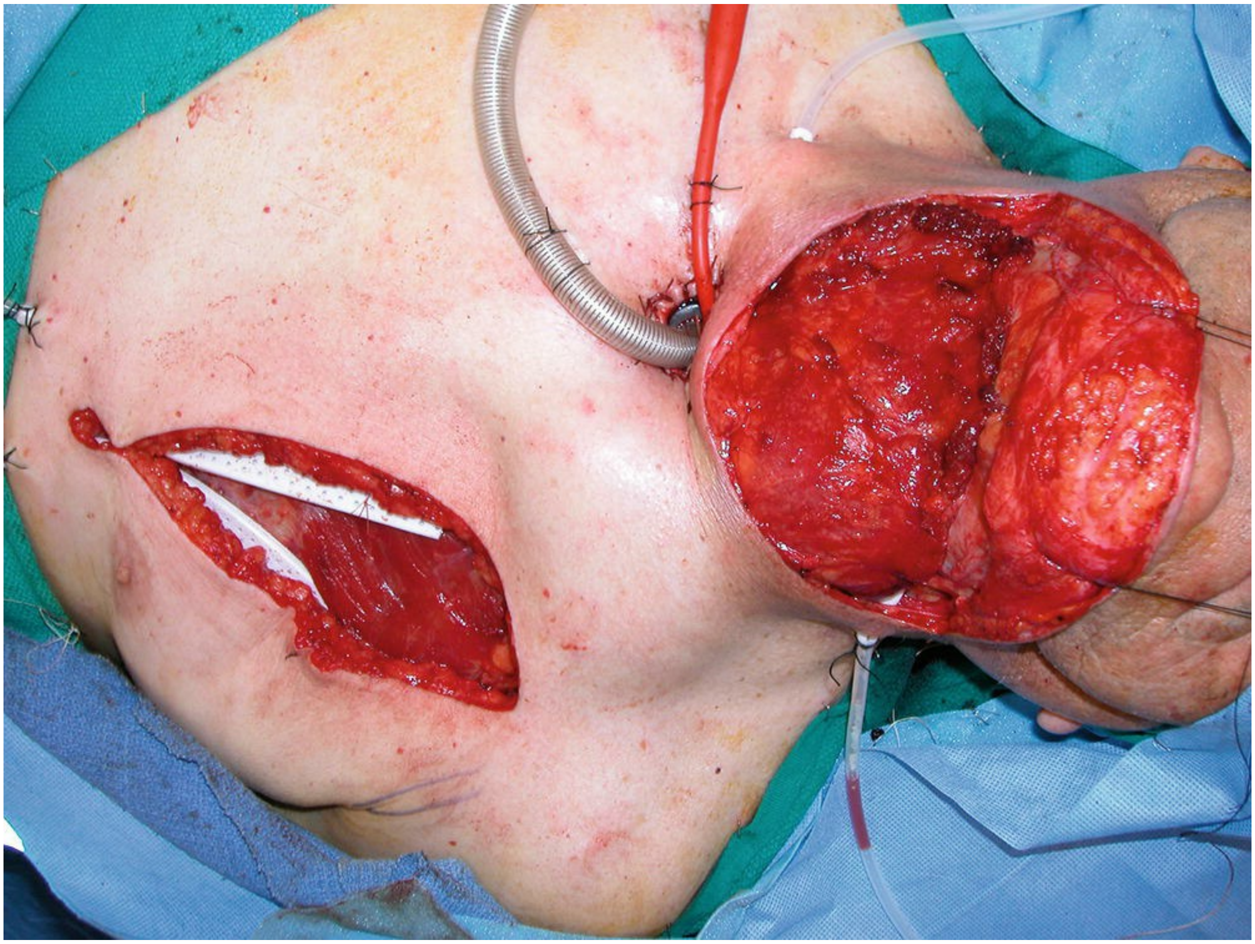

Figure 15.21. Pectoralis major (muscle-only) overlay flap used at the time of salvage laryngectomy after recurrence despite prior treatment with chemoradiation. Primary pharyngeal mucosal closure was performed without flap augmentation.

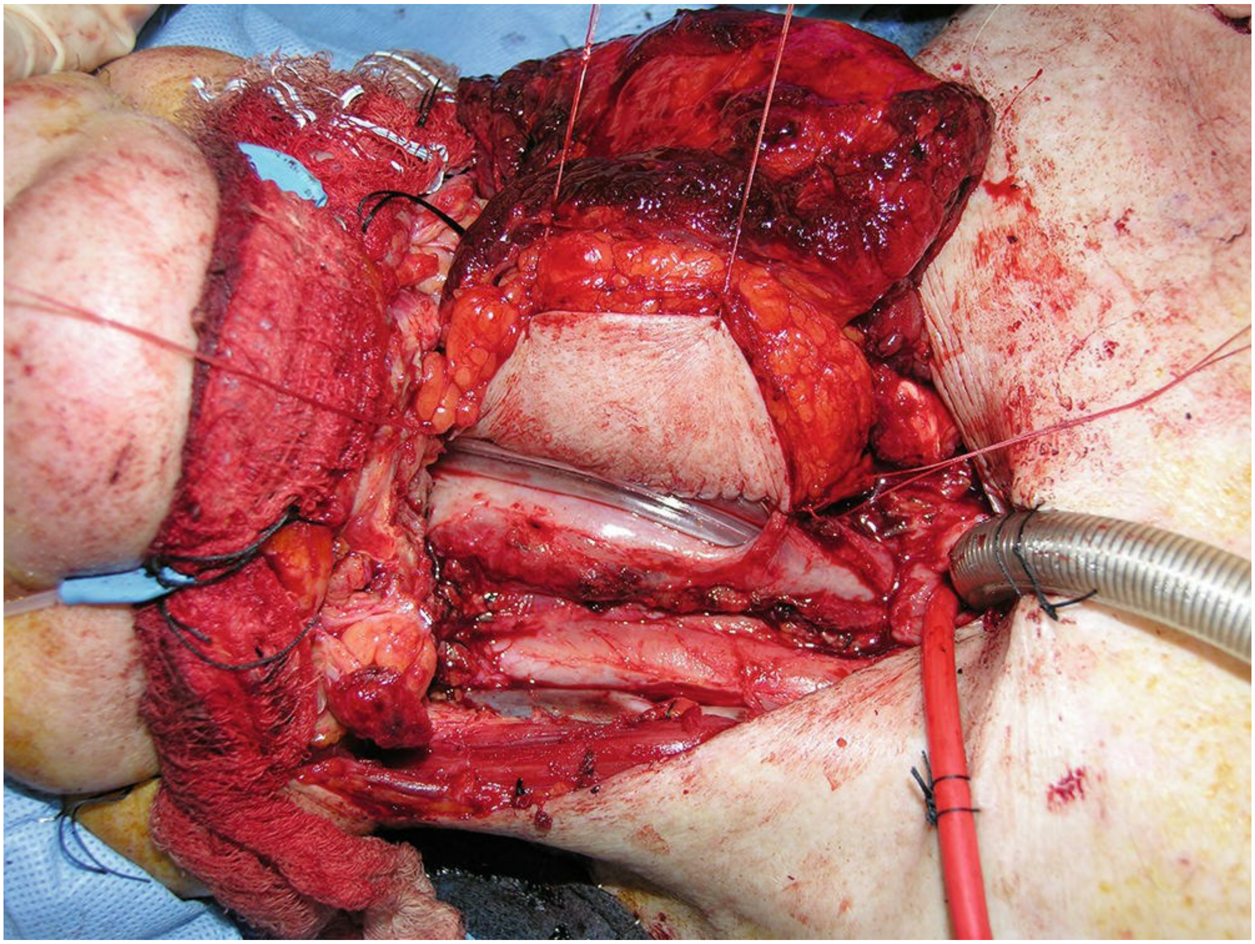

Figure 15.22. Pectoralis major flap ("patch") reconstruction of a partial pharyngeal defect in a patient requiring primary laryngectomy and partial pharyngectomy.

Figure 15.23. Tubed radial forearm free flap reconstruction of a pharyngeal defect after total laryngopharyngectomy (prior to arterial/venous anastomosis).

The most feared complication of a salivary fistula is carotid artery blowout from exposure of the artery and infection in the wound. The high morbidity and mortality associated with urgent carotid ligation have led many to employ routine coverage of the carotid artery in all cases in which laryngectomy is performed after radiation therapy is provided. The sternocleidomastoid muscle often provides adequate coverage. If the muscle has been removed during a concomitant radical neck dissection, dermal grafts and regional flaps have been described either to provide coverage for the artery or to direct the flow of saliva away from the artery.

Late Complication

Late complications following laryngectomy include stenosis of the stoma and

a stricture of the pharyngeal remnant with dysphagia. Stenosis of the tracheostoma is a frequent complication following total laryngectomy that results in reduced airflow. Many authors have attempted to identify factors associated with stomal stenosis; a number of procedures have been recommended for the surgical correction of such stenosis.[63,64]

Dysphagia that develops gradually during the postoperative period is often a sign of pharyngeal stenosis; however, recurrent cancer must first be ruled out. Barium esophagogram is helpful in revealing the site of narrowing, but endoscopy with biopsy under general anesthesia is required to determine if the stricture is recurrent cancer or benign scarring. Benign strictures can usually be managed with serial dilations, but occasionally, patients require excision of the stenotic pharynx with pharyngoesophageal reconstruction and regional or free-tissue transfer.

The number of deaths in patients with laryngeal cancer is generally higher in those with supraglottic primary cancers, more so than glottic, and increasingly related to intercurrent diagnoses, long-term complications of treatment (aspiration pneumonia), and the development of metachronous primary cancers.[65] The distant metastatic rate for patients with cancers of the larynx is generally lower than other sites in the head and neck and is ~8%.

Voice Rehabilitation After Total Laryngectomy

A major challenge faced by the head and neck surgeon and the speech pathologist in treating a patient who has had a total laryngectomy is the restoration of speech. The first artificial larynx was devised by Gussenbauer in 1874. Voice restoration using the fistula technique was reintroduced by Asai in 1965. In 1979, Singer and Blom introduced the tracheoesophageal puncture (TEP) and silicone prosthesis for generating tracheoesophageal voice.

The patient who is undergoing a total laryngectomy is offered three options: the artificial larynx or electrolarynx, esophageal voice, and tracheoesophageal voice.

Electrolarynx

The artificial larynx is available as an external device that is placed against the neck or as an oral type. Both types are electrically driven and produce a mechanical sound. This sound is articulated by the tongue, lips, and teeth as understandable speech. Advantages of the electrolarynx include the short learning time required for its use, its ability to be used during the immediate postoperative period, and its relative availability and low cost. Disadvantages include its mechanical sound and dependence on batteries, as well as the need for maintenance of the intraoral tubes.

Esophageal Voice

A speech pathologist or another laryngectomy patient usually teaches the patient insufflation behavior in acquiring esophageal speech. This entails trapping air in the mouth or pharynx and propelling it into the esophagus. This produces a belch-like sound that can be articulated by the tongue, lips, and teeth. The patient learns how to rapidly insufflate and eject air through the esophagus to produce understandable speech.

Tracheoesophageal Voice

Tracheoesophageal speech is considered by many to be the preferred modality for rehabilitation of a patient following laryngectomy. It is based on the concept of shunting of tracheal air to the pharynx through a controlled fistulous tract during exhalation to produce sound through vibration of the mucosa of the upper esophageal segment. Speech is produced by articulation of this sound at the level of the oral cavity.[66]

Technique of Tracheoesophageal Puncture

TEP can be performed at the time of laryngectomy (primary TEP) or later as an independent procedure (secondary TEP). The timing of TEP is an area of debate and is usually based upon the surgeon’s preference. Primary TEP offers the advantages of avoiding a secondary procedure and providing early voice rehabilitation; the transesophageal fistula can be used temporarily as a feeding esophagostome. Primary TEP is performed after the stoma has been constructed and before the pharynx has been closed.

The most common problem following TEP is failure of voice restoration. Studies have shown that failure rates range from 3% to 15%. Some of the common causes of failure of voice restoration following TEP include inadequate patient motivation and learning capabilities. In addition, patients with poor vision, arthritis, or neurologic disabilities have been found to be poor candidates for the procedure. In many instances, patients may be fitted with a hands-free, self-retaining unit that precludes the need for digital manipulation of the stoma. These conditions should be considered during the preoperative evaluation of the patient by a speech pathologist.

Another cause of failure is pharyngoesophageal spasm, which appears to be caused by reflex contraction of cricopharyngeal constrictor muscles when the mid-esophagus is distended with air. It is believed to be a cause of TEP speech failure in 10% to 12% of patients. Therapeutic options for pharyngoesophageal spasm include cricopharyngeal and constrictor myotomies, pharyngeal neurectomies, and injection of the pharyngeal muscles with botulinum toxin.

Other complications resulting from TEP include bleeding from around the tract (usually granulation tissue), air in the stomach, salivary leakage around or through the prosthesis, and aphonia during radiation therapy. More serious and potentially life-endangering, although fortunately rare, complications include mediastinitis, cervical cellulitis, and aspiration of the prosthesis.[67]

Radiation Therapy for Cancer of the Larynx

Radiation therapy has a long history as a key component of treatment for cancer of the larynx[68] and may be used as a single modality in definitive therapy or in combination with surgery and/or chemotherapy, depending on patient and disease factors.

Indications and Techniques

Early Cancer of the Glottis (Stage I and II Disease)

Radiation therapy alone is a standard, effective treatment option for the majority of early squamous carcinomas of the glottis, and supporting data for this approach are largely based on institutional reports. Investigators from the University of Florida reported 5- and 10-year local control rates of 94% and 93% for T1a, 93% and 91% for T1b, 80% and 80% for T2a, and 70% and 67% for T2b following radiation therapy, respectively.[69] These results compare favorably to other large contemporary institutional series (**Table 15.3**). Overall, the rates of local control following radiation therapy compare favorably with modern surgical outcomes[80] (3), and severe complication rates following radiation therapy are quite low (<2%)[69] (2). As for early invasive carcinomas, radiation therapy can be an effective treatment for extensive or recurrent CIS of the glottis, with expected control rates exceeding 90%.[81]

Table 15.3 Local Control Rates at 5 Years for Early Glottic Carcinomas Following Radiation Therapy, According to T Category

First Author, Year	Follow-up	*n*	T1a	T1b	T2a	T2b
Chera et al., 2009[69]	Median 12 y	585	94%	93%	80%	70%
Nomiya et al., 2008[70]	Median 7.4 y	163	92%	85%		
Groome et al., 2006[71]	Median 5.9 y	704	82%	82%	63%	63%
Cellai et al., 2005[72]	Mean 9.3 y	831	84%	81%		
Frata et al., 2005[73]	Mean 7.5 y	256			73%	73%
Cho et al., 2004[74]	Median 14.4 y	246	83%	83%	62%	62%
Gowda et al., 2003[75]	Median 5.8 y	200	93%	89%		
Garden et al., 2003[76]	Median 6.8 y	230			74%	70%
Warde et al., 1998[77]	Median 6.8 y	735	91%	82%	69%	69%

Adapted from Chera BS, Amdur RJ, Morris CG, et al. T1N0 to T2N0 squamous cell carcinoma of the glottic larynx treated with definitive radiotherapy. *Int J Radiat Oncol Biol Phys.* 2010;78(2):461–466, with permission.

Nearly all T1–T2N0 tumors are suitable for radiation therapy–based treatment, but a number of patient (e.g., anemia and smoking), cancer (e.g., anterior or posterior commissure involvement, bulky cancers, impaired vocal cord mobility, and subglottic extension), and treatment factors (e.g., lower daily dose, prolonged overall treatment time, smaller field size, and use of higher-energy photons) have been reported to negatively influence local

control in various series.[72,76–78,82] Radiation oncologists must take great care to identify potentially modifiable risk factors and eliminate any potential technical causes of treatment failure, such as geographic miss, low radiation dose given volume of cancer, and improper technique.[83] It is notable that patients irradiated for early glottic cancers are far more likely to die of a second primary upper aerodigestive tract cancer than their index larynx cancer, which has implications for long-term follow-up and survivorship care.[72]

Generally, compared to T1 cancers, reported absolute local control rates fall ~10% to 25% when vocal cord mobility is impaired (i.e., T2b disease). A number of radiation therapy intensification approaches have been pursued to improve results, most commonly through the use of altered fractionation radiation schedules (acceleration and/or hyperfractionation). For example, the Radiation Therapy Oncology Group (RTOG) trial 95-12 randomized patients with T2N0 squamous carcinoma of the vocal cord to standard fractionation (70 Gy in 35 fractions) versus a hyperfractionated schedule (79.2 Gy in 1.2 Gy fractions delivered twice daily). Presented preliminary results which demonstrated a nonstatistically significant absolute local control advantage of ~10% in favor of the twice daily radiation arm,[84] which is comparable to the absolute local control gains in other trials and institutional series reporting altered fractionation outcomes versus standard fractionation.[76,85] However, results of RTOG 95-12 have not to date been fully published and have been long awaited.

Given the absence or scarcity of draining lymphatics from the true vocal cords, radiation treatment fields for stage I and the majority of stage II glottic cancers are limited to the larynx only (i.e., no “elective” lymph node/neck irradiation). This larynx-only radiation field has traditionally been delivered through mostly opposed lateral, slight anterior tilt, or wedge-pair low-energy (4 to 6 MV) photon fields (typical size 4 to 6 cm^2) commonly used with beam modifiers, such as photon attenuating wedges to improve dose homogeneity across the treatment volume, and surface bolus to ensure adequate dose to the AC when involved. These traditional field arrangements, while providing good coverage of the larynx, inherently lead to unnecessary radiation of the surrounding nontarget soft tissues of the neck and nearby carotid artery segments, which may have a long-term effect on producers on carotid atherosclerosis and subsequent cardiovascular events. Multiple studies have

investigated the technical feasibility of intensity-modulated radiation therapy (IMRT) technique to reduce dose to the carotid artery, particularly to the contralateral carotid artery in the setting of T1a disease. In general, IMRT produces more conformal dose distributions compared to traditional opposed lateral beam arrangements by applying multiple oblique beams of varying shape and intensity around the target in order to create geometrically complex dose distributions. Rosenthal and colleagues from the University of Texas MD Anderson Cancer Center conducted a dosimetric comparison study of traditional opposed lateral photon beam plans versus IMRT plans. IMRT plans provided comparable target volume coverage but significantly reduced intermediate and high doses to the carotid arteries compared to the traditional plans[86] (**Fig. 15.24**).

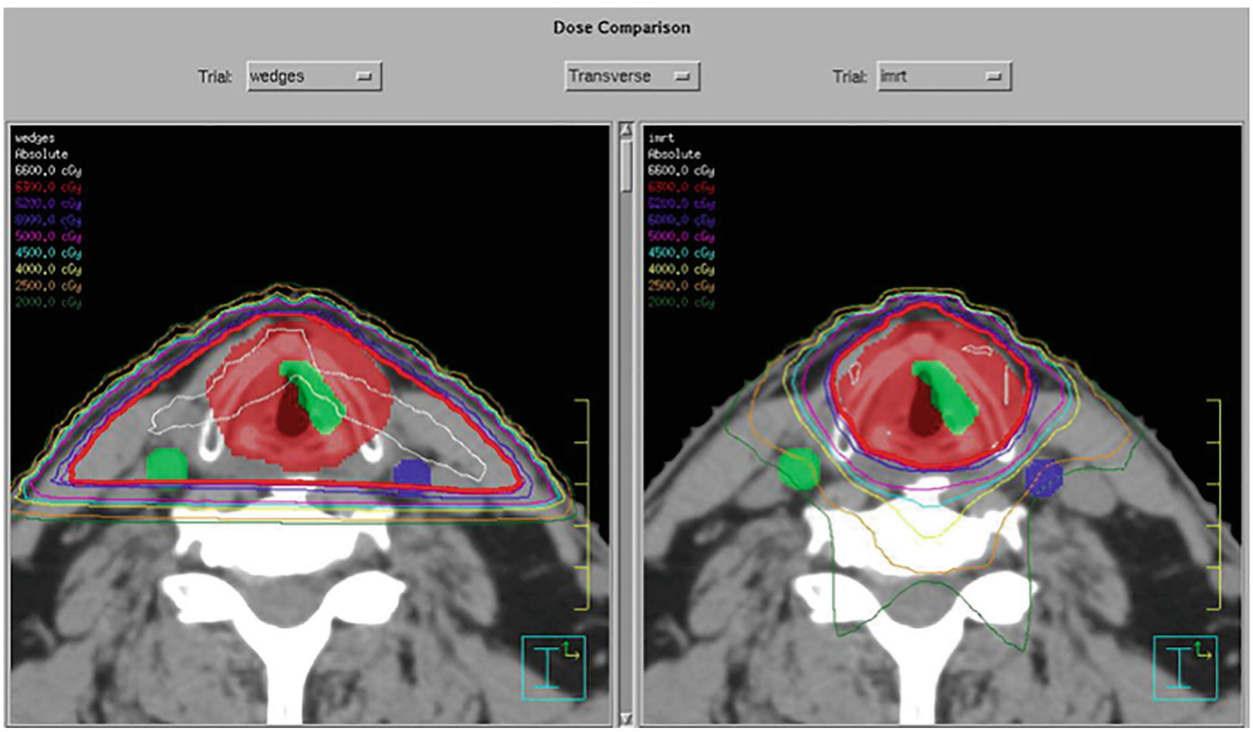

Figure 15.24. Stereotypic isodose plans for a traditional lateral field setup with wedges **(left panel)** and intensity-modulated radiotherapy (IMRT; **right panel**) for early glottic cancer (tumor in *green color* wash). Both plans demonstrate full coverage of primary target volume (shown in *red color* wash) by the 63 Gy prescription isodose line (*thick red line*), but the IMRT plan achieved target dose conformality resulting in sparing of adjacent carotid arteries from intermediate and high-dose distributions, with each carotid receiving <40 Gy in this case.

(Reproduced from Rosenthal DI, Fuller CD, Barker JL Jr, et al. Simple carotid-sparing intensity-modulated radiotherapy technique and preliminary experience for T1-2 glottic cancer. *Int J Radiat Oncol Biol Phys.* 2010;77(2): 455–461, with permission.)

Commonly used dose and fractionation regimens for T1N0 glottic larynx cancers in the United States include 66 Gy in 33 and 63 Gy in 29 fractions, with daily doses ≥2 Gy highly preferred. For T2N0 disease, accepted schedules include 70 Gy in 35 fractions delivered in 6 or 7 weeks, 74.4 to 79.2 Gy in 1.2 Gy twice daily fractions, or 65.5 Gy in 29 fractions. When concurrent chemoradiation is delivered for unfavorable T2N0 cancers, conventional fractionation to 70 Gy is preferred.

Advanced Glottic Cancer (Stage III and IV Disease)

The current standards for definitive radiation therapy–based treatment as an alternative to total laryngectomy for select patients with locoregionally advanced-stage cancer have been established through the serial execution of landmark clinical trials. The first of these, conducted by the Veterans Affairs Laryngeal Cancer Study Group, randomized patients with stage III/IV disease to surgery with postoperative radiation therapy versus induction chemotherapy followed by definitive radiation therapy for responders. Overall, larynx preservation was achieved in approximately two-thirds of patients, but nearly 60% of patients with full-thickness cartilage invasion required a salvage total laryngectomy. This trial demonstrated proof of principle that an attempt at larynx preservation was feasible for most patients without compromise in survival.[87] Building upon these results and excluding patients with full-thickness cartilage invasion and extensive involvement of the base of the tongue, the RTOG conducted a three-arm larynx preservation trial (RTOG 91-11) comparing induction chemotherapy followed by radiation therapy for responders, versus concurrent chemoradiation, versus radiation therapy alone. Long-term local control and larynx preservation rates were superior for those receiving concurrent chemoradiation compared to the other arms, but there was no statistically significant difference in overall survival between the groups. Teasing out detailed long-term laryngeal functional outcome differences in this trial has proven difficult,[88] but the increased number of deaths deemed unrelated to cancer that were observed in the concurrent chemoradiation arm has caused some to question the long-term toxicity of concurrent chemoradiation compared to radiation alone or

sequential chemoradiation.[89] Such deaths were more pronounced in elderly patients (older than 70 years). Generally, patients with more advanced local cancer (i.e., destructive T4 primaries) or poor laryngeal function at presentation (e.g., aspiration or poor airway protection) are best managed with surgery and postoperative radiation therapy or chemoradiation for the presence of high-risk pathology features such as compromised surgical margins and/or extracapsular extension of lymph node metastases.[90]

When treating locally advanced cancer in the setting of larynx preservation, the radiation treatment volumes are extended to include the involved and at-risk draining cervical lymphatics, and three-dimensional radiation therapy techniques, including IMRT, are commonly used. Whether treating in the definitive or postoperative setting and particularly when the upper neck is part of the radiation target volume, IMRT has been preferred over conventional techniques due to the ability to conform doses around the targets and facilitate relative sparing of the adjacent parotid glands and thereby reduce long-term xerostomia consequently improving QOL. In the setting of concurrent chemoradiation, dose delivered to locally advanced gross cancer is typically 70 Gy in 33 to 35 fractions with lower “elective” doses delivered to surrounding soft tissue and lymph node regions at risk of harboring occult microscopic disease, and this is typically accomplished using a single integrated IMRT plan.

Cancer of the Supraglottic Larynx

Single-modality definite radiation therapy is an effective treatment option for favorable primary squamous carcinomas of the supraglottis. Investigators from the University of Florida reported low complication rates and 5-year local control rates of 100% and 86% following radiation therapy for T1 and T2 tumors, respectively.[91] In contrast to the typical treatment volumes described above for stage I/II glottis cancers, treatment volumes must include the at-risk draining lymphatics for supraglottic primaries of all T categories. For properly selected patients with more locoregionally advanced disease, combined modality therapy as an alternative to total laryngectomy is preferred as supported by the aforementioned larynx preservation trials. As for locally advanced glottic cancer, IMRT is a preferred technique for most supraglottic cancers due to its ability to spare the parotid. When designing IMRT target volumes and treatment fields for cancers of any larynx subsite,

radiation oncologists must take great care to account for patient set-up uncertainties, possible daily variations of target/larynx position in the neck, and larynx motion during treatment delivery, whether due to swallowing or respiration (**Fig. 15.25**).

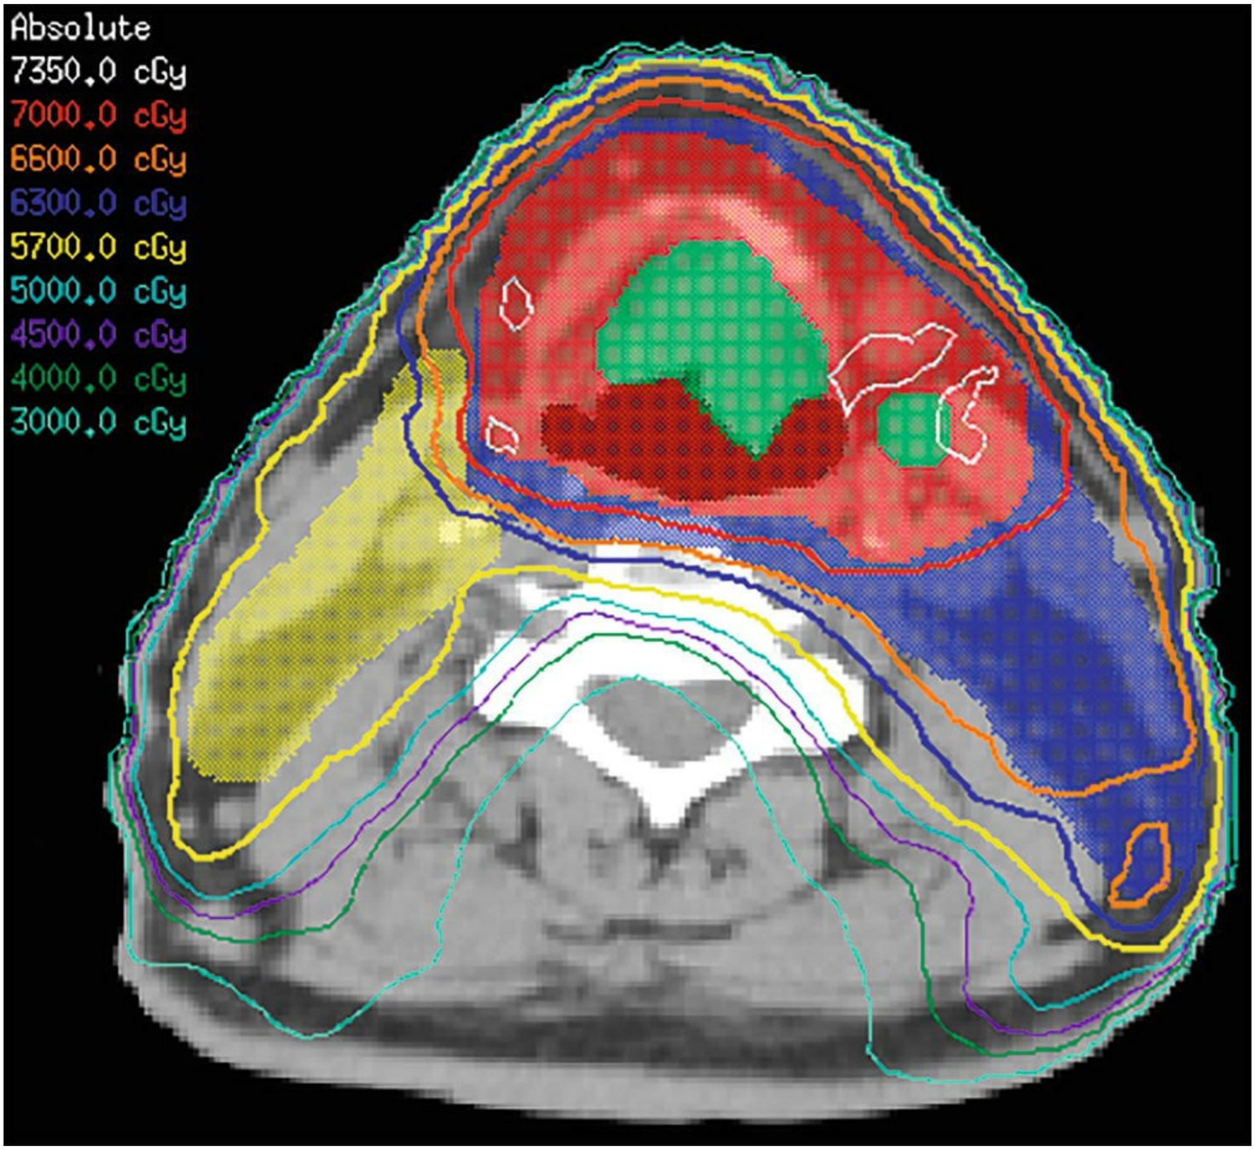

Figure 15.25. Representative axial CT image from IMRT treatment plan showing target volumes and accompanying isodose distributions for a 62-year-old male with left supraglottic squamous carcinoma, clinical stage T3N2bM0 treated with definitive concurrent chemoradiation. (*Green color wash* = gross primary tumor and adjacent positive lymph node; *red color wash* = 70 Gy high-risk treatment volume; *blue color wash* = 63 Gy intermediate-risk treatment volume; *yellow color wash* = 57 Gy standard-risk

treatment volume.)

Chemotherapy for Cancer of the Larynx

Though chemotherapy alone for cancer of the larynx is palliative, chemotherapy in combination with other treatment modalities can improve outcomes. Chemotherapy has been studied in multiple different settings—concurrently with radiation as definitive treatment, prior to definitive treatment as induction therapy, in the postoperative setting, and for palliation in patients with incurable recurrent or metastatic cancer.

Concurrent Chemoradiation for Cancer of the Larynx

In an attempt to improve cure rates and functional outcomes for patients with cancer of the larynx, the addition of chemotherapy to radiation therapy has been studied in multiple clinical trials.

RTOG trial 91-11 compared three treatments for locally advanced laryngeal cancer—radiation therapy alone, induction chemotherapy with cisplatin and fluorouracil followed by radiation, and concurrent chemoradiation with cisplatin, administered at 100 mg/m^2 on days 1, 22, and 43 of radiation therapy.[92] Though survival was not significantly different between the three arms, locoregional control and laryngeal preservation were superior in those receiving concurrent chemoradiation. Based on this data, concurrent chemoradiation with cisplatin became the standard of care for patients with good performance status and locally advanced cancer of the larynx.

Many other randomized trials have studied the combination of chemotherapy and radiation for cancer of the head and neck. The results of 93 randomized trials reported between 1994 and 2000 were summarized in the Meta-Analysis of Chemotherapy in Head and Neck Cancer (MAHC-NC). In all of these trials, patients were randomized to receive either definitive local therapy (surgery or radiation) alone or with chemotherapy.[93] These trials enrolled some patients with cancer of the larynx, but also those with

cancer of the oral cavity, oropharynx, and hypopharynx. Patients receiving concurrent chemoradiation had a survival benefit of 8% at 5 years. Multiple different chemotherapy regimens were used; however, cisplatin appeared to be the most effective single agent.

Though high-dose cisplatin administered at 100 mg/m^2 IV every 3 weeks during radiation is considered the preferred standard for concurrent treatment, it is quite toxic and is best used in patients with a good performance status and without major comorbidities. Other schedules for cisplatin, including daily and weekly dosing, have been studied but have not been compared to high-dose cisplatin in a randomized trial.[94,95] Carboplatin has been studied as an alternative to cisplatin, as it has a lower risk of nephrotoxicity, ototoxicity, and neurotoxicity. Compared to radiation alone, concurrent treatment with a combination of carboplatin and 5-fluorouracil shows a survival benefit compared to radiation alone and is an acceptable regimen for patients who cannot tolerate cisplatin.[96]

Cetuximab, an anti-EGFR monoclonal antibody, has also been studied as concurrent treatment with radiation. In a randomized trial comparing cetuximab with radiation to radiation alone in stage III or IV cancer of the head and neck, cetuximab with radiation was superior to radiation alone in terms of overall survival and progression-free survival, though at the cost of increased toxicity.[97] About 25% of the patients enrolled in this trial had cancer of the larynx; the remainder had cancer of the hypopharynx or oropharynx. Concurrent cetuximab has not been compared directly with cisplatin for cancer of the larynx in a prospective trial; several retrospective series suggest inferior outcomes with concurrent cetuximab compared to concurrent cisplatin.[98,99] Cisplatin remains the standard of care for concurrent therapy for patients with locally advanced cancer of the larynx.

Induction Chemotherapy for Cancer of the Larynx

Induction chemotherapy has potential benefits over concurrent chemotherapy. Higher doses of chemotherapy can be used for induction rather than concurrent therapy, which may reduce the risk of distant metastases by treating micrometastatic disease before it becomes clinically apparent. It also may be better tolerated in some cases than concurrent therapy and can be used to select patients for organ preservation.[87] Data from

clinical trials, however, have not shown a definitive benefit for induction chemotherapy, and this approach remains controversial.

Induction chemotherapy has been studied as a way to select patients with cancer of the larynx for organ preservation approaches. In the VA Larynx Study, 332 patients with locally advanced squamous cell carcinoma of the larynx were randomized to receive either induction chemotherapy (cisplatin 100 mg/m^2 and fluorouracil 100 mg/m^2/day for 5 days every 3 weeks for two cycles) followed by radiation or surgery followed by radiation.[87] Patients assigned to the induction chemotherapy arm who did not respond to the first two cycles of chemotherapy underwent a laryngectomy. Disease-free survival and overall survival were not significantly different between the arms, and the larynx was preserved in 64% of patients receiving chemotherapy, demonstrating that induction chemotherapy could allow an organ preservation approach in the majority of patients without compromising outcomes compared to primary surgery. However, another trial from the GETTEC group with a similar design,[100] randomizing patients to primary laryngectomy versus induction chemotherapy followed by radiation therapy in responders, demonstrated inferior disease-free and overall survival in the induction chemotherapy group, with 2-year overall survival of 69% in the induction chemotherapy group and 84% in the laryngectomy group (p = 0.006).

As mentioned above, RTOG 91-11 compared induction chemotherapy followed by radiation, single-modality radiation, and concurrent chemoradiation.[92] A total of 547 patients were randomly assigned to receive radiation therapy alone, induction chemotherapy with cisplatin and fluorouracil followed by radiation, or radiation with concurrent cisplatin. Though overall survival was similar among all three groups, laryngeal preservation was significantly improved with concurrent therapy rather than either induction chemotherapy or radiation alone (84% vs. 72% vs. 67%). Toxicity was similar between the two chemotherapy arms and was increased compared to the radiation alone arm. Following the results of this trial, concurrent chemoradiation with cisplatin became the standard of care for locally advanced squamous cell carcinoma of the larynx, and the role of induction chemotherapy became less clear.

More recent induction trials have added taxanes to the traditional regimen of cisplatin and docetaxel. Induction with the TPF regimen (cisplatin,

docetaxel, and 5-fluorouracil) was shown to be superior to induction chemotherapy with cisplatin and 5-fluorouracil (PF) when followed by either radiation alone or radiation with carboplatin in the TAX 323 and TAX 324 studies.[101,102] Both of these trials enrolled patients with laryngeal cancer, in addition to patients with other primary sites, mainly oropharynx and hypopharynx.

Though studies show that TPF is a superior regimen to PF if induction chemotherapy is chosen, there are unanswered questions regarding induction chemotherapy. The optimal regimen for concurrent treatment following induction is not known, and it is also not known whether chemoradiation with concurrent cisplatin is superior to induction. There is significant disagreement in the head and neck community regarding the optimal role for induction chemotherapy—currently, it is not considered standard of care and should be performed in a tertiary care center with expertise in this area.

Adjuvant Chemoradiation Following Surgery for Cancer of the Larynx

For patients with adverse features, adjuvant radiation following surgical resection of laryngeal cancer is known to be beneficial.[103] Combinations of chemotherapy and radiation have also been studied in the adjuvant setting in two large trials, EORTC 22931 and RTOG 9501.[104,105] About 20% of the patients enrolled on these trials had cancer of the larynx; other sites including oral cavity were also well represented.

Patients with resected cancer of the head and neck with extracapsular extension, positive margins, or multiple involved lymph nodes were eligible for enrollment in RTOG 9501 and were randomized to either radiation alone or radiation with high-dose cisplatin (cisplatin 100 mg/m^2 on days 1, 22, and 43 of radiation therapy).[105] Patients who received chemotherapy had improved locoregional control and disease-free survival; however, overall survival was equivalent between the arms. EORTC 22931 used identical treatment regimens, but inclusion criteria were slightly different—eligible patients had T3 or T4 tumors or N2 or N3 cancer or other unfavorable features (extracapsular extension, positive margins, perineural involvement, or vascular tumor emboli).[104] This trial showed an improvement in progression-free as well as overall survival for the patients receiving

chemotherapy. Both trials showed that adding chemotherapy increased toxicity.

Results from these two trials were combined in an analysis to try to determine which patients might benefit from this approach.[90] Analysis showed that chemotherapy was of benefit in patients with extracapsular extension or positive margins; other patients did not have a clear benefit with the use of chemotherapy.

Currently, cisplatin combined with radiation therapy is the standard of care for patients with resected laryngeal cancer and positive margins or extracapsular extension. For patients with other high-risk features, concurrent chemotherapy can be considered, though the benefits are unproven. High-dose cisplatin is the preferred option; for patients who cannot tolerate high-dose cisplatin, weekly cisplatin or carboplatin-containing regimens can be considered.

Palliative Chemotherapy for Recurrent or Metastatic Cancer of the Larynx

For patients with cancer of the larynx who develop distant metastatic disease, or those who develop locally recurrent cancer not amenable to local therapy, chemotherapy is an option for palliation of disease. Chemotherapy can result in shrinkage of the cancer, improved control of symptoms, and possible prolongation of survival. Details of chemotherapeutic treatment for incurable head and neck squamous cell carcinoma will be discussed in another chapter.

Quality-of-Life Outcome

QOL outcome is very important in the formulation of treatment protocols. In a study from Europe, the QOL assessment included five treatment groups: cordectomy, PL, irradiation as primary therapy, laryngectomy, and combined laryngectomy and radiation therapy. Evaluation of the functional scales of the European Organization for Research and Treatment of Cancer Quality-of-Life Questionnaire (EORTC QLQ-C 30) revealed a higher QOL of patients with a maintained larynx compared with laryngectomies. On the symptom scales, patients after laryngectomy and/or radiation therapy suffered more

from fatigue, pain, and appetite loss. Laryngectomies stated enhanced financial difficulties. Evaluation of the ENT-specific EORTC module showed that patients after laryngectomy reported increased symptoms. Typical symptoms after radiation therapy included dry mouth, thickened secretions, and coughing.

Gourin et al. published a retrospective analysis of 2,370 cases using SEER Medicare data directed at assessing quality indicators of care for elderly patients with cancer of the larynx. Quality indicators were derived from the NCCN guidelines in addition to performance and end-of-life indicators. The authors noted that "high-quality" care in the primary treatment setting was associated with improvements in cost and survival; however, these findings were not seen when treating recurrence in this population. Patients treated with surgery and adjuvant radiation therapy demonstrated a potential survival advantage compared to individuals managed with nonoperative treatment in the review.[106]

Studies assessing QOL have demonstrated that patients with earlier-stage cancer of the larynx tend to feel they have better end organ function and QOL than individuals with more advanced-stage cancer after at 3 years after treatment. In patients with T1 disease, Robertson et al. showed no difference in QOL scores of T1 patients treated with primary radiation versus TLM. Their research did show that the mucosal injury associated with current chemoradiation techniques does translate negatively on the quality scores of patients later in life and their functional outcome.[107]

QOL after TLM was prospectively assessed in a study of 93 disease-free patients with predominantly early-stage glottic and supraglottic tumors. Speech was found to be the most important variable to 46% of patients within the study and voice quality was noted to improve for patients after treatment with TLM. Adjuvant radiation therapy and neck dissection were noted to be negative factors that independently impacted disease-specific QOL in the study population.[108]

Salvage Laryngeal Surgery

After treatment of locally advanced cancer of the larynx, some patients suffer

a local or regional failure that requires salvage surgery. The anatomic subsite in the head and neck where patients have the highest potential for successful surgical salvage is the larynx. Individuals with advanced-stage cancer of the larynx that recur after a organ-sparing chemoradiation protocol typically have disease extending to at least the boundaries of their pretreatment staging. As such, total laryngectomy is frequently required for salvage in these patients.[109]

Reynolds et al. reported on a prospective study that included 10 patients (5 supraglottic, 5 glottic) with T1/T2N0 cancer of the larynx that recurred after primary radiation therapy and were treated with transoral CO_2 laser salvage resection. Two patients required temporary tracheostomy and four required temporary gastrostomy tube placement. Local recurrence occurred in three patients after salvage surgery and two were salvaged with an open surgical procedure. The authors reiterate the theme that with careful patient selection, salvage endoscopic CO_2 resection for early-stage recurrent glottic and supraglottic tumors is a viable oncologic option.[110]

Endoscopic CO_2 laser surgery in the setting of recurrent cancer of the larynx can be challenging and requires appropriate patient selection. In a review of 11 articles by Ramakrishnan et al., the local control rate at 2 years for 249 patients after initial transoral laser microsurgical salvage procedure was 56.9%. For those capable of undergoing subsequent endoscopic re-resection, this number rose to 63.8%. The pooled mean laryngeal preservation among the studies reviewed was 72.3%. The majority of patients were initially clinically T1 (67%) and T2 (20.5%). The authors did note that the reported oncologic outcomes of open partial laryngectomy were superior to the findings of their review of endoscopic salvage. Endoscopic salvage for recurrent AC involvement was considered the least likely presentation to result in successful retreatment for cure and may be unsuitable for the transoral laser microsurgery approach.[111]

Salvage surgery was assessed in a review of 75 patients with recurrence of early (T1/T2) cancer of the glottis, treated previously with radiation therapy. The authors found that over 50% of patients were upstaged at the time of recurrence compared to their original pretreatment staging, with 39% of patients having cancer consistent with T3/T4 staging at recurrence. Only 16% of patients were considered candidates for salvage partial laryngectomy

with the remainder requiring total laryngectomy. The restaging of the patient's cancer at the time of recurrence was found to be the only prognostic factor associated with overall survival ($p = 0.004$).[112]

Hong et al. reported on their experience with salvage endoscopic CO_2 laser resection for recurrent supraglottic carcinoma in a series of seven patients (2 T1, 2 T2, 3 T3). One patient experienced recurrence requiring salvage total laryngectomy. Contraindications to endoscopic salvage in their group included cricoid, hyoid, or thyroid cartilage invasion, cardiopulmonary dysfunction, extensive preepiglottic spread, and vocal cord fixation. Salvage neck dissection was performed simultaneously with endoscopic resection. The majority of patients (6/7) required a tracheostomy at the time of surgery and had a mean time to decannulation of 10.7 days. Fixation of the vocal cord was experienced as a complication by two patients. Oral feeding was initiated in all patients by postoperative day 3. The 5-year overall survival for the group was 68.6%. The authors commented that endoscopic salvage of selected recurrent T3 cancers of the supraglottis was possible when preepiglottic space extension was limited.[113]

Short-term implications of postlaryngectomy fistula formation include prolonged hospitalization, increased cost of care, and a potential delay in the initiation of adjuvant care. Long-term complications of fistula formation include dysphagia, stricture, and prolonged dependence on gastrostomy tube assistance for nutrition. Use of the pectoralis major flap or free-tissue transfers after salvage laryngectomy have been suggested for the ability to decrease the severity and shorten the length of time to resolution of postoperative fistula versus primary closure in the postradiation setting.

As a follow-up to the RTOG 91-11 organ preservation trial, Weber et al. reviewed the incidence of complications experienced with salvage total laryngectomy following induction chemotherapy followed by radiation, CRT, and radiation alone. Of the 517 patients originally enrolled, 129 ultimately required salvage laryngectomy, with 5% of patients requiring salvage for the indication of aspiration and necrosis of the larynx. The incidence of minor (self-limited and did not extend hospitalization) and major (prolonged admission and were life threatening) complications varied between 52% and 59% in the three arms. The rate of postoperative fistula ranged from 15% (radiation alone) to 30% (concomitant CRT). The incidence of fistula was independent of the timing of salvage laryngectomy relative to prior primary

therapy. The mortality rate of surgical salvage was low with only one perioperative death occurring from myocardial infarction. The 2-year survival rate for patients requiring salvage laryngectomy was 72%.[114]

In one study, individuals who underwent salvage laryngectomy (partial and total) had a reported locoregional control rate of 70%. Open partial laryngectomy options, including VPL and supracricoid laryngectomy, were predominantly used in patients with early-stage recurrence. Contraindications to partial laryngectomy in the study included preepiglottic space invasion, interarytenoid extension, arytenoid fixation, and extralaryngeal extension of cancer. Total laryngectomy, the most common procedure used in the series of 100 patients, was performed in 66.6% with early-stage recurrence and in 85.7% with advanced-stage recurrence. Of note, tumor staging (initial or recurrent), type of salvage treatment, and cervical lymph node metastases did not demonstrate a statistical impact on survival. Most of the patients within the series developed recurrent cancer within 11 to 15 months after the completion of primary therapy, which re-emphasizes the importance of close clinical follow-up in the first 2 years after treatment. The authors also suggested that neck dissection should be strongly considered at the time of salvage surgery given that nearly one-third of patients in their series who underwent neck dissection harbored regional metastases on final histopathology.[115]

Sayles et al. performed a review of 171 patients to determine the fistula rate of patients after undergoing salvage laryngectomy after organ preservation therapy versus those undergoing primary surgical management. The fistula rate for the entire study population was 29%. Individuals undergoing salvage laryngectomy after radiation +/− chemotherapy experienced a statistically significant increase in the development of postoperative fistula (37.3% vs. 17.0%, $p = 0.03$) than individuals undergoing primary laryngectomy. As a result of their findings, the authors suggested the use of vascularized tissue flaps to reduce the rate of fistula incidence and severity in individuals requiring salvage surgery.[116]

In a review comparing pectoralis flaps, myofascial overlay versus myocutaneous (integrated into pharyngeal closure), in patients undergoing salvage laryngectomy after radiation therapy (37.5% CRT), fistula rates associated with the two forms of reconstruction were compared. The difference in fistula rates between the two groups was not found to be

statistically significant (myofascial overlay 26.3%, myocutaneous 33.3%). As a result, the authors suggest the use of the pectoralis myofascial overlay flap when the use of a skin paddle is unnecessary for adequate pharyngeal closure.[117]

Stomal Recurrence

Stomal recurrence refers to a local recurrence arising from the margins of the tracheal or pharyngeal resection in the peristomal area, after a total laryngectomy. This disappointing result has a poor associated prognosis, yet surgical salvage can be offered in selected situations versus radiation/reirradiation or palliative chemotherapy.

Classification

The classification system of Sisson and colleagues[118] describes in the following ways the location of the recurrent cancer for the purposes of staging and prognosis:

Type I-cancer involves the superior half of the stoma without esophageal involvement.

Type II-cancer involves the superior half of the stoma with esophageal involvement.

Type III-cancer involves the inferior half of the stoma and extends into the mediastinum.

Type IV-cancer extends out laterally underneath the clavicles.

Incidence

In their comprehensive review of references encompassing 4,281 laryngectomies, Esteban and coworkers calculated the overall incidence of stomal recurrence to be 6%. Of the many risk factors identified, subglottic extension of the cancer is the one factor unanimously agreed upon as a significant risk.[119] Rubin et al.[120] studied line-independent variables with multivariate analysis and found that cancer involving the subglottis and the size of the primary cancer (stage T4) were the only significant predictors of

stomal recurrence.

Concerns have existed for an increased risk of stomal recurrence after laryngectomy when preceded by emergent tracheotomy because of the hypothetical possibility of cancer “seeding” into the trachea and peristomal soft tissues. Some have even endorsed the idea of “emergency laryngectomy,” performed in the same setting as the tracheotomy for the obstructing cancer, to help prevent stomal recurrence. However, studies have failed to show previous tracheotomy to be an independent risk factor. A study of 444 laryngectomy patients found no difference in stomal recurrence rate among the subglottic cancers that required emergent tracheotomy.[120] The authors proposed that the size and location of cancer of the subglottis made it more prone to both stomal recurrence and the need for urgent tracheotomy and that the tracheotomy itself was not an independent risk factor.

Management

The management of stomal recurrence is primarily surgical. Currently, mediastinal dissection is recommended for type I and type II stomal recurrence with possible postoperative radiation. Patients with type III and type IV disease can be offered surgery if they are medically fit and are willing to accept higher morbidity and mortality rates. Radiation therapy has been reported to provide palliation but is ineffective when used as a single agent. Furthermore, many patients have already had full-course radiation to control their primary cancer and are not able to receive further therapeutic doses. Combinations of radiation and chemotherapy when feasible have been used with encouraging early results.

Surgery includes resection of the tracheostoma and the surrounding skin, mediastinal dissection with removal of the manubrium (with or without removal of the heads of the clavicles), and resection of involved pharyngoesophageal segments with reconstruction and obliteration of dead space using various flaps (**Figs. 15.26 and 15.27**). Perioperative mortality approaches 15%, and death most often results from mediastinitis and rupture of the great vessels. Gluckman and coworkers reported the results of 41 mediastinal dissections for stomal recurrence of all types. Overall survival was a dismal 16% with a 24% determinate survival rate. Survival among type I and II lesions was 45%, but among types III and IV, it was only 9%. Acceptable palliation of pain and airway obstruction was achieved in the

nonsurvivors.[121]

Figure 15.27. Postoperative view after salvage resection for peristomal recurrence with pectoralis major flap reconstruction of the anterior neck and superior “neostoma.”

Pet Scanning in Posttreatment Evaluation

With regard to local response, Brouwer et al. reviewed 30 patients suspected of having recurrent cancer of the larynx after radiotherapy who underwent PET and direct laryngoscopy with biopsy. Recurrence was diagnosed by biopsy in 8/30 patients. Sensitivity and specificity of PET were 88% and 82%, respectively. The authors noted that, among radiologists involved in the study, the interobserver agreement and variability seen in the study were reasonable and suggested that PET represented an option to operative biopsy

to assess patients for recurrence.[122] The cost-effectiveness of PET in the selection of patients for operative biopsy with suspected recurrent laryngeal carcinoma after radiotherapy was reviewed by van Hooren et al. The direct medical costs of 30 patients comparing an approach where all patients underwent direct laryngoscopy was compared to a PET strategy in which only patients with a positive or equivocal PET underwent direct laryngoscopy. The mean cost of the PET-based strategy was noted to cost 399 Euros less than the empiric direct laryngoscopy strategy.[123]

In assessing the need for regional salvage, Gilbert et al. reviewed the ability of preoperative PET–CT (15 patients) to predict the pathologic status of the neck in N0 patients with locally recurrent cancer of the larynx. In this series, three patients with clinically N0 necks and negative PET–CT had positive pathology in the lymph nodes, resulting in a sensitivity of 70% and an NPV of 62.5%. The authors felt that the false-negative rate warranted recommending clinically N0 patients with recurrent cancer of the larynx be offered neck dissection at the time of salvage laryngectomy independent of preprocedure PET–CT results.[124] Gourin et al. reviewed 32 patients with N2/N3 cancer that experienced a complete clinical response after CRT underwent PET–CT 8 to 11 weeks after treatment to assess the ability of the imaging technique to predict the need for staged neck dissection. PET–CT was considered positive in 20 patients (63%). Final pathology revealed viable carcinoma in 10 of the 32 neck dissections. Only 6 of the 20 PET–CT positive scans correlated with a positive neck dissection, whereas 4 of 12 negative PET–CT scans were associated with persistent regional metastases. The sensitivity and specificity of PET–CT were 60% and 36%, respectively. The authors concluded that PET–CT does not reliably predict the need for planned posttreatment neck dissection in patients with a complete clinical response following CRT. Their data also suggested that delaying the timing of PET–CT beyond 8 to 11 weeks, with surgery reserved for positive findings, could be a reasonable alternative to empiric neck dissection.[125]

Treatment of the Neck

Surgical Treatment of the Neck in Cancer of the Larynx

Debate exists regarding the management of the clinically negative and positive neck in cancer of the larynx. Elective treatment of the neck is recommended for supraglottic cancers staged T2 or higher and for glottic or subglottic tumors staged T3 or higher. The neck may be treated electively by either surgery or radiation, with radiation employed for cases in which that modality is employed for the primary cancer.

Elective neck dissection provides important information for prognostic purposes and therapeutic decisions by establishing the presence, number, location, and nature of occult lymph node metastases. Selective lateral neck dissection (levels II, III, and IV), unilateral or bilateral, is the procedure of choice for elective treatment. Paratracheal nodes (level VI) should be dissected in cases of advanced glottic and subglottic cancer. Complete radical or functional neck dissections are often excessive in extent in that levels I and V are rarely involved. Sentinel lymph node biopsy procedures have not been shown to be effective for primary cancer of the larynx. The clinically involved neck is usually treated by a functional neck dissection of levels I through V or MRND/RND as indicated.

Selective neck dissection has been employed successfully in selected cases, particularly for N1 or occasionally N2 nodal involvement. Selective neck dissection can be extended to include structures at risk. More advanced cancer has been treated in this manner, often in association with adjuvant chemotherapy and/or irradiation. Although the benefit of adjuvant treatment is difficult to assess, it appears most useful in cases with extracapsular spread —a feature associated with the worst prognosis.

Either modified type III radical neck dissection (MRND) or lateral neck dissection (LND) is considered valid treatment for patients with cancer of the larynx with clinically negative neck findings (N0) who are undergoing surgical management of the primary. A prospective study was performed to compare complications, neck recurrences, and survival results of elective MRND and LND on the management of laryngeal cancer patients. A total of 132 patients were included in the trial. All patients had previously untreated T2–T4 N0M0 supraglottic or transglottic SCC. Seventy-one patients underwent MRND (13 bilateral) and 61 underwent LND (18 bilateral). The rate of occult metastasis detected on histologic examination was 26%, and most positive nodes occurred at levels II and III.[126]

Treatment of the Neck in Cancer of the Supraglottis Cancer

The role and extent of neck dissection after definitive radiation therapy in patients with cancer of the supraglottis specifically for N0 and N1 disease is controversial. Regional response has been related to the size of the lymph nodes at presentation. Most patients with nodal size of 3 cm or less had a complete response, whereas patients with nodal size >3 cm had a partial response. For patients with a complete response in whom postradiation therapy neck dissection was withheld, regional control rates were 75% and 86% for N1 and N2, respectively. In multivariate analysis, significant favorable factors predictive for regional control were female sex, accelerated hyperfractionation, and complete response; factors predictive for overall survival were Karnofsky Performance Scale score and regional response. Isolated regional relapse is not common among patients with cancer of the supraglottis when a complete response is achieved at 4 to 6 weeks after definitive radiation therapy is provided and postradiation therapy neck dissection is not performed.[127]

Outcomes Research

As part of a larger project, 597 patients with laryngeal carcinoma had data abstraction performed relative to their survival and functional outcomes at MD Anderson Cancer Center. Overall survival at 1- and 2-year posttreatment was 93% and 87%, respectively. Tier 1 outcomes at 1 year for tracheostomy-free and feeding tube-free status were 96% and 90%, respectively. Tracheostomy-free status correlated with the capacity for functional speech production.[128]

Sandulache et al. reported the Veterans Affair Medical Center (VAMC) experience with laryngeal cancer in their review of 205 patients treated over a 12-year period. They reported an overall 2-year DFS of 68% and OS of 74%. The cohort of patients seen at the Michael E. DeBakey VAMC was predominantly early-stage glottic and advanced-stage supraglottic primaries with regional spread. As would be expected, the 2-year DFS and OS for glottic (72%, 77%) was better than for cancer of the supraglottis (63%, 69%). The authors cited their high compliance with the NCCN guidelines as a factor

associated their favorable oncologic outcomes. The rate of second cancers in the series was high at 21%, with the majority of these being cancers of the lung. Additionally, 97% of this group reported a history of tobacco use. There was no difference observed in DFS or OS between black and white male patients treated during this time frame leading the authors to suggest that when access to care is equal, outcomes should be similar independent of race.[129]

In a multicenter, retrospective review of 234 patients with early glottic carcinoma, Kerr et al. compared TLM (143) versus radiation therapy (91) in voice outcomes and laryngeal preservation rates. The 2-year organ preservation rates for stage 1 disease for TLM and radiation therapy were 100% and 92%, respectively ($p < 0.004$), whereas in rates for stage 2 disease, there was no significant difference. The VHI-10 scores favored radiation therapy at all time points when compared to TLM.[130]

Summary

The treatment of cancer of the larynx is dependent upon the anatomical location and stage of the presenting lesion. In addition to purely oncologic considerations, the preservation of QOL metrics helps drive decisions in the primary management of these patients. Early-stage cancers may be considered for single modality therapy whereas advanced-stage cancers frequently require combination chemoradiation or surgery with adjuvant radiation therapy. Prospective multidisciplinary management of laryngeal cancer affords patients the best available oncologic and functional outcomes.

16 Cancer of the Hypopharynx and Cervical Esophagus

Parul Sinha Bruce H. Haughey

Cancer of the hypopharynx and cervical esophagus often present significant challenges in management, owing to the critical role these anatomical sites play in the normal function of the upper aerodigestive tract (UADT). The structural proximity, close physiologic coordination, and similarity in oncologic aspects allow concurrent discussion of cancer arising from the two sites. Treatment of cancer of the hypopharynx and cervical esophagus includes the use of surgery, radiotherapy, and chemotherapy in different combinations depending upon the stage of the cancer. With a growing emphasis on organ preservation, the selection of therapeutic option, surgical or nonsurgical, which maximally controls disease and preserves function, remains critical. This chapter focuses on the approaches to the management of cancers of the hypopharynx and cervical esophagus with relevant anatomic, pathologic, and etiologic details.

Surgical Anatomy

The hypopharynx extends from its junction with the oropharynx at the level of the tip of the epiglottis to its junction with the cervical esophagus inferiorly (**Fig. 16.1**). The bony landmarks are the hyoid superiorly, the lower border of the cricoid cartilage inferiorly, and C3 to C6 vertebrae posteriorly. The hypopharynx is comprised of three anatomical subsites—the pyriform sinus (PFS), the postcricoid area, and the posterior pharyngeal wall. These three subsites are continuous with one another and cancers often involve more than one subsite.

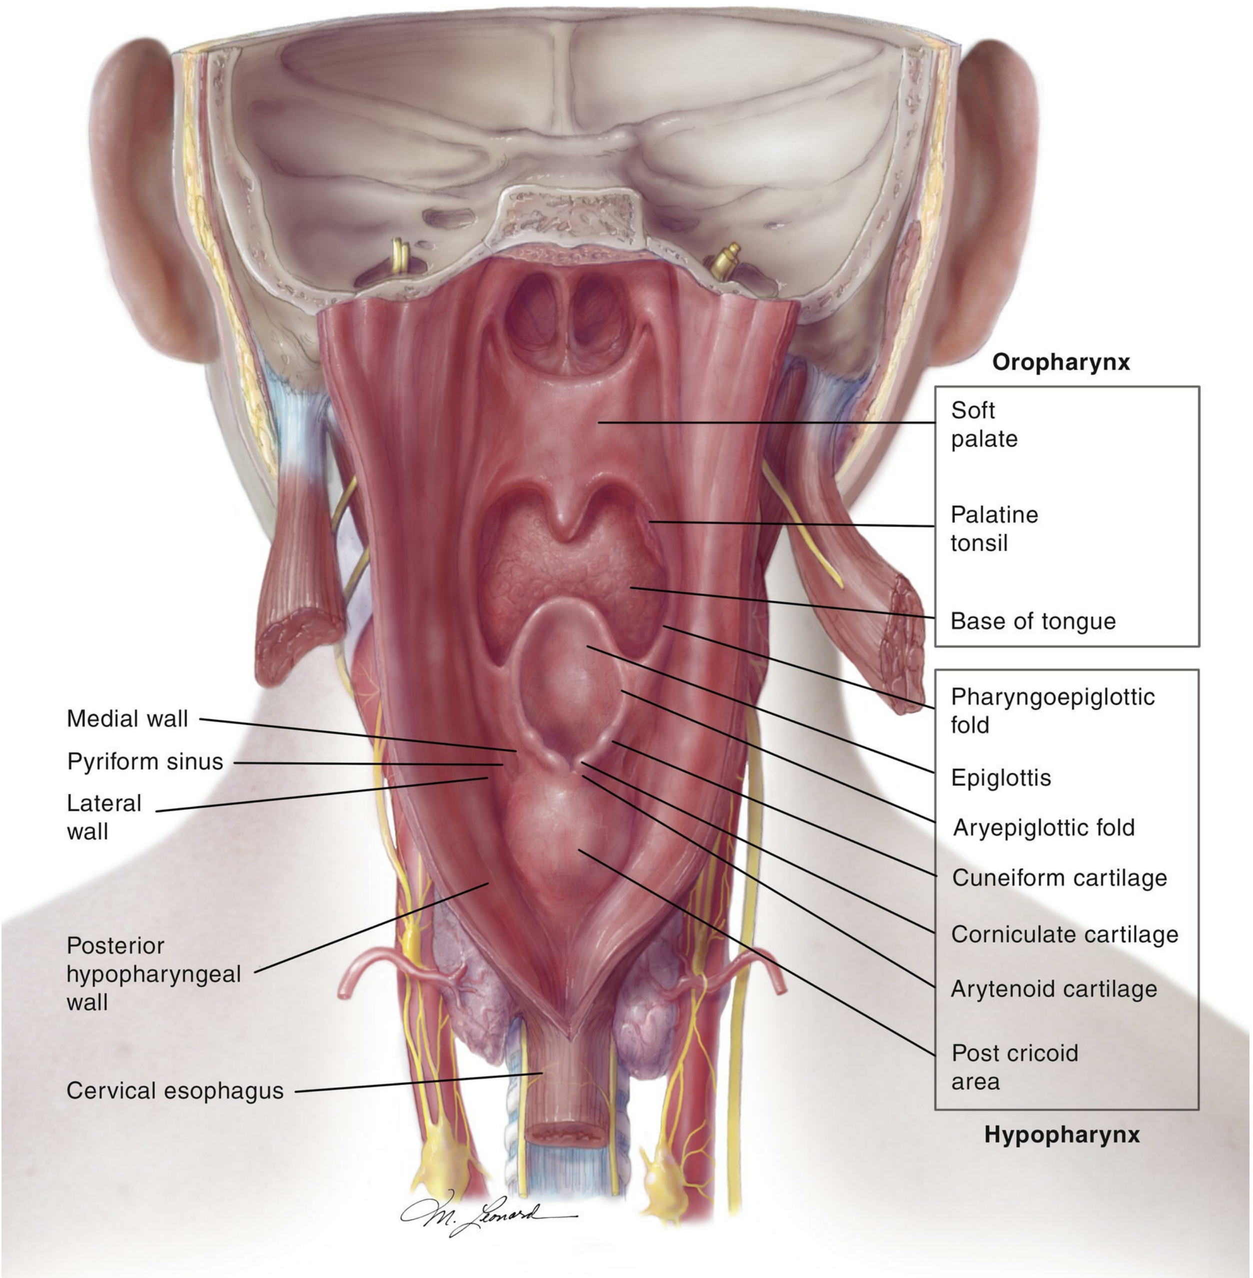

Figure 16.1. Anatomical subdivisions of the pharynx (posterior view).

The PFS is a conical structure located on each side of the hypopharynx that extends from the pharyngoepiglottic fold down to its inferior-most extent, the apex, which opens medially into the cervical esophagus. The superior part of the PFS is bounded by the thyrohyoid membrane and thyroid cartilage laterally and the aryepiglottic fold (AEF) and arytenoid cartilage medially. The apex of the PFS is bounded by the thyroid cartilage laterally and by the cricoid cartilage medially. The medial wall of the PFS is separated from the

endolarynx by the AEFs.

The postcricoid area extends from the level of the arytenoid cartilages to the inferior border of the cricoid cartilage at the pharyngoesophageal junction. It lies in close proximity to the posterior cricoarytenoid muscles and the medial wall and apices of the PFSs.

The posterior wall of the hypopharynx extends from the level of the tip of the epiglottis (or the floor of the vallecula) to the level of the inferior border of the cricoid cartilage. The superior and inferior boundaries of the posterior wall of the hypopharynx merge with the walls of the oropharynx and the esophagus, respectively, whereas the lateral boundaries are continuous with the PFS. The mucosal lining of the wall of the hypopharynx is separated from the prevertebral space by a fibrous layer formed by the pharyngeal aponeurosis; a muscular layer formed by the middle and inferior constrictors; the buccopharyngeal fascia; the retropharyngeal space; and the prevertebral fascia. The distal-most fibers of the inferior constrictor muscles form the cricopharyngeus muscle, which constitutes the primary muscle of the upper esophageal sphincter and marks the junction between the postcricoid area and the cervical esophagus.

The cervical esophagus lies posterior to the trachea and thyroid gland, extending from the inferior border of the cricoid cartilage (opposite C6 vertebra) to the level of the thoracic inlet (opposite T1 vertebra). It deviates to the left in the inferior aspect of the neck and is medial to the common carotid artery and recurrent laryngeal nerve on either side and the thoracic duct on the left. The esophageal wall from inside out is made up of a mucosal, submucosal, muscular, and an external fibrous layer. The muscular layer consists of internal circular fibers, which are continuous with the cricopharyngeus muscle, and external longitudinal fibers that are covered with a fibrous layer in continuity with the wall of the hypopharynx.

Nerve supply: The pharyngeal constrictor muscles receive motor innervation through the pharyngeal plexus with additional innervation of the inferior constrictors from branches of the external laryngeal and the recurrent laryngeal nerves. The recurrent laryngeal nerve provides motor innervation to the cricopharyngeus and the posterior cricoarytenoid muscles, whereas the sensory innervation of the hypopharynx is derived primarily from the internal branch of the superior laryngeal nerve. This branch synapses with a branch of the vagus, Arnold’s nerve, which provides sensation to the external auditory

canal and which accounts for the symptom of referred otalgia from cancer of the hypopharynx. Additional sensory innervation is also provided by branches of the recurrent laryngeal nerve. Innervation to the cervical esophagus is derived from the recurrent laryngeal nerve and sympathetic chain.

Vascular supply: The superior laryngeal branch of the superior thyroid artery is the primary blood supply to the superior aspect of the hypopharynx; the inferior part is supplied by the inferior laryngeal branch of the inferior thyroid artery. The vascular supply of the cervical esophagus is derived primarily from the inferior thyroid artery. Venous drainage from the hypopharynx occurs through the submucosal pharyngeal venous plexus, which drains into the internal jugular vein, whereas the cervical esophagus drains into the inferior thyroid vein.

Lymphatic drainage: The hypopharynx is rich in lymphatics, which pierce the thyrohyoid membrane to drain into the deep jugular chain (level II, III, and IV) nodes. Lymphatics from the inferior aspect of the PFS and the postcricoid area pierce the cricothyroid membrane and drain into the paratracheal chain (level VI) nodes. From the posterior pharyngeal wall, drainage occurs into the retropharyngeal nodes (RPLNs) including the nodes of Rouviere superiorly. Lymphatics from the cervical esophagus usually drain first into the paratracheal and paraesophageal nodes, and second, into the cervical and superior mediastinal nodes.

Patterns of Spread

Cancers from the medial wall of the PFS spread medially to the endolarynx by invading the AEF or the paraglottic space causing fixation of the hemilarynx. Posterior extension into the postcricoid area can lead to infiltration into the posterior cricoarytenoid muscle with fixation of the ipsilateral vocal cord. Infrequently, fixation of the hemilarynx can also result from the direct invasion of the cricoarytenoid joint or the recurrent laryngeal nerve. Anterior and lateral spread leads to involvement of the lateral wall of the PFS and/or the wall of the hypopharynx. From the lateral wall of the PFS, cancer can extend into the cervical soft tissues to involve the strap muscles, thyroid gland, and other extralaryngeal structures through direct invasion of

the thyroid cartilage or by spread around the posterior border of the thyroid cartilage at the insertion of the inferior constrictor muscles. Posterior extension involves the posterior wall of the hypopharynx, whereas the lateral wall of the oropharynx, pharyngoepiglottic fold, and the base of the tongue can be involved by superior extension. Cancers reaching the apex of the PFS can involve directly the postcricoid area and the cricoid cartilage.

Cancers of the postcricoid area can extend directly to the cricoid cartilage and the trachea and, submucosally, toward the cervical esophagus. Submucosal spread of cancer superiorly to the oropharynx and inferiorly to the esophagus can also occur from the posterior wall of the hypopharynx. Cancers from this site can involve the pharyngeal constrictors and the buccopharyngeal fascia. The fascia is a weak barrier, and further posterior spread can involve the prevertebral fascia and the prevertebral musculature, ultimately reaching the periosteum of the vertebral column.

Cancers of the cervical esophagus can spread anteriorly to the trachea, laterally to the tracheoesophageal groove and recurrent laryngeal nerve(s), and posteriorly to the prevertebral space.

Epidemiology

Cancer of the hypopharynx is rare and accounts for 3% to 5% of the malignancies in the UADT.[1] The American Cancer Society estimates 3,400 cases in 2014, ~2,725 in men and 675 in women. The worldwide age-standardized incidence estimated by GLOBOCAN 2012 report from the International Agency for Research on Cancer (IARC) is 1.9 per 100,000 and a total number of 142,387 new cases.[2] The precise incidence for either the hypopharynx or the individual hypopharyngeal subsites is, however, difficult to estimate due to the combined reporting on all cancers of the pharynx by the IARC. In addition, a marked gender and geographical variation is known to exist, with a higher incidence in males and in certain regions of Central and Eastern Europe, France, and Southeast Asia.

Cancer of the PFS and posterior hypopharyngeal wall occurs predominantly in males, aged 55 to 70 years, and is strongly associated with excessive alcohol consumption and smoking. Carcinoma of the postcricoid

area is more common in females, aged 30 to 50, with underlying nutritional factors such as Plummer-Vinson syndrome as a possible etiology. It is mainly reported from Sweden and other Scandinavian nations; however, improved nutrition has been shown to decrease the incidence of Plummer-Vinson syndrome and, therefore, the incidence of postcricoid carcinoma from these regions.[3,4] Chronic gastroesophageal reflux and human papillomaviruses are postulated to have an etiologic association to cancer of the hypopharynx in nonsmokers and nondrinkers.[5] Genetic predisposition and occupational exposure to carcinogens such as solvents, polycyclic aromatic hydrocarbons, sulfuric acid, asbestos, welding fumes, wood dust, nickel, and leather have also been implicated as etiologic factors.[3]

Cancers involving the cervical esophagus make up 2% to 10% of all cancers of the esophagus and are derived from the caudal extension of cancers originating in the hypopharynx.[6,7] Cervical esophageal cancer is predominantly seen in males and has a high incidence in certain regions of Iran, Central Asia, Mongolia, and Northern China. The risk factors for the development of cancer of the cervical esophagus are similar to those for the hypopharynx. Prolonged irritation from thermal injury or corrosives such as lye is also associated with increased risk.

Histopathology

Approximately 95% of the cancers of the hypopharynx and cervical esophagus are squamous cell carcinomas (SCC). Invasive SCC may be preceded by premalignant lesions. The PFS is the most common site of involvement, accounting for 65% to 85% of the hypopharyngeal SCC, followed by the posterior wall of the hypopharynx (10% to 20%) and the postcricoid area (5% to 15%). Submucosal spread and skip lesions are an important characteristic of cancers arising from these sites; spread of 5 to 30 mm beyond macroscopically visible cancer has been observed.[8] Whereas cancers of the PFS and posterior pharyngeal wall are more frequently exophytic, postcricoid cancers are more commonly ulcerative. Basaloid carcinoma, undifferentiated carcinoma, and spindle cell carcinoma are rare SCC variants characterized by more aggressive behaviors.[9] Spindle cell carcinoma occurs mostly in patients with a history of prior radiation that

typically presents as a polypoid mass projecting into the pharyngeal lumen.[10] The hypopharynx and cervical esophagus can also give rise to malignant nonsquamous tumors such as, (1) minor salivary gland adenocarcinoma and adenoid cystic carcinoma; (2) sarcomatous lesions such as fibrosarcoma, leiomyosarcoma, liposarcoma, and synovial cell sarcoma; (3) reticuloendothelial tumors such as lymphoma and plasmacytoma; and (4) melanoma.

Tumor Biology

Site-specific chromosomal aberrations are not so well defined in carcinomas of the head and neck; however, 11q13 amplification and loss of p53 heterozygosity have been reported in 78% and 70% of hypopharyngeal SCCs, respectively. The presence of 11q13 amplification has been associated with nodal metastases, greater local aggressiveness, and higher recurrence rates.[11] A loss of chromosome 18 has also been observed in 57% of cancers of the hypopharynx.[12]

Clinical Presentation and Evaluation

Presenting Symptoms and History

The common presenting symptoms, which suggest cancers originating from the hypopharynx and cervical esophagus, are progressive dysphagia, odynophagia, sore throat, referred otalgia, weight loss, and/or a mass in the neck. These cancers usually present at an advanced stage because the nonspecific symptoms of minor irritative sensation or sore throat from early-stage cancer may be too easily dismissed. Aspiration, hemoptysis, and weight loss occur with advanced cancer. Persistent pain in the throat with referred otalgia may be indicative of perineural invasion. Hoarseness and breathing difficulty are indicative of laryngeal involvement. Metastases to the cervical lymph nodes are known to occur in 50% to 80% of the patients at

presentation, and not infrequently, patients may present with only a metastatic mass in the neck in the absence of any of the aforementioned symptoms related to the primary cancer.[1,13] A thorough history should be elicited about prior risk factors including alcohol and smoking habits, laryngopharyngeal or gastroesophageal reflux, nutritional status, Plummer-Vinson syndrome, and occupational exposures; past treatments such as radiation and/or chemotherapy; and general medical condition including coexisting pulmonary or cardiovascular comorbidities.

Physical Examination

A complete examination of the head and neck including an indirect or fiberoptic laryngoscopy to evaluate the pharynx and larynx is the first step in the diagnostic evaluation. The site and extent of the cancer, vocal cord mobility, airway patency, and mobility and appearance of the arytenoids are assessed. Maneuvers such as phonation and/or Valsalva with a pinched nose offer better visualization of the PFSs with fiberoptic endoscopy. In the absence of a frank mass or surface ulceration, findings of pooling of saliva in the PFS, an edematous arytenoid, or submucosal swelling in the posterior pharyngeal wall should raise suspicion of a malignant lesion. Cancers confined to the postcricoid area often evade detection in office laryngoscopy but can be suspected in the presence of edematous arytenoids and/or fixed hemilarynx. Anterior traction on the larynx by grasping the overlying skin and pulling forward may improve the view.

The examination of the neck should include careful palpation on both sides and assessment for number, level, size, and mobility of any enlarged lymph nodes. Tenderness over the lateral expansion of the laryngeal framework or upper trachea may suggest cancer invasion. A side-to-side movement of the laryngeal framework is recommended to assess the laryngeal crepitus at the level of thyroid cartilage. Fixation of cancer to the prevertebral fascia or anterior displacement of the larynx by advanced postcricoid and posterior wall tumors can result in loss or restriction of laryngeal crepitus.

Imaging

Radiologic studies such as contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) are performed to complete the diagnostic

evaluation. Compared to CT, MRI is more susceptible to motion artifacts from swallowing, coughing, or any other movement and is usually the second line of investigation; it may however be preferred to assess cancers that recur after resection or chemoradiation for better tissue delineation.[3] Radiology complements physical examination with information about the inferior extent of cancer, submucosal spread, invasion of the thyroid cartilage, and extralaryngeal involvement. Involvement of the prevertebral fascia or space should be ruled out for the primary cancers arising from or extending to the posterior wall of the pharynx. Imaging can also reveal the presence of a synchronous primary cancer, which is known to have a high incidence in the hypopharynx and cervical esophagus due to *field cancerization* effects from chemical carcinogens. Barium swallow is helpful in ruling out an esophageal cancer. It also facilitates diagnosis of esophageal motility disorders in patients with progressive dysphagia with no risk factors for SCC and a normal physical examination. Endoscopic ultrasonography is considered to be a more accurate imaging technique in determining the T stage of cancers of the cervical esophagus.

Ultrasonography and CT are of help in an accurate search for lymph node metastases; the latter is superior in demonstrating RPLN metastases. High rates of distant metastases of 10% to 30%[1,14,15]are associated with cancers of the hypopharynx and cervical esophagus. Hence, screening with whole-body positron emission tomography (PET) or chest and abdominal CT scans is recommended, particularly in patients with prolonged symptoms and bulky lymph node metastases.

Endoscopy Under Anesthesia and Biopsy

Examination under anesthesia (EUA) of the pharynx, larynx, trachea, and esophagus under anesthesia with rigid endoscopes is fundamental to accurately evaluate the cancer site and stage and detect synchronous primary cancer of the UADT. A rigid esophagoscopy is required to assess spread of the cancer to the cervical esophagus and to rule out a synchronous esophageal primary cancer. EUA allows tissue biopsy for diagnostic confirmation, although a histologic diagnosis can be achieved with fine-needle aspiration in patients with palpable neck nodes. In patients with advanced cancers and widely scattered foci of dysplastic-appearing mucosa in the UADT, mapping biopsies are a useful aid to predict resectability. Mapping biopsies are also

important for chemoradiation-recurrent cancers; many of these cancers do not exhibit typical clinical or radiologic findings, and malignant tissues may lurk beneath intact mucosa far distant from the epicenter of the primary cancer. Palpation of the cancer and movement of the cancer over the prevertebral fascia help to ascertain fixation for cancer of the posterior wall of the hypopharynx. Bronchoscopy is recommended for patients with cancer of the cervical esophagus in order to detect anterior extension of the cancer or a synchronous primary cancer. Based on information from clinical, radiologic, and endoscopic evaluations, a final clinical tumor stage (cT) is determined (**Table 16.1**) according to the American Joint Commission Cancer (AJCC) staging system. EUA for cancer of the hypopharynx also gives an opportunity to determine the access and feasibility for resection via a transoral approach. In cases unsuitable for transoral resection, assessment is directed toward decision-making for conservation versus radical surgical approaches and/or nonsurgical management. Assessment of the extent of the anticipated pharyngeal defect from surgical resection, as well as the most appropriate type of reconstruction, should be made during EUA. For patients likely to undergo a flap reconstruction, a donor site and potential alternatives should be planned.

Table 16.1 American Joint Committee on Cancer T and N Staging of Hypopharynx and Cervical Esophagus Cancer (2010)

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Hypopharynx	
T1	Tumor limited to one subsite of the hypopharynx and/or 2 cm or less in greatest dimension
T2	Tumor invades more than one subsite of the hypopharynx or an adjacent site or measures more than 2 cm but not more than 4 cm in greatest dimension without fixation of the hemilarynx
T3	Tumor more than 4 cm in greatest dimension or with fixation of the hemilarynx or extension to the esophagus
T4a	Tumor invades the thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue, which includes prelaryngeal strap muscles and subcutaneous fat
T4b	Tumor invades the prevertebral fascia, encases the carotid artery, or involves mediastinal structures
N staging	
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension
Esophagus	
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades the lamina propria or muscularis mucosae
T1b	Tumor invades the submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Resectable tumor invading the pleura, pericardium, or diaphragm
T4b	Unresectable tumor invading other adjacent structures, such as the aorta, vertebral body, trachea, etc
N staging	
N1	Metastasis in one to two regional lymph nodes
N2	Metastasis in three to six regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes

Additional Investigations

Routine hematologic and blood chemistry investigations are performed as part of pretreatment evaluation. Assessment of iron deficiency is particularly relevant in females with features of Plummer-Vinson syndrome. Protein deficiency and overall nutritional status should also be evaluated, and corrective measures initiated prior to initiation of treatment. The cachectic patient may benefit from pretreatment insertion of a percutaneous endoscopic gastrostomy (PEG) tube. A majority of patients are heavy smokers; hence, pulmonary reserve is checked with careful history and pulmonary function

tests, and referrals to tobacco cessation programs are made. Patients with poor pulmonary reserve may not be candidates for transoral or open conservation surgery due to the high risk of developing pulmonary complications from postoperative aspiration. Assessment of dentition is done during office examination, and referral is made to a specialist if restorative procedures or dental extractions are required, particularly for patients who are planned to receive radiation as part of the treatment.

Treatment

Among all cancers of the UADT, SCC of the hypopharynx and cervical esophagus are known to have an unfavorable prognosis. Treatment is aimed at achieving locoregional control with improved survival and a good functional outcome. Resectability of the primary cancer and nodal metastasis, medical comorbidities, pulmonary function status, patient preference, and distant metastasis at presentation are the important considerations in making treatment decisions. Surgery followed by adjuvant treatment for adverse features is the most commonly used approach for treatment of cancer of the hypopharynx.[5] Single modality therapy with surgery or radiation alone may be an effective therapeutic approach for early T1 or T2 disease, but most of these cancers are diagnosed at a more advanced stage. For advanced cancer, the most common conventional treatment approach has been partial or total pharyngectomy with a total laryngectomy. With a goal to cure and to preserve the larynx, nonsurgical treatment approach with various chemoradiation protocols started to gain favor in the late 1990s.[1,16] The risk of long-term toxicity, principally dysphagia and aspiration, from chemoradiation and poor outcomes after salvage surgery for postchemoradiation-recurrent tumors[16–18] rekindled interest in organ-preserving, conservative surgical approaches including transoral laser microsurgery (TLM).

For SCC of the cervical esophagus, radical surgery with laryngopharyngoesophagectomy and adjuvant radiotherapy was regarded as the gold standard of treatment. Nonsurgical approaches have been employed as alternatives to radical resection; newer, minimally invasive thoracoscopic surgery is also evolving for early cancers of this site.

Surgical Treatment

The goal of surgery is to achieve a resection with clear margins with or without laryngeal preservation, and extent of surgery is dictated by the site of the cancer, its stage, and functional status at presentation as well as the patient’s pulmonary reserve. Extension of cancer to the vertebral column and mediastinal structures and encasement of the carotid artery(s) are often features associated with unresectable cancer. When feasible, conservation surgery is performed with the objective to cure, minimize operative morbidity, and maximize function and quality of life (QOL). Laryngeal preservation with a transoral approach facilitates faster recovery of swallowing compared to conventional, open conservation approaches, due to better preservation of suprahyoid musculature, constrictor muscle, and the pharyngeal neural plexus.

Transoral Approaches

Transoral Laser Microsurgery

TLM as an approach for the management of hypopharyngeal SCC was first reported by Steiner in 2001.[19] When feasible, this approach reduces the need for permanent tracheotomies or feeding tube dependency by avoiding resection of tissues that are critical for airway, speech, and swallowing functions. The application of TLM to resect select advanced SCC of the hypopharynx has broadened as experience and technology advance.
